Advances in percutaneous coronary interventions (PCI) are also likely contributing to the increasing prevalence of high-risk patients referred to coronary surgery, as lesser risk anatomic substrates and patient subsets are preferentially referred to nonsurgical revascularization. As PCI procedural techniques continue to improve, there has been growing interest among interventional cardiologists in tackling higher risk patients. Nonetheless, in the PCI era there is a paucity of studies evaluating revascularization for HF and low EF. The Bypass Angioplasty Revascularization Investigation compared balloon angioplasty with coronary surgery among patients enrolled from 1989 to 1992 with coronary anatomy deemed approachable by either revascularization approach. Although very few patients had HF or an EF less than 50%, HF was one of the most powerful predictors of mortality in both the surgical and medical groups.[50] The VA AWESOME (Angina With Extremely Serious Operative Mortality Evaluation) trial and registry experience evaluated percutaneous and surgical revascularization among 2431 patients with medically refractory ischemic coronary disease and high operative risk of whom approximately 20% had an EF of 35% or less and

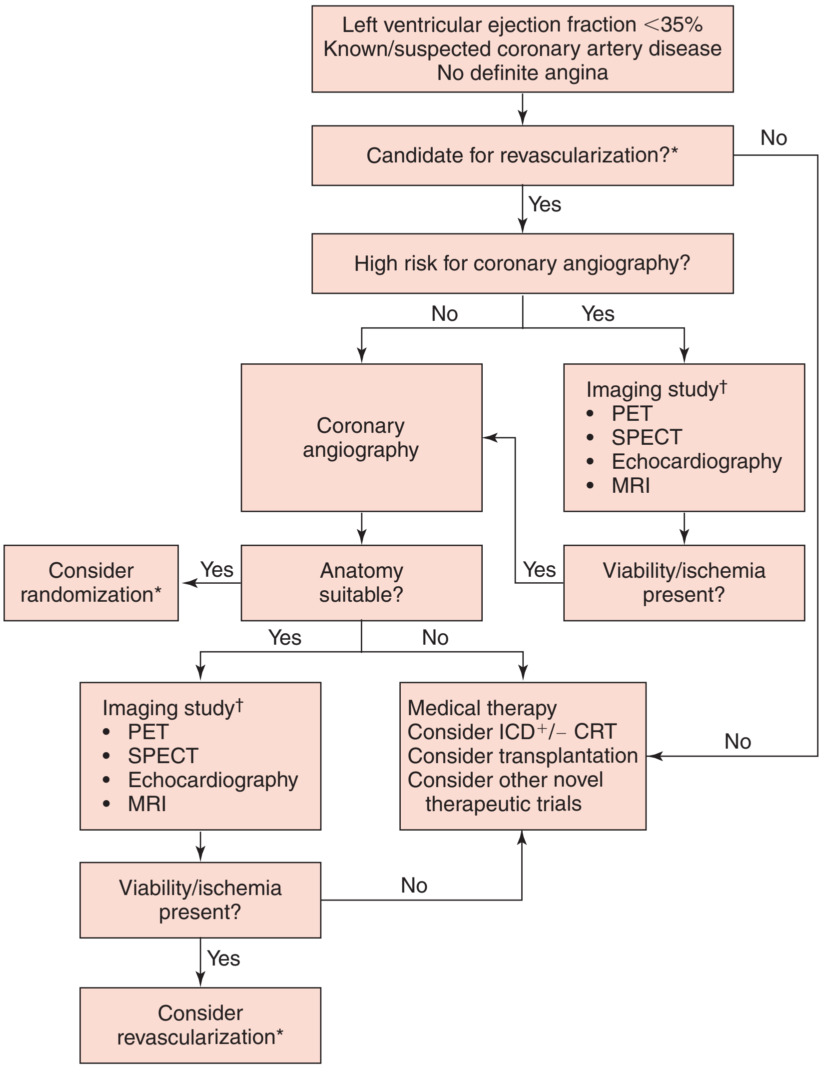

Figure 16–3 Algorithm of proposed clinical approach to revascularization in ischemic cardiomyopathy integrating diagnostic and therapeutic decisions. (Adapted from Chareonthaitawee P, Gersh BJ, Araoz PA, et al: Revascularization in severe left ventricular dysfunction. J Am Coll Cardiol 2005;46:567-74, reproduced with permission.)

found comparable morbidity and mortality rates.[51] In contrast to the VA AWESOME results, Hannan and coworkers[52] reported on the results of 37,212 patients who received coronary surgery and 22,102 patients who underwent a PCI with stents for multivessel coronary disease. Patients with an EF of 40% or less were proportionally more common among those receiving coronary surgery compared with PCI (25.9% versus 18.5%). Coronary surgery was associated with better adjusted long-term outcomes when compared with PCI for patients with LVSD with two-vessel disease and proximal left anterior artery lesions and for three-vessel disease. When comparing coronary surgery with PCI in patients with multivessel disease, complete revascularization is more frequently achieved by coronary surgery and likely relates to the higher rates of repeat revascularization found among those receiving PCI.[53] The impact on short- and long-term outcomes of incomplete revascularization and/or repeat revascularization among low EF patients has not been well studied but likely further differentiates PCI and coronary surgery in HF. Because the current state of the evidence for PCI in low EF patients does not support widespread adoption, the proportion of patients with HF and LVSD referred to CABG is anticipated to climb in the near future.

CABG has evolved within a changing environment of heart disease[54] (Fig. 16–4). Over the last 35 years, coronary surgery for patients with HF and LVSD has gone from contraindicated to conventional. Advancements in the use of arterial conduits and endarterectomy, improved techniques for myocardial protection and reduction of stroke risk, success with reoperation CABG, and emerging experience with off-pump surgery have all contributed to improved surgical outcomes.[48a] It is also important to recognize that nonsurgical approaches for HF have undergone equally remarkable advances.[55] For example, patients randomized to medical therapy in CASS did not systematically receive any of the evidence-based therapies that are now reported cardiac care quality indicators, including aspirin, statins, angiotensin-converting enzyme inhibitors, and β-blockers. Furthermore, none of the current adjunctive pharmacologic and device therapies to reduce morbidity and mortality in HF was available. The impact of an EF less than 35% and/or moderate-to-severe HF on long-term survival in CASS was sobering—with a 12-year survival rate of approximately 10%.[56] Today, clinical trials in similar patient subsets report 80% survival at 2 to 3 years.[57] As nonsurgical therapy advances, it will be critically important to understand whether CABG adds any incremental benefit beyond the optimal medical therapy and whether certain patient subsets are at risk for worse outcomes without CABG. The National Heart, Lung and Blood Institute (NHLBI)-funded STICH (Surgical Treatment for Ischemic Heart Failure) trial (*www.stichtrial.org*) promises to address this and many other questions regarding coronary surgery for HF (Fig. 16–5).[58]

SURGICAL VENTRICULAR RESTORATION

In some of the earliest series of coronary artery surgery for HF, the operation was combined with myocardial resection of asynergic predominantly anterior or apical ventricular segments.[59] As early as 1969 and on the understanding of the Frank-Starling mechanism and the Laplace relationship, modification of ventricular asynergy was considered a theoretically attractive potential treatment for HF.[60] The recognition of the important association between ventricular dilatation and HF symptom severity and outcomes[61] fueled the hopes that surgical removal of akinetic, dyskinetic, or aneurysmal segments would (1) reduce wall tension, myocardial oxygen consumption, and the sequestration of stroke volume; and (2) increase contractile function in the remaining ventricle with and without concomitant coronary artery surgery.[62-65] The recognition that ventricular asynergy could result from chronic ischemia without infarction and that coronary artery bypass surgery alone could lead to improvements in hemodynamics, ejection fractions, and ventricular volumes in patients with and without previous infarction

began a debate still raging today regarding the role of myocardial resection as a treatment for HF.[66]

Left ventricular aneurysmectomy as first described by Cooley in 1958[67] appeared to reverse HF by lowering left ventricular wall stress, but this linear amputation of dyskinetic scar commonly deformed the LV cavity into a box-like shape and did not improve left ventricular performance.[68] Intracavitary reconstruction techniques have been developed for repairing defects left by aneurysm resection that reduced LV cavity size.[69,70] The general reconstruction technique (Fig. 16–6) uses an endoventricular circular continuous suture to exclude dysfunctional septal and apical regions and has evolved with multiple variations, such as direct closure versus patch plasty with or without myocardial resection. Several sizing balloons and devices are now used to define optimal volume reduction. A more detailed description of the surgical technique is available elsewhere.[71] This surgical ventricular restoration (SVR) strategy as initially popularized by Dor[70] has been applied not only to patients with dyskinetic scar but also to those with only akinetic myocardial segments. At the time of cardiac operation, the epicardium of these akinetic zones may appear normal, and palpable thinning is often minimal in the arrested, decompressed heart. This appearance derives from preservation of a rim of normal myocardium covering the myocardial fibrosis and contrasts with the leather-like appearance and thinness typical of a left ventricular aneurysm.

Unlike the LV aneurysmectomy that removed myocardial scar or the Batista operation[72] that reduced left ventricular size by removal of portions of the wall, the SVR operation mechanically decreases the circumference of the zone of endocardial scar through an incision in normal epicardium. The surgical repair uses the intrinsic scar or an extrinsic patch to absorb excess linear wall tension from the adjacent myocardium. A decrease in wall stress appears to reduce the tendency for continued gradual expansion of the akinetic zone. The endocardial repair acutely decreases ventricular size and mitral regurgitation; this surgical remodeling acutely enhances function in myocardial regions remote from the repair and improves forward stroke volume.

Dor and colleagues, along with other groups, have reported favorable short-term hemodynamic results and long-term results with SVR in patients with ischemic cardiomyopathy.[74-77] Limited studies have also examined endoventricular circular restorative procedures as a treatment for nonischemic dilated cardiomyopathy and have shown similar improvements in hemodynamic and ventricular volumes, although the high operative mortality reported in this population has dampened enthusiasm.[78,79] Suggested patient selection criteria include post-infarction patients with New York Heart Association functional class III-IV heart failure, predominant involvement of the anterior, anteroseptal and apical walls with regional asynergy of at least 35% of the ventricle, depressed EF, and end-diastolic and end-systolic volume indices >100 and 60 mL/m^2, respectively. Preoperative functional class and LV volumes appear strongly associated with early and late mortality after SVR.[73,80] Although echocardiography may be used to assess ventricular structure and function, cardiac MRI or CT is preferred by many surgeons to define the region of scar and assess change in LV volumes and EF.

Some concerns have been raised about postoperative increased pulmonary pressures and new or worsening mitral regurgitation, which may be correctible by judicious ventricular sizing and the use of concomitant mitral repair.[81] Other relative contraindications to SVR include multiple areas of infarction, loss of basilar myocardial function, pulmonary hypertension with right ventricular failure, and inoperable coronary disease.[71]

The RESTORE registry group[82] detailed the results of 1198 patients who underwent SVR due to significant post-infarction left ventricular dilation along with concomitant procedures, including coronary artery surgery in 95% and mitral valve repair in 22%, at 12 centers from 1998 to 2003. At baseline, patients had a mean age of 63 years, EF of 30%, and NYHA class of 2.9; the mean time between anterior myocardial infarction and SVR was 4.4 years. The RESTORE investigators reported a 5.3% 30-day mortality following SVR with worse 30-day mortality among those who received a mitral valve procedure (8.7% versus 4.0%) and among patients 75 years or

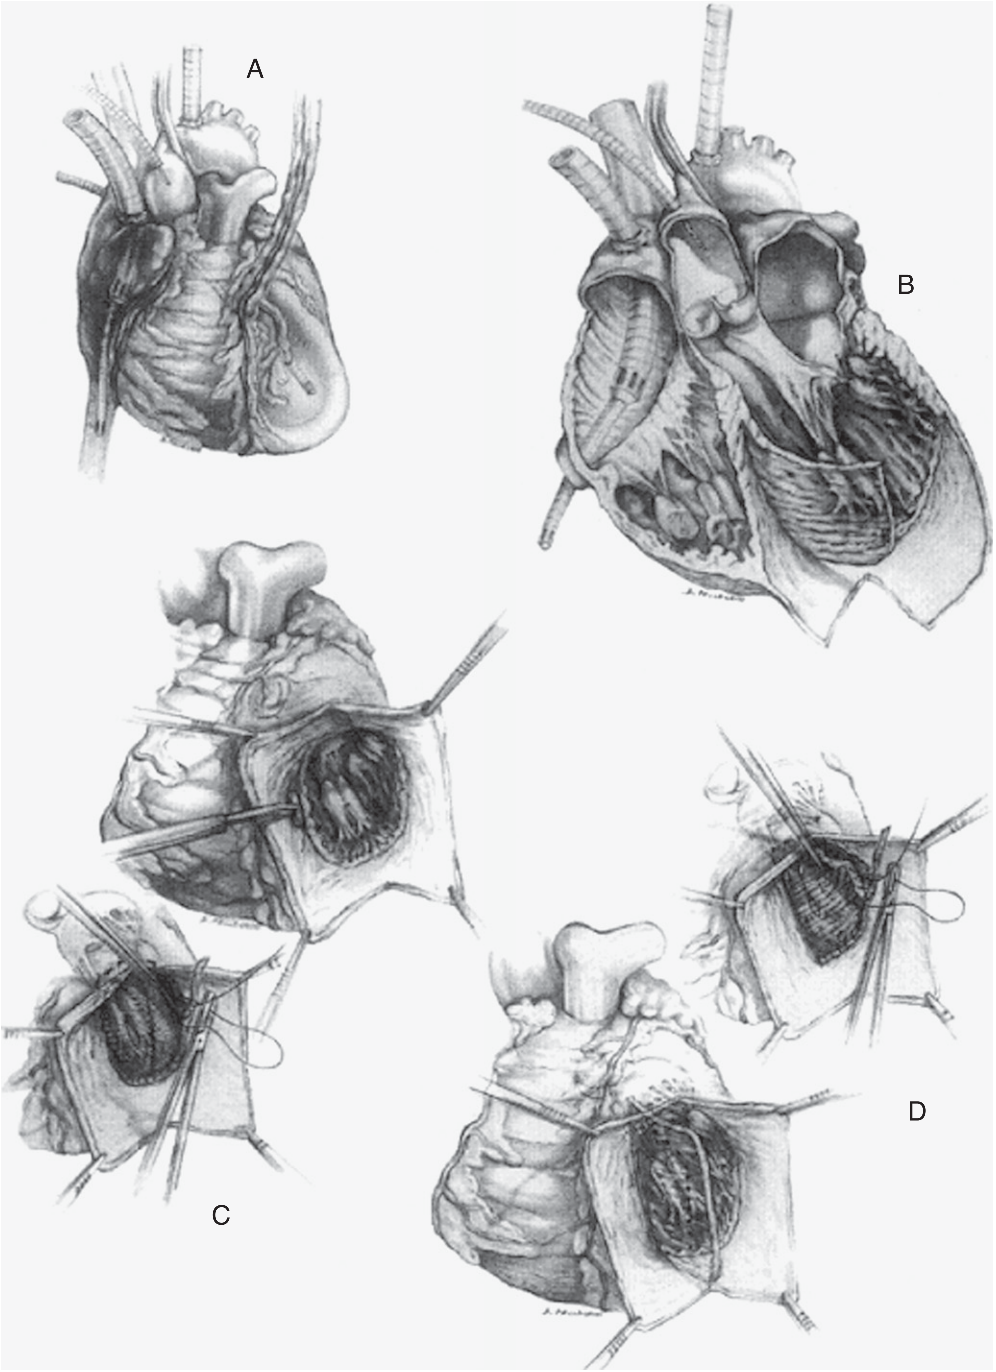

Figure 16–6 Technique of endoventricular circular patch repair. **A,** Lesions exposed under total cardiac arrest after implantation of left internal mammary artery. **B,** Mobilization of the endocardial scar on the septum and up to contractile muscle. **C,** Cryotherapy probe on the limit of resection (in case of ventricular aneurysm). Dacron patch inside the LV on contractile muscle with 2-0 monofilament on pericardial strip. **D,** Autologous endocardial patch is cut in the mobilized septal scar and sutured on contractile muscle. (From Dor V, Sabatier M, DiDonato M, et al: Late hemodynamic results after left ventricular patch repair associated with coronary grafting in patients with post-infarction akinetic or dyskinetic aneurysm of the left ventricle. J Thorac Cardiovasc Surg 1995;110:1291-9, reproduced with permission.)

older (13%). Other risk factors for death included an EF less than 30%, end-systolic volume index greater than 80 mL/m^2, and NYHA class III or IV, which was present at baseline in 40% and 29%, respectively. Functional class and indices of left ventricular size and global systolic function were significantly improved postoperatively. The overall 5-year survival rate was 69%. Unfortunately, the lack of either a coronary surgery alone or medically treated comparator group limits an understanding of the additive benefits of SVR in the LVSD population. However, it appears that HF symptom relief and survival reported with SVR compares favorably with contemporary series among a similar population of patients with dilated ventricles and anterior scar.[83]

The SVR operation is now sufficiently mature and is being performed more and more frequently at an additional cost to treat HF and LVSD. The Society of Thoracic Surgeons (STS)

procedural data base was interrogated to understand the current use and clinical outcomes of patients undergoing SVR.[76] In this 2002 to 2004 national sample of U.S. patients, 731 patients underwent SVR at 141 of the 576 STS hospitals. Importantly, only at 20 of these centers were 10 or more SVR procedures performed. The perioperative complication rates were higher than reported from the RESTORE experience with a 30-day mortality rate of 9.3% and a death or major complication rate of 33.5%. Further analyses are needed to determine the relation between center (and surgeon) volume and surgical outcomes. Based on the above experiences, SVR is increasingly used as a treatment strategy for HF. However, the safety of the procedure across the spectrum of operative skill and disease severity and whether it adds clinical value beyond state-of-the art medical therapy with or without CABG are lacking. The future role of SVR in the management of HF will likely depend on the results of ongoing clinical trials such as STICH.[58]

SURGERY FOR MITRAL REGURGITATION

Mitral regurgitation (MR) is highly prevalent among patients with HF and LVSD and moderate or severe MR has been demonstrated in up to 59% of patients with advanced heart disease.[84,85] The presence and severity of chronic MR are known to be powerful markers of poor prognosis among asymptomatic patients,[86] patients with HF and/or LVSD following acute myocardial infarction,[87] and those with chronic ischemic and nonischemic cardiomyopathy.[88-90] MR is well described as a primary cause of LV dysfunction but is also increasingly recognized as a secondary phenomenon in many patients with cardiomyopathy. Dynamic changes in MR severity in patients with LVSD occur and have been implicated as contributing to acute exacerbations of decompensated HF.[91,92]

Chronic MR can cause, as well as result in, LVSD. Functional MR (defined as abnormal function of normal leaflets in the context of impaired ventricular function) is dependent on a dynamic interplay of structural and functional changes of the left ventricle and mitral valve apparatus, and is influenced by loading conditions.[93] Progressive adverse left ventricular remodeling and dilation augment the predisposing geometric conditions for functional MR. The resulting lateral displacement of the papillary muscles, dilation of the mitral valve annulus, and abnormal leaflet tethering result in leaflet malcoaptation and worsening MR. Furthermore, in patients with ischemic cardiomyopathy, MR may be exacerbated by inferior ischemia causing dysfunction of the posterior papillary muscle. The increased volume load imposed on the left ventricle from MR then leads to more ventricular dilation and sphericity, and a vicious cycle is propagated that contributes to HF progression.[94] Current data show that secondary MR in patients with advanced HF may be associated with changes in the extracellular matrix of the mitral valve leaflets, suggesting that MR may not be purely "functional" and that the valves are not "normal."[95] These considerations have made functional MR an increasing target for intervention in patients with HF.[96] Historical observations in patients with LVSD and MR who underwent mitral valve replacement suggested that correcting MR was associated with high operative risk and worsening HF symptoms and left ventricular function, and tempered any initial enthusiasm for surgical correction.[97] Reports from Bolling and others[98-103] of mitral valve repair (MVR) without replacement led to a resurgence in surgical confidence. MVR is typically performed via a median sternotomy with standard cardiopulmonary bypass with the placement of an undersized flexible annular ring and with preservation of the subvalvular apparatus. Disappointing results owing to persistent MR in some patient subsets led several groups to develop modifications in the surgery—such as the use of an edge-to-edge approach or the addition of chordal or papillary muscle modification.[104-106]

Although national surgical data bases report ever-increasing use and expanding indications of isolated and combined mitral valve procedures,[107,108] available data on MVR as a therapy for HF are mixed. Early hemodynamic, structural, and functional results have been encouraging, but longer-term follow-up studies have questioned whether MVR has any enduring effect on improving quality of life and exercise capacity, and reducing morbidity and mortality rates in HF.[109,110] Particularly among patients with ischemic cardiomyopathy, reports suggest that quality of life and long-term survival are not improved when mitral valve operations are added to coronary revascularization procedures.[111,112] These data, along with an acknowledgment of the growing importance of mitral regurgitation on prognosis, have led to the development of promising percutaneous mitral reparative techniques using either transseptal[113] or coronary sinus[114] approaches. Whether moderate or severe functional MR in patients with HF and LVSD should be managed with medical therapy alone or in combination with revascularization and/or mitral valve surgery remains unclear and awaits prospective, controlled studies although none is currently ongoing.

OTHER NOVEL APPROACHES

Progressive ventricular remodeling, despite the use of neurohormonal antagonists and device therapies, is associated with adverse clinical outcomes in patients with LVSD and HF. This has spurred the development of new surgical approaches to passively restrain the myocardium, with the goals of mechanically minimizing further ventricular dilatation and, in turn, reducing the morbidity and mortality rates.[115] The conceptual approach to mechanically restraining the myocardium derived from experimental work with latissimus dorsi cardiomyoplasty and the Myosplint device (Myocor, Inc.).[116,117] The CorCap Cardiac Support Device (Acorn Cardiovascular, Inc.) has been extensively studied (Fig. 16–7). The CorCap device is made from a mesh-like open-weave polyester fabric and is surgically placed around the heart. In animals, the placement of the CorCap device has been shown to decrease ventricular volumes, enhance contractility, minimize mitral regurgitation, and lead to favorable alteration of cellular and extracellular determinants of ventricular remodeling.[118,119] Initial human studies with the CorCap device in patients with NYHA functional class III-IV HF, low EF, and left ventricular end-diastolic dimension index greater than 30 mm/m^2 suggested that the device could be implanted safely without device-related intraoperative complications and lead to improvements in ventricular size, function, and functional class over a 2-year follow-up period.[120] This early experience led to a randomized clinical trial (the ACORN Pivotal Trial) in 300 patients with NYHA functional class III-IV HF and

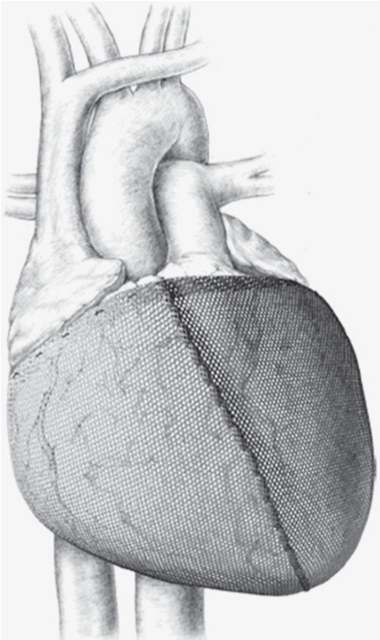

Figure 16–7 CorCap Cardiac Support Device (Acorn Cardiovascular, Inc.) (From Mann DL, Acker MA, Jessup M, et al: Rationale, design, and methods for a pivotal randomized clinical trial for the assessment of a cardiac support device in patients with New York Health Association class III-IV heart failure. J Card Fail 2004;10:185-92, reproduced with permission.)

dilated cardiomyopathy with or without mitral regurgitation requiring MVR.[121] Preliminary data presented at the AHA 2004 Scientific Sessions suggested that patients randomized to CorCap had an improvement in the clinical composite score (driven by the need for further major cardiac procedures) that was associated with decreased left ventricular volumes. However, no significant benefits in rehospitalization rates or mortality were found, which led an FDA advisory panel to recommend against approval of the device pending further studies.

SUMMARY

The surgical management of heart failure associated with left ventricular systolic dysfunction has evolved dramatically since the 1960s. Although reduced ejection fraction and heart failure remain important prognostic determinants of intraoperative and long-term survival, they no longer are considered compelling contraindications to surgery. Significant improvements in medical and device therapy for HF over the last 2 decades have paradoxically led to a growing proportion of patients with LVSD referred for cardiac surgery. Further advances in the surgical management of HF will depend on the development and perfection of new devices and technologies—as well as on a clearer understanding of the role of established surgical options relative to contemporary medical therapy. In this new era, randomized trials of surgical therapies for HF hold great promise for establishing new guidelines and improving patient care.

Chapter 17

Strategies for Management of Decompensated Heart Failure

Michael M. Givertz, Lynne W. Stevenson, and Wilson S. Colucci

CHAPTER CONTENTS

Heart failure is a common reason for hospital admission, especially in older patients.[1] The majority of patients hospitalized for heart failure have previously been diagnosed with heart failure but have subsequently developed progressive clinical and hemodynamic decompensation that leads to admission. All patients admitted to the hospital with heart failure should undergo a rapid clinical evaluation for risk stratification and for determining the degree of elevation in cardiac filling pressures and the adequacy of systemic perfusion. In addition, effective management should include a careful search for correctable factors. In select cases, hemodynamic monitoring with a pulmonary artery catheter may be indicated for the purpose of initiating and titrating inotropic, vasodilator, and diuretic therapy. Clinical and hemodynamic goals of therapy should be set and specific pharmacologic agents chosen to meet these goals. In cases of refractory heart failure, evaluation for ventricular assist device implantation or cardiac transplantation should be performed in potential candidates. For nontransplant candidates with end-stage heart failure, strategies focusing on symptom management and end-of-life care are appropriate.

TERMINOLOGY

Decompensated heart failure has been defined as heart failure with a relatively rapid onset of signs and symptoms, resulting in hospitalization or unplanned office or emergency room visits.[2] Most of these episodes result from worsening or decompensation of chronic heart failure (Table 17–1).[181,182] Some investigators have arbitrarily divided this group further into patients with *acute* versus *chronic decompensated heart failure*, depending on the time course of worsening symptoms before hospitalization (e.g., days versus weeks or months). However, these terms lack diagnostic accuracy and are limited by the subjectivity of the medical history as provided by the patient or interpreted by the physician. *Stage D heart failure*, as defined by the ACC/AHA guidelines,[3] designates patients with refractory heart failure who might be eligible for specialized, advanced treatment strategies (e.g., mechanical circulatory support, continuous inotropic infusions) or end-of-life care (Fig. 17–1). Approximately 30% of hospitalizations are due to new-onset heart failure, also termed *acute heart failure*, which may be caused by an acute coronary syndrome, uncontrolled hypertension, or acute valvular dysfunction. *Acute pulmonary edema* is a clinical term used to describe patients presenting with rapid worsening of symptoms associated with physical and radiologic findings of pulmonary congestion due to acute elevation of the pulmonary capillary wedge pressure.

EPIDEMIOLOGY

It is estimated that five million persons in the United States are being treated for heart failure, with 550,000 new cases diagnosed each year.[4] The prevalence of heart failure increases dramatically with age, occurring in 1% to 2% of persons aged 45 to 54 and up to 10% of individuals older than age 75.[5,6] Between 1979 and 2002, the number of heart failure hospitalizations per year rose from 377,000 to 970,000, an increase of 157% (Fig. 17–2).[4] Approximately 80% of all heart failure admissions occur in patients older than 65; as a result, heart failure is the leading discharge diagnosis among Medicare beneficiaries with an average length of stay of 5.3 days.[1] Large registries have recently defined the demographics and concomitant diseases associated with acute decompensated heart failure (see Table 17–1). Approximately 50% of patients are women, and nearly 75% have a history of heart failure. Hypertension and coronary artery disease are present in more than 50% of patients, and 30% or more of hospitalized heart failure patients present with diabetes, atrial fibrillation, and renal insufficiency.

Admission to the hospital with heart failure is associated with poor short- and long-term outcomes.[7-9] The Acute Decompensated Heart Failure National Registry (ADHERE)

Table 17–1 Demographics and Co-morbidities of Acute Decompensated Heart Failure

	ADHERE (N = 107,920)	EHFS (N = 11,327)	OPTIMIZE-HF (N = 34,059)
Mean age, years	75	71	73

ADHERE, Acute Decompensated Heart Failure National Registry[8]; EHFS, Euro Heart Failure Survey[7]; OPTIMIZE-HF, Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure registry[181]; LVEF, left ventricular ejection fraction; CAD, coronary artery disease. Adapted from Gheorghiade M, De Luca L, Fonarow GC, et al: Pathophysiologic targets in the early phase of acute heart failure syndromes. Am J Cardiol 2005;96:11G.

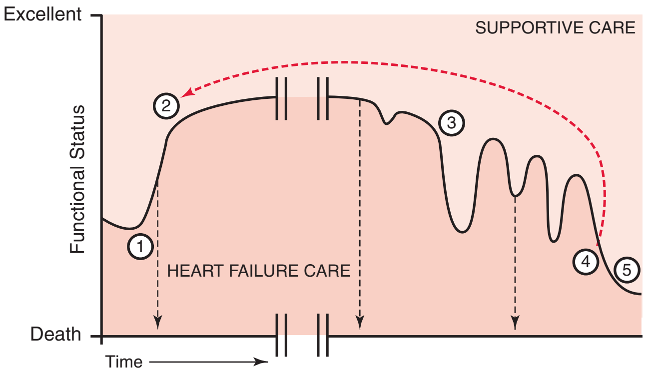

Figure 17–1 Time course of symptomatic heart failure. Patient presents with symptoms of heart failure (1) and treatment is initiated. Stable functional status (2) is maintained for a variable length of time on optimal medical therapy, but subsequently declines (3) with intermittent decompensation that responds to hospital-based therapy or sudden death (*vertical dashed lines*). Patient subsequently develops refractory heart failure (4) requiring consideration of ventricular assist device or cardiac transplant (*dashed line*), or end-of-life care (5). (Adapted from Goodlin SJ, Hauptman PJ, Arnold R, et al: Consensus statement: Palliative and supportive care in advanced heart failure. J Card Fail 2004;10:200.)

tracked outcomes of more than 107,000 heart failure hospitalizations and found an in-hospital mortality rate of 4.0%.[8] In the Euro Heart Failure Survey of more than 11,000 admissions, 6.9% of patients died during a heart failure hospitalization.[7] In community-based studies, crude mortality rates following a heart failure hospitalization range from 8% to 14% at 30 days, and increase to 26% to 37% at 1 year.[9] For survivors, readmission with heart failure is common, ranging from 20% to 25% at 60 days and increasing to nearly 50% at 6 months.[10,11]

Owing to direct medical costs, disability, and loss of employment, heart failure has an enormous economic impact on the U.S. health care system. In 2003, $3.6 billion ($5,456 per discharge) was spent on Medicare beneficiaries for the in-hospital management of heart failure.[12] Estimated treatment costs for all inpatients with heart failure in 2005 were $27.9 billion.

PATHOPHYSIOLOGY

Heart Failure with Reduced versus Preserved Systolic Function

In patients with reduced systolic function (e.g., ejection fraction less than 40%), heart failure reflects an abnormality of contractile function in which the end-systolic pressure volume relation is shifted downward. End-systolic volume, end-diastolic volume, and end-diastolic pressure are increased, and elevated end-diastolic filling pressures are transmitted to the pulmonary venous circulation—resulting in signs and symptoms of pulmonary congestion. In some patients, elevated right-sided filling pressures cause systemic venous congestion, leading to symptoms of abdominal distress. Contractile dysfunction may result from both direct and indirect insults to the myocardium, including loss of myocytes after myocardial infarction, chronic volume or pressure overload, toxins such as alcohol or doxorubicin, or a primary myocardial process (e.g., idiopathic dilated cardiomyopathy). Decreased contractility results in a fall in stroke volume leading to symptoms of decreased cardiac output.

Up to 50% of patients admitted to the hospital with heart failure have normal or near normal left ventricular systolic function (see Table 17–1) and are presumed to have an abnormality in diastolic function.[13,14] The end-diastolic pressure volume relationship may be shifted upward reflecting impaired ventricular filling. Pulmonary vascular and systemic venous congestion results from an increase in left and right ventricular end-diastolic pressures, respectively. Diastolic dysfunction may be due to impaired early relaxation, increased chamber stiffness, or both,[15] and is frequently associated with hypertension and abnormal vascular compliance.[16] Maladaptive volume regulation may also contribute to heart failure with preserved systolic function, and evidence suggests

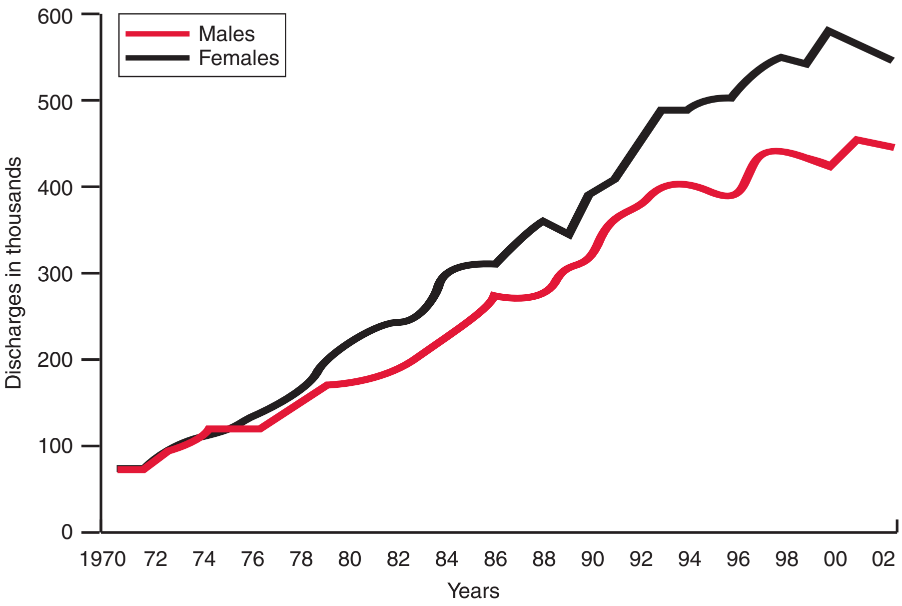

Figure 17–2 Hospital discharges for heart failure by gender in the United States between 1970 and 2002. Among men (*red line*), the number of discharges increased from 90,000 per year in 1970 to 430,000 per year in 2002. Among women (*black line*), the number of discharges increased from 90,000 per year in 1970 to 520,000 per year in 2002. (From Centers for Disease Control and Prevention, National Center for Health Statistics. From American Heart Association. Heart Disease and Stroke Statistics—2005 Update. Dallas, Tex, American Heart Association, 2005.)

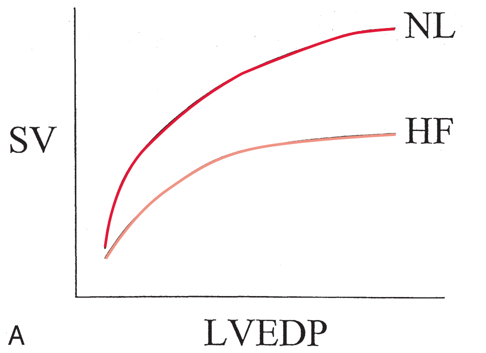
that in elderly hypertensive patients, volume expansion, renal dysfunction, and anemia play important roles in disease progression.[17] Common underlying causes of heart failure with preserved systolic function include ischemia and left ventricular hypertrophy; restrictive, infiltrative, and hypertrophic cardiomyopathies are encountered less frequently.[18,19]

To promote standardization in practice, specific diagnostic criteria for diastolic heart failure have been proposed.[20] However, it is important to remember that systolic heart failure and diastolic heart failure are not mutually exclusive. Although these terms may underscore a predominant pathophysiologic mechanism in the individual patient, many patients with heart failure have abnormalities of both systole and diastole. In patients with ischemic cardiomyopathy, for example, systolic heart failure is caused by both chronic loss of myocardium secondary to infarction and the acute loss of contractility due to ischemia; diastolic heart failure is due to reduced compliance caused by chronic replacement fibrosis and the acute reduction in distensibility by ischemia. For the purposes of patient management, similar principles are often applied to patients regardless of ejection fraction. However, most of the approved diagnostic tools and treatment strategies have been validated in patients with reduced systolic function. In the ADHERE registry, in-hospital mortality was lower in patients with preserved systolic function (2.8% versus 3.9%), although intensive care unit and total length of stay were similar.[21] More complete discussions of diastolic heart failure may be found in Chapter 14 and elsewhere.[22]

Acute Compensatory Mechanisms

In the presence of a primary abnormality in contractile function, the heart depends on a number of compensatory mechanisms to maintain adequate cardiac output and vital organ perfusion (discussed in detail in Chapter 21 of the HD7e). Acutely, ventricular performance may be maintained within normal limits by an increase in preload: the higher the preload, the greater the force of ventricular contraction and the greater the stroke volume. However, the Frank-Starling mechanism is advantageous only if the relationship between preload and contractility is positive. Although this relation may hold true in the setting of acute ischemia with normal chamber dimensions, in chronic systolic heart failure associated with left ventricular dilation, the ventricular function curve may be flat at higher diastolic volumes (Fig. 17–3A). Increased filling may result in little augmentation in cardiac output, and further elevation in end-diastolic pressures may result in increased wall stress, decreased subendocardial perfusion, and worsening mitral regurgitation. Hemodynamic studies in patients with decompensated heart failure have shown that maximal stroke volumes can be achieved by lowering pulmonary capillary wedge pressure (PCWP) into the normal range with parenteral vasodilator (see Fig. 17–3B) and diuretic therapy.[23] This improvement in ventricular function may be due in large part to a reduction in secondary mitral or tricuspid regurgitation, or both, that often complicates dilated ischemic or nonischemic cardiomyopathy, but may also reflect improved myocardial oxygen supply and/or decreased demand.

In addition to the beat-to-beat alterations in contractile function determined by the Frank-Starling mechanism, short-term stabilization of cardiac output or blood pressure may be achieved by activation of the sympathetic nervous and renin-angiotensin-aldosterone systems. Decreased perfusion pressure sensed by carotid sinus and aortic arch receptors results in increased sympathetic and decreased parasympathetic nervous system activity. Consequences of an increase in circulating catecholamines during cardiac decompensation include increased heart rate and contractility to augment cardiac output, systemic vasoconstriction to increase preload and maintain systolic blood pressure, and redistribution of blood flow away from the skin and splanchnic beds to the heart and central nervous system. Activation of the renin-angiotensin-aldosterone system acts in concert with increased sympathetic activity to maintain arterial pressure. Elevated levels of circulating angiotensin II result in systemic vasoconstriction and intravascular volume expansion—the latter effect due to increased aldosterone secretion by the adrenal cortex and



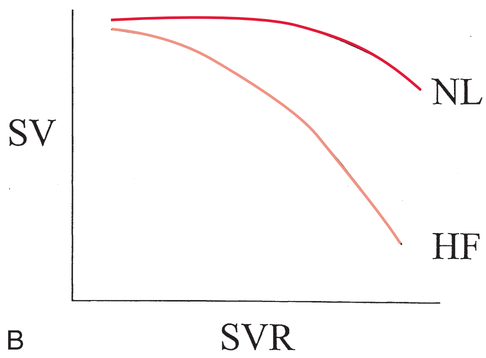


Figure 17–3 Preload and afterload effects on cardiac output/stroke volume in patients with normal (NL) and decreased (HF) left ventricular systolic function. **A,** Ventricular function curve in patients with HF may be flat at higher filling pressures. Thus, further increases in left ventricular end-diastolic pressure (LVEDP) may result in no change in stroke volume (SV). **B,** Alternatively, a reduction in systemic vascular resistance (SVR) by vasodilator therapy may result in a significant increase in SV.

sodium and water retention by the kidney. Elevated circulating levels of arginine vasopressin[24] and endothelin[25] may also contribute to volume expansion and vasoconstriction in decompensated heart failure. In response to an increase in intracardiac pressure and volume, atrial and B-type natriuretic peptides are secreted from cardiac chambers, and act as counter-regulatory hormones by causing vasodilation, diuresis, natriuresis and aldosterone and endothelin antagonism.

Myocardial Injury

Circulating levels of cardiac troponins are increased in the serum of patients with advanced heart failure[26] and may increase further during episodes of acute decompensation in the absence of ischemia.[27] Elevated cardiac troponins predict adverse short-term outcomes, including worsening heart failure and in-hospital mortality, independent of ischemia. These clinical observations raise the possibility that decompensated heart failure is associated with an accelerated loss of cardiac myocytes,[28] which in turn contributes to ventricular remodeling and disease progression. Underlying mechanisms of myocyte loss include necrosis and apoptosis. In addition to ischemia, several apoptotic stimuli are active in the setting of acute decompensation, including oxidative stress, mechanical strain, and neurohormones (e.g., norepinephrine and angiotensin).

Table 17–2 Potentially Reversible Factors Contributing to Decompensation in Patients with Heart Failure

Myocardial ischemia
Uncontrolled hypertension
Tachyarrhythmias or bradyarrhythmias
Noncompliance with medications and/or salt and fluid restriction
Heavy alcohol consumption
Periodic hypoxia (e.g., due to sleep apnea)
Anemia
Recent viral illness
Noncardiac medication causing fluid retention (e.g., NSAID, TZD)
Acute or acute-on-chronic renal failure
Hyperthyroidism

NSAID, nonsteroidal anti-inflammatory drug;
TZD, thiazolidinedione.

COMMON PRECIPITATING FACTORS

Patients with heart failure may be asymptomatic or mildly symptomatic, either because the cardiac impairment is mild or because compensatory mechanisms help to balance or normalize cardiac function. Symptoms of heart failure necessitating hospital admission may develop when one or more precipitating factors increase cardiac workload and disrupt the balance in favor of decompensation (Table 17–2). Specific factors may be identified in 50% to 90% of admissions, and are often correctable.[29,30] In one study of 435 patients admitted nonelectively to an urban hospital with the diagnosis of heart failure, acute chest pain and noncompliance with medications or diet were the precipitating factors in 33% and 21%, respectively.[31] The rate of noncompliance with heart failure medications is particularly high among elderly persons.[32] Failure to take prescribed heart failure medications or adhere to dietary restrictions may result in progressive fluid retention and worsening congestion. However, inadequate therapy is not always caused by patient noncompliance. Physician underuse of angiotensin-converting enzyme (ACE) inhibitors and β-blockers in patients with heart failure is well documented.[21,33] Likewise, digoxin may be withdrawn owing to concerns about toxicity,[34] thereby precipitating heart failure hospitalization.

Cardiac arrhythmias are common in patients with heart failure and often precipitate or exacerbate episodes of moderate-to-severe decompensation.[35,36] Atrial fibrillation with rapid ventricular response results in elevated atrial pressures and may further reduce cardiac output in a patient with limited baseline systolic reserve.[37,38] In patients with ischemic heart disease, tachycardia may induce or intensify ischemia and result in worsening systolic or diastolic function, or both, by increasing myocardial oxygen demands. In addition, a

regular narrow complex tachycardia may occasionally be misinterpreted as sinus in origin when, in fact, atrial flutter or atrioventricular nodal reentry tachycardia is present. In some cases, atrial arrhythmias may be the primary cause of a tachycardia-mediated cardiomyopathy, which is potentially reversible with effective antiarrhythmic therapy or radiofrequency ablation.[39,40] Assessment of thyroid function is warranted in new onset atrial arrhythmias, particularly in the elderly.

Although less common than atrial arrhythmias, sustained or paroxysmal nonsustained ventricular tachycardia often associated with implantable cardioverter-defibrillator (ICD) therapies may precipitate admission to the hospital in a patient with impaired left ventricular function. In patients with heart failure and either reduced or preserved systolic function, symptomatic bradyarrhythmias may be due to intrinsic sinus or atrioventricular nodal dysfunction, adverse drug effects or electrolyte abnormalities (e.g., hyperkalemia). Early recognition and aggressive management of cardiac arrhythmias may be critical to achieving the goal of recompensation. However, it should be remembered that in addition to precipitating heart failure, arrhythmias may be caused by heart failure or result from proarrhythmic effects of drugs used in the management of heart failure. Although not an arrhythmia per se, ventricular dyssynchrony induced by right ventricular pacing is associated with an increased risk of heart failure hospitalization and atrial fibrillation, and warrants consideration of biventricular pacing.[41]

Myocardial ischemia or infarction should be considered as a possible precipitant, not only in patients with known ischemic heart disease presenting with heart failure, but also in patients with other forms of heart disease. For example, patients with previous heart failure secondary to hypertension or valvular heart disease may be well compensated until they develop unstable angina or an acute coronary syndrome. Diabetic patients with silent ischemia or infarction may also present with insidious heart failure. Infection is another common precipitating cause of heart failure. In a study by Tsuyuki and coworkers,[29] 11% of patients with an exacerbation of heart failure had pneumonia. Common viral infections, including influenza A and respiratory syncytial virus (RSV),[42] may also cause acute-on-chronic impairment of ventricular function and precipitate an admission with decompensated heart failure. It is not known whether direct viral infection of the myocardium, myocardial inflammation, or myocardial dysfunction secondary to circulating or local cytokines plays a significant role in such patients. Guidelines recommend that all patients with current or prior symptoms of heart failure receive yearly influenza vaccinations, which have been shown to reduce the rate of influenza by 40% to 50%.[3,43]

Comorbid conditions that are common in patients with heart failure and that may exacerbate symptoms leading to hospitalization include uncontrolled hypertension and anemia (see Table 17–1). In addition, the development of acute or acute-on-chronic renal failure may further impair the ability of patients with heart failure to excrete sodium or free water and thus may exacerbate fluid retention.[44] Other potentially correctable factors contributing to decompensation in heart failure include excessive alcohol consumption,[45,46] and medications that either depress myocardial function (e.g., β-blockers, amiodarone), or cause salt and water retention (e.g., nonsteroidal anti-inflammatory drugs, thiazolidinediones).[47,48] It is essential to search for these and other less common precipitating causes (e.g., hyperthyroidism, pulmonary embolism) in patients admitted to the hospital with heart failure because failure to recognize them may lead to refractory or recurrent heart failure.

GENERAL MANAGEMENT

Initial Patient Evaluation

Regardless of the etiology or underlying precipitant, patients admitted to the hospital for the treatment of heart failure have the potential for hemodynamic deterioration, including the development of cardiogenic shock. Therefore, a rapid bedside evaluation of circulatory status and cardiac rhythm, and assessment for ischemia should be performed even before the medical records or diagnostic studies are reviewed. In addition to ruling out an acute coronary syndrome that may require urgent revascularization or thrombolysis, evidence for marked elevation of intracardiac filling pressures and/or inadequacy of systemic perfusion should be sought. In select cases, inotropic or vasopressor therapy may need to be initiated before obtaining additional diagnostic data or invasive hemodynamic measurements. However, in the majority of patients who are clinically more stable, a complete review of the medical history and a detailed physical examination may provide important information regarding the underlying cause and acute precipitants of heart failure, as well as appropriate targets of therapy.

Risk Stratification

Clinical information obtained at the time of a heart failure admission may help to predict outcomes during the hospitalization and following discharge. Chin and Goldman first sought to determine the risk of a major complication or death in 435 patients admitted nonelectively to an urban university hospital with heart failure.[49] Two thirds of the patients had a previous history of heart failure. Compared with patients with new onset heart failure, these patients were older, and had more comorbidities, lower left ventricular ejection fraction, and lower initial blood pressure. In a multivariate analysis, independent predictors of in-hospital death or major complications that were noted at the time of admission were a systolic blood pressure of less than 90 mm Hg, respiratory rate greater than 30 breaths per minute, serum sodium of less than or equal to 135 mEq/L, and ischemic electrocardiographic changes not known to be old.

Using data from the ADHERE registry, Fonarow and colleagues[8] sought to develop a practical bedside tool for risk stratification of patients with acute decompensated heart failure. Derivation and validation cohorts of more than 65,000 patient records were subjected to classification and regression tree (CART) analysis to identify predictors of in-hospital mortality. Based on this empiric analysis, the single best predictor for mortality was an elevated admission level of blood urea nitrogen (greater than or equal to 43 mg/dL) followed by low systolic blood pressure (less than 115 mm Hg) and high serum creatinine (greater than or equal to 2.75 mg/dL). A simple risk tree identified patient groups with mortality rates

Table 17–3 Risk Stratification for In-Hospital Mortality in the ADHERE Registry

BUN ≥ 43 mg/dL	SBP < 115 mm Hg	Creatinine ≥ 2.75 mg/dL	Mortality, %
–	–	–	2.3
+	–	–	5.7
–	+	–	5.7
+	+	–	13.2
+	+	+	19.8

JAMA 2005;293:572.

ranging from 2.3% to 19.8% (Table 17–3). Additional clinical and laboratory predictors of adverse outcomes obtained at the time of hospital admission include presence of congestion,[50] ischemic etiology,[51] reduced ejection fraction,[21] anemia,[52] hyponatremia, elevated B-type natriuretic peptide (BNP) levels,[53,54] and positive cardiac troponins.[27]

Clinical Assessment of Intracardiac Filling Pressures

Most hospitalizations for decompensated heart failure occur because of congestion rather than low cardiac output.[7,55] Although congestion is often readily apparent in patients with acute heart failure, marked elevation in filling pressures may be underappreciated in patients with chronic heart failure.[56] In one study of nonedematous heart failure patients, unrecognized hypervolemia was present in 65% and predicted reduced survival.[57] Increased capacity for pulmonary lymphatic drainage resulting from chronic pulmonary congestion may lead to clinical situations in which PCWPs exceeding 30 to 35 mm Hg are tolerated. Conversely, a history of dyspnea on exertion is common in patients with heart failure and lacks the specificity to detect elevated cardiac filling pressures. Alternative mechanisms of dyspnea include decreased pulmonary function, increased ventilatory drive, and respiratory muscle fatigue.[58,59] Not surprisingly, investigators have been unable to demonstrate a close correlation between symptoms of exercise tolerance and measures of resting left ventricular performance in patients with heart failure. However, dyspnea on minimal exertion or at rest, including orthopnea and paroxysmal nocturnal dyspnea, are more specific historical clues to increased left-sided filling pressures in patients with known left ventricular failure. In patients with biventricular heart failure, abdominal discomfort, early satiety, nausea, vomiting, and anorexia suggest increased right-sided filling pressures. In addition, changes in baseline symptoms in an individual patient may suggest a clinically important worsening of heart failure.

Rales are a relatively specific, but insensitive, sign of pulmonary vascular congestion. In a series of patients with chronic heart failure and reduced ejection fraction, rales were present in only 60% of patients with an elevated PCWP.[60] However, rales were also detected in 16% of patients with normal PCWP and may be due to coexistent pulmonary or pleural disease. In the ADHERE registry, rales were present in two thirds of patients with acute decompensated heart failure.[21] Signs of increased right-sided filling pressures, including jugular venous distention, ascites, and peripheral edema, are relatively reliable indicators of increased left-sided filling pressures.[56] However, in specific clinical situations such as right ventricular infarction or pulmonary embolism, jugular venous distention may occur without signs of left-sided congestion. Significant interobserver variability regarding the extent of jugular venous elevation limits its usefulness at the bedside.[61] Both ascites and peripheral edema are less sensitive signs of volume overload than jugular venous distention, particularly in young adults, and may be preceded by the development of tender hepatomegaly. A third heart sound may suggest the presence of previously undiagnosed cardiomyopathy, but its presence is neither sensitive nor specific for acute decompensated heart failure. Increased intensity of the pulmonic component of the second heart sound in association with a holosystolic murmur suggests pulmonary hypertension due to chronic heart failure and associated mitral and/or tricuspid regurgitation.

Rarely, experienced examiners may use the bedside Valsalva maneuver with sphygmomanometric determination of arterial blood pressure response to help clarify the left ventricular filling pressure.[62] However, limited patient effort due to dyspnea or discomfort, and arrhythmias may interfere with this examination. An automated device that quantifies the blood pressure response to the Valsalva maneuver,[63] as well as contrast-enhanced and tissue Doppler echocardiographic techniques[64] have been developed for the noninvasive determination of left ventricular filling pressures. In addition, intrathoracic impedance monitoring[65] and plasma volume analysis[57] are new methods to assess fluid status in heart failure patients. However, prospective data demonstrating the usefulness of these new "tools" in patient management are lacking.

Like the physical examination, routine chest radiography has been shown to be an insensitive clinical tool for demonstrating congestion in the setting of chronic heart failure.[66] In one study, 68% of patients with advanced heart failure and PCWP ≥ 25 mm Hg had minimal or no evidence of pulmonary congestion on admission chest radiographs.[67] When present, however, interstitial or alveolar edema suggests markedly elevated filling pressures. Bilateral or unilateral pleural effusions are common in acute decompensated heart failure,[68] and may not necessarily respond to diuresis. In these instances, ultrasound-guided thoracentesis[69] or chest tube thoracostomy may be necessary to relieve respiratory distress and improve arterial oxygenation.

Clinical Assessment of Systemic Perfusion

Fatigue and weakness, which are common complaints in patients with heart failure, may be due to reduced cardiac output and poor perfusion of skeletal muscles. In addition, abnormal endothelium-dependent vasodilation, respiratory muscle fatigue, and altered skeletal muscle structure and function may contribute to exercise intolerance in heart failure.[70] However, fatigue is a nonspecific symptom that may be caused by many noncardiopulmonary diseases (e.g., anemia, renal failure, depression), disordered sleep (e.g., sleep apnea, restless legs), drugs (e.g., β-blockers, sedatives) or electrolyte abnormalities. If a patient is admitted to the hospital with decompensated heart failure, mental obtundation or anuria are highly suggestive of critically reduced perfusion. A more subtle history of altered mentation such as lack of concentration or memory may be obtained from a family member. In severe low-output states, the patient may appear anxious or diaphoretic or exhibit signs of air hunger. Patients with advanced heart failure may be cachectic from a low-output state and catabolic/anabolic imbalance,[71] whereas those with more recent onset heart failure will be well nourished. Other physical signs of acute hypoperfusion include cool extremities, digital or circumoral cyanosis, and marked hypotension with a rapid, thready pulse. Pulsus alternans signifies advanced myocardial disease and tends to be present during tachycardia.

In measuring the blood pressure noninvasively, it is important to deflate the cuff slowly, listening closely to define the systolic blood pressure and pulse pressure, especially in patients with atrial fibrillation. Prior studies have shown that when the pulse pressure is less than 25% of the systolic blood pressure, there is a high likelihood that the cardiac index is below 2.2 liters/minute/m^2.[56] Thus, in a patient with severe heart failure, a blood pressure of 100/90 mm Hg may be more worrisome than a blood pressure of 80/50 mm Hg. However, preliminary data from the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) demonstrate lack of correlation between the estimated and invasive assessment of cardiac index.[72]

Laboratory Assessment

Routine chemistry and hematology studies obtained on admission may be helpful in the initial assessment of patients with decompensated heart failure, and in formulating a therapeutic plan. Dilutional hyponatremia may result from a combination of sodium restriction, aggressive diuresis, and an impaired ability to excrete free water.[73,74] Increased circulating levels of renin and vasopressin are also important mediators of hyponatremia in heart failure.[24] Although ACE inhibitors alone or in combination with loop diuretics may acutely correct hyponatremia in severely ill patients with heart failure, overactivity of the renin-angiotensin-aldosterone system may predispose these same patients to the development of hypotension, worsening renal function, and hyperkalemia on initiation of, or rechallenge with, an ACE inhibitor. Use of nonsteroidal anti-inflammatory agents should be avoided in hyponatremic patients because they may aggravate hemodynamic abnormalities and cause worsening renal function.[47]

Prolonged, high-dose diuretics may predispose patients to hypokalemia and hypomagnesemia,[75] both of which are associated with an increased risk of ventricular arrhythmias. Hyperkalemia may result from marked reductions in glomerular filtration rate and inadequate delivery of sodium to the distal renal tubule. Excess total body potassium may be exacerbated by the use of ACE inhibitors, potassium supplements, or aldosterone receptor antagonists.[76] The risk of hyperkalemic arrhythmias appears to be highest during potassium replacement, when intracellular potassium concentrations are still low; and hyperkalemia is a common cause of iatrogenic morbidity, and even mortality, during a heart failure hospitalization. Other laboratory abnormalities that may complicate management of decompensated heart failure include elevated liver enzymes, hyperbilirubinemia, and a prolongation of the prothrombin time. If right-sided heart failure is long-standing, cardiac cirrhosis may result in hypoalbuminemia and an exacerbation of extravascular fluid accumulation as well as inappropriate vasodilation. Low serum prealbumin levels and elevated C reactive protein levels are pro-inflammatory markers associated with cachexia in patients with end-stage heart failure.

In patients with chronic heart failure, blood urea nitrogen and serum creatinine levels are elevated secondary to reductions in renal blood flow and glomerular filtration rate. Decreased renal perfusion can precipitate bouts of acute tubular necrosis and lead to reduced renal mass. Other factors contributing to the presentation of combined cardiac and renal dysfunction, or "cardiorenal syndrome,"[77] include an altered balance of vasoconstrictor and vasodilating hormones, and comorbidities such as diabetes and hypertension. In patients with advanced heart failure, several commonly used classes of drugs including inhibitors of the renin-angiotensin-aldosterone system and diuretics may exacerbate renal impairment. During a heart failure hospitalization, approximately 25% of patients will develop worsening renal function defined variably as an increase in serum creatinine by greater than or equal to 0.3 mg/dL or 25% above baseline. The mechanisms underlying worsening renal function remain unknown, but are believed to include diuretic-induced reductions in glomerular filtration rate and neurohormonal activation. From a clinical standpoint, worsening renal function often results in interruption of diuretic therapy and discontinuation of other disease-modifying agents such as ACE inhibitors (Table 17–4). Worsening renal function is an independent predictor of increased length of stay and excess mortality both in-hospital and post-discharge.[44]

B-Type Natriuretic Peptides

B-type natriuretic peptide (BNP) is synthesized and secreted by the cardiac ventricles in response to an increase in wall stress or filling pressure. N-terminal pro-BNP (NT-proBNP) is an inactive fragment that results from cleavage of BNP from its pro-hormone. Both BNP and NT-proBNP can be used to help diagnose and risk stratify patients with acute decompensated heart failure.[53,54,78] In patients with chronic heart failure and reduced systolic function, BNP levels are elevated in relation to disease severity and provide strong independent prognostic information. Plasma BNP levels are also elevated in patients with heart failure and preserved systolic function, correlate with wall stress[79] and may predict survival.[80] In

Table 17–4 Potential Consequences of Worsening Renal Function During a Heart Failure Admission

Hospital discharge is delayed
Diuretic doses are decreased, often despite persistent congestion
ACE inhibitors, ARBs, and aldosterone receptor antagonists are discontinued
Noncardiac medications (e.g., antibiotics) are dose-adjusted
Positive inotropic agents are initiated to "increase renal perfusion"
Pulmonary artery catheter is placed to assess hemodynamics
Foley catheter is placed to record urine output
Renal ultrasound is ordered to rule out post-obstructive uropathy

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

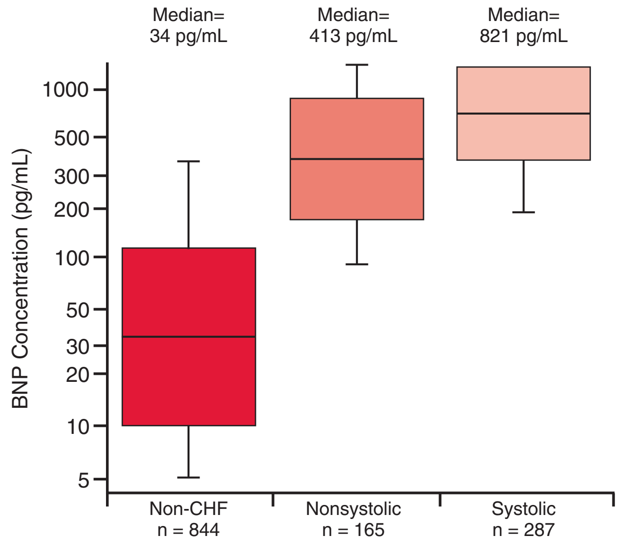

Figure 17–4 Box and whisker plots showing median BNP levels in patients presenting to the emergency department with dyspnea not due to heart failure (non-CHF) compared with patients with a final adjudicated diagnosis of diastolic (nonsystolic) versus systolic heart failure. (From Maisel AS, McCord J, Nowak RM, et al: Bedside B-type natriuretic peptide in the emergency diagnosis of heart failure with reduced or preserved ejection fraction. Results from the Breathing Not Properly Multinational Study. J Am Coll Cardiol 2003;41:2010.)

the acute setting, low or normal BNP levels (e.g., less than 100 pg/mL) have a reasonably high negative predictive value for excluding heart failure as the cause of dyspnea.

In one study of patients presenting to the emergency room with shortness of breath, patients with diastolic heart failure had lower BNP levels compared with those with systolic heart failure (median 413 pg/mL and 812 pg/mL, respectively) (Fig. 17–4).[81] However, BNP added only modest discriminatory value in differentiating these two groups. In patients with advanced heart failure, BNP levels correlate only modestly with LV filling pressures,[82] and the diagnostic accuracy of BNP for predicting an elevated PCWP is limited by a high false-negative rate. BNP levels decrease in parallel with a reduction in filling pressures during acute diuretic and vasoactive therapy, and change in BNP (Fig. 17–5A) and predischarge BNP (see Fig. 17–5B) are independent predictors of subsequent events.[53] In practice, however, BNP levels can vary substantially between individuals with the same degree of heart failure (Table 17–5). For example, natriuretic peptide levels are higher in women, increase with age and renal insufficiency, and decrease with obesity.[83] Currently, there is no proven role for BNP-guided therapy in the inpatient setting, although a BNP level obtained at the time of presentation to the emergency room may decrease resource use.[84]

Noninvasive versus Invasive Management

Although practice patterns differ greatly, the majority of patients with acute decompensated heart failure can be managed safely and effectively on a cardiac telemetry unit without invasive monitoring. Admission to an intensive care unit should be reserved for patients with: (1) hemodynamic instability requiring titration of vasoactive therapy, placement of a pulmonary artery catheter or mechanical circulatory support; (2) unstable cardiac rhythms requiring cardioversion, defibrillation, or temporary pacing; (3) acute respiratory failure requiring noninvasive or mechanical ventilation; or (4) severe renal failure requiring electrolyte management and urgent consideration of dialysis. For all patients, clinical goals of therapy should be set (Table 17–6), including the relief of symptoms related to congestion such as orthopnea and abdominal fullness, and improvement in symptoms of low cardiac output (e.g., fatigue, anorexia). Physical findings of volume overload, including jugular venous distention, lower extremity edema, hepatomegaly, and ascites, should also be targets of therapy. Despite optimal care, not all patients will be free of congestion at the time of discharge, including patients in whom diuresis is limited by worsening renal function, hypotension, or both. If possible, the patient should be discharged with a systolic blood pressure above 80 mm Hg and warm extremities.

The insertion of a pulmonary artery catheter for the purpose of hemodynamic monitoring may be helpful in select patients, but is not recommended for the routine management of acute decompensated heart failure. As described above, a reasonable noninvasive assessment of volume status and adequacy of perfusion may be obtained by history and physical examination. If severely elevated filling pressures, critically reduced perfusion, or both, is evident, placement of a pulmonary artery catheter should not take precedence over initiation of appropriate therapy (e.g., parenteral diuretics, positive inotropic or vasopressor agents). In select cases, hemodynamic measurements will be helpful in the choice and titration of parenteral agents to optimize loading conditions and improve clinical status rapidly. However, routine clinical use of the pulmonary artery catheter for heart failure management has not proved effective in observational or controlled clinical studies.

In an observational study of critically ill patients with a variety of conditions including acute respiratory failure, multisystem organ failure, and heart failure, right heart catheterization was associated with an increased 30-day mor-

tality rate and increased use of resources.[85] However, this study was methodologically flawed (e.g., use of post-hoc matching, lack of control for the collection, interpretation and use of hemodynamic data), and in the subgroup of patients with heart failure, the relative hazard of death was 1.02 ($P = 0.94$).

The ESCAPE Trial sought to determine whether pulmonary artery catheter use is safe and improves clinical outcomes in patients hospitalized with severe heart failure.[86] Four hundred and thirty three patients were randomized to receive therapy guided by clinical assessment and pulmonary artery catheter or clinical assessment alone. The target of therapy in

both groups was resolution of congestion, with additional hemodynamic targets (right atrial pressure 8 mm Hg, PCWP 15 mm Hg) set for the invasive group. Therapy in both groups led to substantial reduction in signs and symptoms of congestion, but there was no difference in morbidity or mortality rates in the two groups (Table 17–7). In a meta-analysis of randomized clinical trials in critically ill patients that included data from ESCAPE, use of the pulmonary artery catheter had no effect on hospital length of stay or mortality.[87]

Despite these negative findings, there may be select indications for invasive hemodynamic monitoring during treatment of acute decompensated heart failure. These include evidence of severe hypoperfusion, marked congestion at rest associated with acute ischemia, infarction or renal failure, fluid retention that is refractory to high-dose or combination diuretics, hypoxemia with coexistent cardiac and pulmonary disease, and shock of unclear etiology. In addition, hemodynamic assessment is routine in considering patients for cardiac transplantation, in whom the degree and reversibility of pulmonary hypertension[88] are important predictors of post-transplant outcomes.[89] Similarly, invasive hemodynamic measurements are helpful in the evaluation of patients for ventricular assist device implantation, either as a bridge to cardiac transplant or permanent therapy, and in their perioperative management (see Chapter 18). The benefits of pulmonary artery catheter use may be more evident at centers experienced with hemodynamic monitoring for advanced heart failure.[64]

Hemodynamic Profiles

Initial *clinical assessment* of cardiac filling pressures and systemic perfusion can be used to categorize patients into broad *hemodynamic profiles* that help guide medical management and provide prognostic information.[50] If the patient is found to be *clinically well compensated* despite presenting with shortness of breath at rest, an evaluation for intermittent ischemia or paroxysmal arrhythmias is indicated. In addition, noncardiac causes of dyspnea, both pulmonary and extrapulmonary, as well as psychological causes, such as anxiety, should be considered.

The most common hemodynamic profile encountered in patients with acute decompensated heart failure is pulmonary and/or systemic venous *congestion with normal perfusion*. In these patients, symptoms will generally respond to diuresis using an intravenous loop diuretic or the combination of a loop and thiazide diuretic. If the patient does not respond to initial attempts at diuresis, vasodilator therapy, (either oral or intravenous), may require titration because elevated filling pressures can be exacerbated by systemic and pulmonary vasoconstriction in addition to volume expansion. If the patient is already taking an ACE inhibitor or angiotensin receptor blocker, the dose should be titrated after an effective diuresis has been achieved, while monitoring closely for orthostatic hypotension, worsening renal function, or both. In select patients, a combination of vasodilators may be used such as isosorbide dinitrate, hydralazine, or an angiotensin receptor blocker in addition to an ACE inhibitor. Large pleural effusions or ascites that do not respond to diuresis may require thoracentesis or paracentesis, respectively. Symptomatic goals of diuretic therapy include resolution of orthopnea and dyspnea at rest or on minimal exertion. For patients in whom a pulmonary artery catheter has been placed, hemodynamic goals are discussed subsequently.

Hypoperfusion without pulmonary venous congestion, manifested by progressive fatigue and anorexia and often accompanied by azotemia, may precipitate hospitalization in patients with severe heart failure. Use of positive inotropic agents is often necessary when perfusion is critically reduced, although open-label and controlled studies as well as registry data[90] suggest that short-term exposure to an inotrope is associated with an increased risk of adverse events, including death. Use of parenteral vasodilators may be considered if systemic vasoconstriction is suspected, but are usually poorly tolerated if filling pressures are not also elevated. Vasodilators can precipitate hypotension[11] and lead to worsening renal function[91] in the setting of low or normal cardiac filling pressures. In addition, further reflex neurohormonal activation can lead to clinically significant arrhythmias. In patients with underlying ischemic heart disease, decreased coronary artery perfusion pressure and reflex tachycardia may aggravate ischemia. Some patients may develop significant hypoperfusion secondary to overdiuresis. In this situation, the judicious use of intravenous fluids may be considered, but patients should be observed closely to avoid onset of congestive symptoms.

For patients who present with the combination of *pulmonary and/or systemic venous congestion and inadequate*

systemic perfusion, simultaneous reduction in filling pressures and optimization of systemic vascular resistance (see Fig. 17–3B) can generally be accomplished with intravenous vasodilator therapy, with intermittent or continuous infusion diuretics, over 1 to 3 days. Once clinical goals are achieved, conversion to an oral regimen that maintains stability of clinical and laboratory parameters may require an additional 24 to 48 hours of treatment.

Hemodynamic Goals of Therapy

For patients in whom a pulmonary artery catheter has been placed to guide treatment, the ideal goal of parenteral therapy in the management of decompensated heart failure is to achieve an effective cardiac output at relatively normal filling pressures. For patients with severe hemodynamic compromise, a reduction in filling pressures and systemic vascular resistance (SVR) is often associated with a 30% to 50% increase in forward stroke volume. Although the optimal hemodynamics for a given patient cannot be predicted with certainty, specific goals of hemodynamically guided therapy should be set (see Table 17–6). A PCWP of less than or equal to 16 mm Hg is appropriate for most patients with chronic heart failure, whereas a slightly higher filling pressure may be necessary to maintain cardiac output in the setting of acute myocardial infarction (i.e., decreased left ventricular compliance without significant dilation). A right atrial pressure less than or equal to 8 mm Hg is optimal in most settings as long as the PCWP is not reduced excessively. With exceptions such as right ventricular infarction and pulmonary embolism associated with hypotension, a higher right atrial pressure may be required. Maintaining a cardiac index greater than or equal to 2.2 L/minute/m^2 is often necessary to avoid cerebral, renal, or hepatic hypoperfusion. However, lower cardiac indices may cause relatively little organ dysfunction if the low-output state has developed gradually. SVR is optimal in the range of 1000 to 1200 dynes-sec·cm^{-5}. Although cardiac output may be increased further with additional lowering of the SVR (i.e., in the range of 800 to 900 dynes-sec·cm^{-5}), a reflex increase in sympathetic tone may result in unwanted tachycardia, orthostatic hypotension, and renal dysfunction.[91] Finally, the above goals should be aimed for while maintaining a systolic blood pressure ≥80 mm Hg or a mean arterial pressure ≥60 mm Hg.

It should be remembered that thermodilution measurements may overestimate the cardiac output in patients with low-output states, possibly due to a loss of the cold indicator across the myocardium. Thermodilution measurements may also be unreliable in the setting of significant tricuspid regurgitation or marked respiratory variation, although one study showed a good correlation between thermodilution and Fick outputs in patients with chronic heart failure and moderate-to-severe tricuspid regurgitation.[92] Alternatively, mixed venous oxygen saturations may be used to calculate cardiac output using the Fick equation with oxygen consumption measured by a metabolic rate meter. Given that oxygen consumption may be influenced markedly by infection, other stresses, or sedation, and has been shown to vary greatly among adults at the time of cardiac catheterization, the use of "assumed" Fick outputs is not recommended. An alternative is to follow changes in the mixed venous oxygen saturation to estimate cardiac output trends.[93]

In choosing an initial parenteral agent, particular attention should be paid to the systemic vascular resistance (see following discussion of specific agents). Patients with an elevated SVR will generally tolerate initiation of a vasodilator such as nesiritide or nitroglycerin without hypotension and will achieve significant hemodynamic benefit. On the other hand, patients with a low SVR (e.g., secondary to concomitant sepsis or anesthesia) often will not tolerate further vasodilation without developing symptomatic hypotension. Dobutamine, which provides inotropic support in addition to mild vasodilation, is the preferred initial agent in this situation. An alternative choice would be dopamine at lower doses (3 to 5 mcg/kg/minute). Higher doses may increase filling pressures and elevate the SVR by stimulating α-adrenergic receptors. In patients with an SVR in the normal range, both vasodilators and positive inotropes are often effective and may be used in combination. An alternative to the combination of a vasodilator and inotrope is the phosphodiesterase inhibitor, milrinone, which exerts both direct inotropic and vasodilator effects in patients with decompensated heart failure. The incidence of hypotension is higher with milrinone, owing to greater peripheral vasodilation.

FLUID MANAGEMENT

Parenteral Diuretic Therapy

The initiation of an effective diuresis is integral to the management of elevated cardiac filling pressures associated with acute decompensated heart failure. For patients admitted to the hospital, this can best be accomplished with parenteral diuretics because the intravenous route will more reliably deliver high drug concentrations to the renal tubular lumen.[94,95] Furosemide is the most widely used loop diuretic, although bumetanide and torsemide are also available for patients with documented intolerance or unresponsiveness to furosemide. Furosemide can be given intravenously in doses ranging from 20 to 240 mg (or higher) depending on the patient's diuretic history, and as frequently as every 4 to 6 hours. Addition of a thiazide-type diuretic such as metolazone (2.5 to 10 mg orally) or chlorothiazide (250 to 500 mg intravenously) often potentiates the diuresis. A continuous infusion of furosemide (e.g., 5 to 40 mg per hour) may be used to treat refractory fluid retention.[96] A Cochrane review of 8 trials in 254 patients found that urine output was significantly greater with a continuous infusion, although the difference was modest (mean difference 271 mL per 24 hours). Less tinnitus and hearing loss occurred with continuous infusion.[97] The addition of hypertonic saline to intravenous furosemide may result in more rapid achievement of dry weight, but this novel strategy remains to be tested in a multicenter study.[98]

For patients with hypokalemia requiring significant potassium supplementation, a potassium-sparing diuretic such as spironolactone or triamterene may be used. Aldosterone receptor antagonists are additionally beneficial in the management of fluid retention associated with cirrhosis,[99] and chronic therapy with spironolactone reduces morbidity and mortality in patients with severe heart failure.[100] For patients with marked fluid overload unresponsive to diuretics or for those who develop worsening renal function requiring

discontinuation of diuretics, ultrafiltration or hemodialysis (if there is coexistent renal failure) may be considered (see later).

In the setting of acute pulmonary edema, the rapid clearance of congestion by parenteral diuretics is mediated by natriuresis and diuresis, decreased intravascular volume, and systemic vasodilation. In patients with acute or chronic decompensated heart failure, the goals of diuretic therapy include the elimination of edema and orthopnea (see Table 17–6). Reduction in atrial and ventricular diastolic pressures reduces wall stress and ventricular volumes and may improve subendocardial perfusion and reduce valvular regurgitation, respectively. Frequent reevaluation of clinical status and renal function, as well as hemodynamics if available, is necessary to guide frequency and duration of therapy. Mild azotemia may be tolerated to achieve hemodynamic compensation, but may identify high-risk patients that require closer follow-up after discharge. Fluid and sodium restriction and cautious replacement of potassium and magnesium are important adjunctive measures that should not be overlooked. Once treatment goals are achieved, the patient should be converted to an oral diuretic regimen that maintains stable weight and renal function. Adverse effects of aggressive diuresis include electrolyte abnormalities and associated arrhythmias, worsening renal function,[44] metabolic alkalosis, muscle cramps, and ototoxicity.[101]

Ultrafiltration

Ultrafiltration removes excess plasma volume without causing a significant change in electrolytes. In patients with chronic heart failure and diuretic resistance, ultrafiltration improves symptoms, neurohormones, and hemodynamics without hypotension.[102] Reductions in peripheral and pulmonary edema, and a subsequent increase in diuretic efficacy have been reported. Recent pilot studies in acute decompensated heart failure suggest that early ultrafiltration is associated with greater fluid removal and symptom relief than medical therapy alone,[103] and may decrease length of stay and readmission rates.[104] The effects of ultrafiltration on renal function and outcomes were tested in a large, multicenter randomized trial (UNLOAD). Preliminary data from UNLOAD suggest that ultrafiltration removes more fluid and reduces readmission rates compared with standard diuretic therapy in patients with acute decompensated heart failure.[104a] Additional data on safety and cost effectiveness are needed.

VASOACTIVE THERAPY

Nitroglycerin

When administered intravenously, nitroglycerin has an immediate onset of action and a plasma half-life of 1 to 4 minutes. It is cleared by the vascular endothelium, hydrolyzed in the blood, and metabolized in the liver. At lower infusion rates, its main cardiovascular effect is venodilation with a resultant fall in ventricular volumes and filling pressures (Table 17–8). At higher infusion rates, nitroglycerin also causes arterial dilation resulting in decreases in both pulmonary and systemic vascular resistance.[11,105] Nitroglycerin may be of particular use in patients who are refractory to diuretic therapy and continue to manifest elevated filling pressures, have disproportionate right-sided failure or unstable ischemia, or are intolerant to nitroprusside.

Table 17–8 Hemodynamic Effects of Parenteral Vasodilators

	PCWP	SVR	CO
Nitroglycerin	↓↓	↔↓	↑↔↓
Nesiritide	↓↓	↓	↑
Nitroprusside	↓↓	↓↓	↑↑
Milrinone	↓↓	↓↓	↑↑

CO, cardiac output; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance.

Intravenous nitroglycerin is usually started at a low infusion rate of 20 to 30 mcg/minute, and increased by 10 to 20 mcg/minute every 5 to 10 minutes until the desired response is observed or a dose of 400 mcg/minute is reached. If a pulmonary artery catheter is present, cardiac filling pressures and SVR are used to guide titration, although careful noninvasive monitoring of blood pressure may be adequate in the absence of severely reduced perfusion. As with other vasodilators, use of nitroglycerin may be limited by hypotension requiring cessation of the drug, intravenous fluids, or leg elevation. In addition, vasodilation may be associated with headache, flushing, and diaphoresis. Patients with significant right-sided heart failure may be resistant to the acute administration of nitroglycerin, but will often respond following diuresis. Pharmacologic tolerance to nitroglycerin may also develop,[106,107] and preventive strategies include avoidance of excessive dosing, limiting fluid retention, and the use of intermittent dosing.

Nesiritide

As discussed above, BNP levels are elevated in patients with heart failure, correlate with severity of illness, and provide prognostic information. The physiologic effects of BNP include vasodilation, diuresis, natriuresis, and antagonism of the renin-angiotensin-aldosterone and endothelin systems.[80] Based on these favorable actions, recombinant human BNP (nesiritide) was developed for the treatment of heart failure. In early clinical studies in patients with mild-to-moderate heart failure, nesiritide was shown to exert potent vasodilator (see Table 17–8)[108] and modest natriuretic effects,[109] and to improve dyspnea and fatigue when compared with placebo.[110] To compare the efficacy and safety of nesiritide with another vasodilator, the Vasodilation in the Management of Acute CHF study randomized 489 patients with acute decompensated heart failure to receive intravenous nitroglycerin or nesiritide in addition to standard therapy.[11] At 24 hours, the reduction in PCWP was greater with nesiritide than nitroglycerin (-8.2 versus -6.3 mm Hg, $P = 0.04$) with no evidence of tachyphylaxis, whereas there was a similar improvement in dyspnea in both groups. The duration of symptomatic hypotension, which occurred in approximately 5% of patients in both groups, was greater with nesiritide; headache and abdominal pain were more common with nitroglycerin. In 2001, the U.S. Food and Drug Administration approved nesiritide for the treatment of patients with acute decompensated heart failure and dyspnea at rest or with minimal activity. Although it may be initiated in the emergency depart-

ment, nesiritide is more commonly used in patients who remain symptomatic despite intravenous diuretic therapy.

The recommended starting dose of nesiritide is a 2 mcg/kg intravenous bolus followed by a continuous infusion of 0.01 mcg/kg/minute. Although the dose may be increased by 0.005 mcg/kg/minute to a maximum of 0.03 mcg/kg/minute to achieve the desired clinical or hemodynamic effects (see Table 17–6), higher doses are associated with increased rates of hypotension[11] and worsening renal function.[91] Thus, nesiritide is not recommended for use in patients with a systolic blood pressure <90 mm Hg or in those suspected of having low cardiac filling pressures. If there is uncertainty regarding volume status, an initial infusion rate of 0.005 mcg/kg/minute without a bolus is recommended. If symptomatic hypotension occurs, the infusion rate should be immediately decreased or discontinued. In patients with the cardiorenal syndrome, there is no evidence that nesiritide improves renal function or enhances diuresis.[111]

In patients awaiting cardiac transplant with secondary pulmonary hypertension, continuous nesiritide infusion for days to weeks has been used alone or in combination with a positive inotrope (e.g., dobutamine) to lower pulmonary artery pressures and pulmonary vascular resistance.[112] It is recommended that nesiritide be discontinued several hours before induction of cardiac anesthesia to avoid the development of catecholamine-refractory vasoplegia following cardiopulmonary bypass.[113] There is no proven role for intermittent outpatient infusions of nesiritide in patients with chronic decompensated heart failure.

Nitroprusside

For patients with decompensated heart failure characterized by low cardiac output, high filling pressures and elevated SVR, nitroprusside can be used either alone or in combination with a positive inotropic agent to rapidly improve hemodynamics.[114] The drug's potent vasodilator effect is mediated by the local production of nitric oxide.[115] The onset of action is rapid (i.e., 1 to 2 minutes), making it an ideal agent for use in urgent situations that require rapid dose titration and a predictable hemodynamic effect. Nitroprusside is a balanced arterial and venous dilator, and reduces both filling pressures and systemic and pulmonary vascular resistance (see Table 17–8). Stroke volume and cardiac output increase, and pulmonary artery, pulmonary capillary wedge and right atrial pressures decrease (Fig. 17–6). In patients with chronic heart failure, heart rate is generally unchanged or may fall due to reflex sympathetic withdrawal.[105] Nitroprusside infusion may be started at a rate of 10 to 20 mcg/minute and increased by 20 mcg/minute every 5 to 15 minutes until the hemodynamic goals are achieved while maintaining a systolic blood pressure ≥80 mm Hg. Doses of 300 mcg/minute or higher are seldom required and increase the risk of toxicity. Cardiac output and SVR should be measured frequently during titration.

Nitroprusside is a potent vasodilator and its use may be limited by hypotension. In patients with ischemic heart disease, decreases in coronary perfusion pressure accompanied by reflex tachycardia may worsen myocardial ischemia. In patients with acute decompensated heart failure, hemodynamic deterioration may occur immediately following the withdrawal of nitroprusside due to a transient increase in systemic vascular tone (Fig. 17–7).[116] Hemodynamic rebound may be avoided by initiating oral vasodilator therapy before nitroprusside withdrawal. Other adverse effects of nitroprusside are due to the accumulation of its metabolites, cyanide and thiocyanate.[117] Cyanide toxicity, which is most likely to occur in patients with hepatic dysfunction or following prolonged infusions, results in lactic acidosis and methemoglobinemia, and may manifest as nausea, restlessness, and dysphoria. If cyanide toxicity is suspected, the infusion should be stopped and serum levels checked. Thiocyanate toxicity may occur gradually in patients with renal insufficiency, and is manifested by nausea, confusion, weakness, tremor or seizures, and rarely, coma. If mild, cessation of the infusion is usually sufficient; in severe cases, hemodialysis may be necessary.

Dobutamine

Dobutamine is a direct-acting synthetic sympathomimetic amine that stimulates β_1-, β_2-, and α-adrenergic receptors in the myocardium and vasculature.[118] Its primary cardiovascular effect is to increase cardiac output by increasing myocardial contractility (Table 17–9). Although dobutamine does not stimulate dopaminergic receptors in the kidney, renal blood flow often increases in proportion to the increase in cardiac output. In contrast to other β-adrenergic agonists (i.e., isoproterenol), the positive inotropic effect of dobutamine is associated with less increase in heart rate. The drug causes modest decreases in left ventricular filling pressure and systemic vascular resistance (see Fig. 17–6) due to a combination of direct vascular effects and the withdrawal of sympathetic tone. Dobutamine also directly improves left ventricular relaxation via stimulation of myocardial β-adrenergic receptors.[119]

Dobutamine may be a useful agent for the initial management of patients with acute or chronic decompensated heart failure characterized by a low cardiac output and end-organ dysfunction. It can be initiated at a dose of 2 mcg/kg/minute and titrated upward by 1 to 2 mcg/kg/minute until clinical or hemodynamic goals are achieved or a dose-limiting event, such as unacceptable tachycardia or an arrhythmia, occurs. Doses of 3 to 5 mcg/kg/minute are often adequate for good clinical response. Maximum effects are usually achieved at a dose of 15 mcg/kg/minute, although higher infusion rates may occasionally be used. The inotropic response to dobutamine may be attenuated owing to desensitization of the β-adrenergic receptor pathway.[120] If the maximally tolerated infusion rate of dobutamine does not result in a sufficient increase in cardiac index or improved end-organ perfusion, a second positive inotropic agent such as milrinone may be added.[121] In patients with elevated cardiac filling pressures and/or SVR, the coadministration of a vasodilator may be required. In patients who remain hypotensive on dobutamine, high-dose dopamine may be added while considering mechanical support and cardiac transplantation (see Chapter 18), if indicated.

Dobutamine may increase heart rate, thereby limiting the dose that can be infused. However, in some patients with very depressed cardiac output, the improvement in hemodynamic function may cause a withdrawal of sympathetic tone such that heart rate actually decreases. Hypotension is uncommon, but can occur in patients who are hypovolemic. Arrhythmias, including supraventricular and ventricular tachycardia, may limit the dose. Likewise, myocardial ischemia secondary to increased myocardial oxygen consumption may occur. Some patients with severe heart failure may show pharmacologic tolerance to dobutamine, or tolerance may develop after several days of a continuous infusion. In patients awaiting

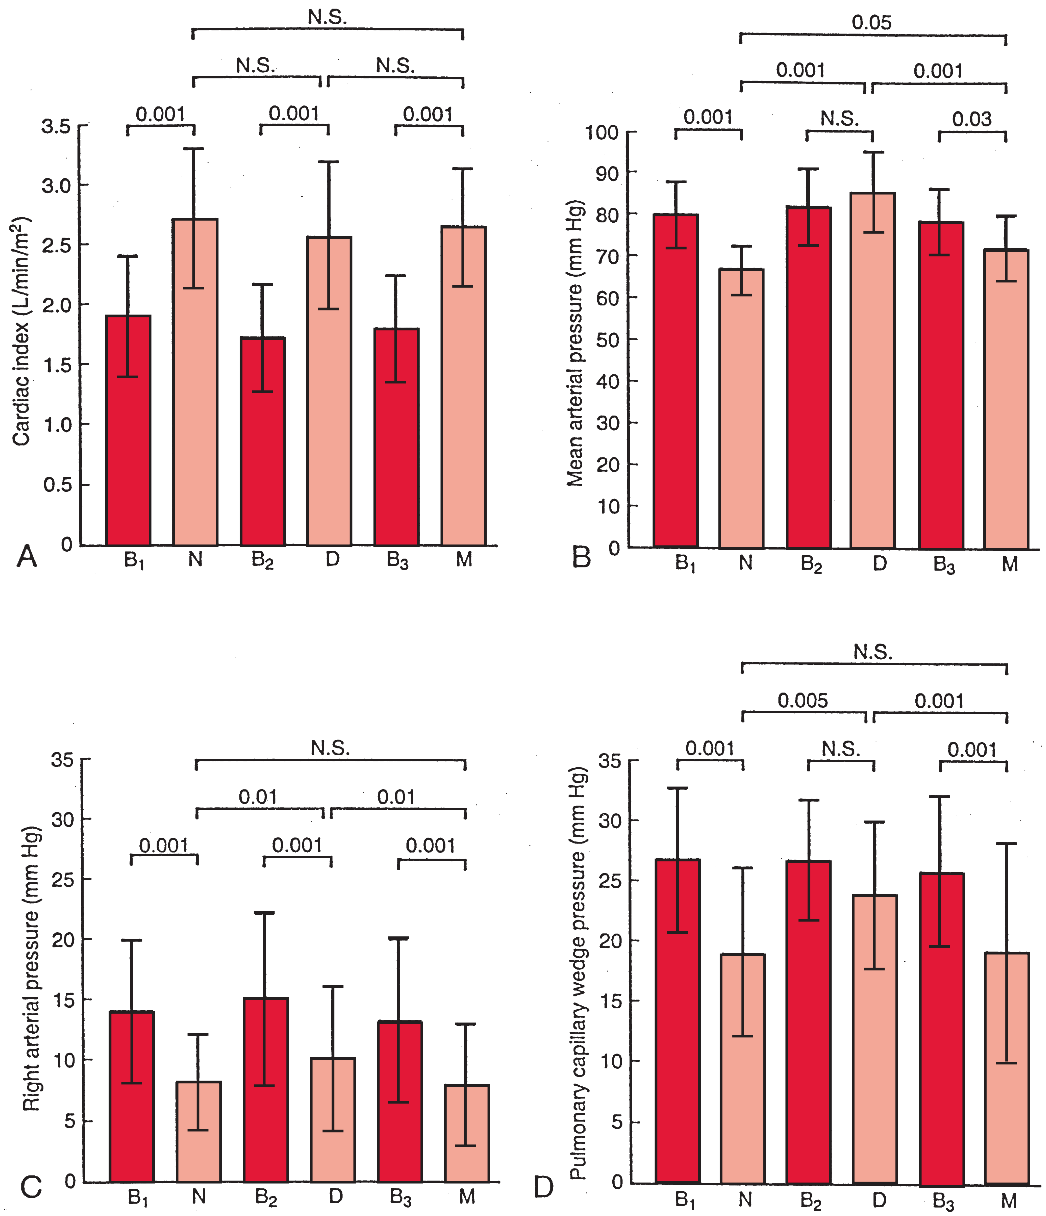

Figure 17–6 Comparative effects of nitroprusside (N), dobutamine (D), and milrinone (M) on cardiac index, mean arterial pressure, right atrial pressure, and pulmonary capillary wedge pressure in patients with severe heart failure (B_1, B_2, and B_3 = baseline measurements). The three agents were administered in doses that caused comparable increases in cardiac index (**A**). Under these conditions, nitroprusside and milrinone significantly reduced arterial pressure, but dobutamine had no effect (**B**). All three agents reduced right atrial pressure (**C**), although the effect of dobutamine was slightly less pronounced. Both nitroprusside and milrinone significantly reduced pulmonary capillary wedge pressure (**D**), and this effect was more pronounced than the effect of dobutamine. (Adapted Monrad ES, Baim DS, Smith HS, et al: Milrinone, dobutamine, and nitroprusside: Comparative effects on hemodynamics and myocardial energetics in patients with severe congestive heart failure. Circulation 1986;73:III168-III174.)

cardiac transplantation, chronic dobutamine therapy may cause hypersensitivity myocarditis[122] leading to hemodynamic deterioration. In these situations, the addition or substitution of a phosphodiesterase inhibitor may be necessary.

Milrinone

In myocardium and vascular smooth muscle, inhibition of the membrane-bound enzyme, phosphodiesterase (PDE), results in an increase in intracellular cyclic AMP. Milrinone is a selective inhibitor of the type III isoform of PDE. In the myocardium, milrinone exerts both positive inotropic and lusitropic effects.[123] Milrinone is also a potent vasodilator in the systemic and pulmonary circulation (see Fig. 17–6).[124] In patients with acute decompensated heart failure, milrinone increases cardiac output due to an increase in stroke volume (see Table 17–9). Balanced arterial and venous dilation causes decreases in right atrial, pulmonary artery, pulmonary capillary wedge, and mean arterial pressures (see Table 17–8). For a comparable increase in cardiac output, milrinone decreases

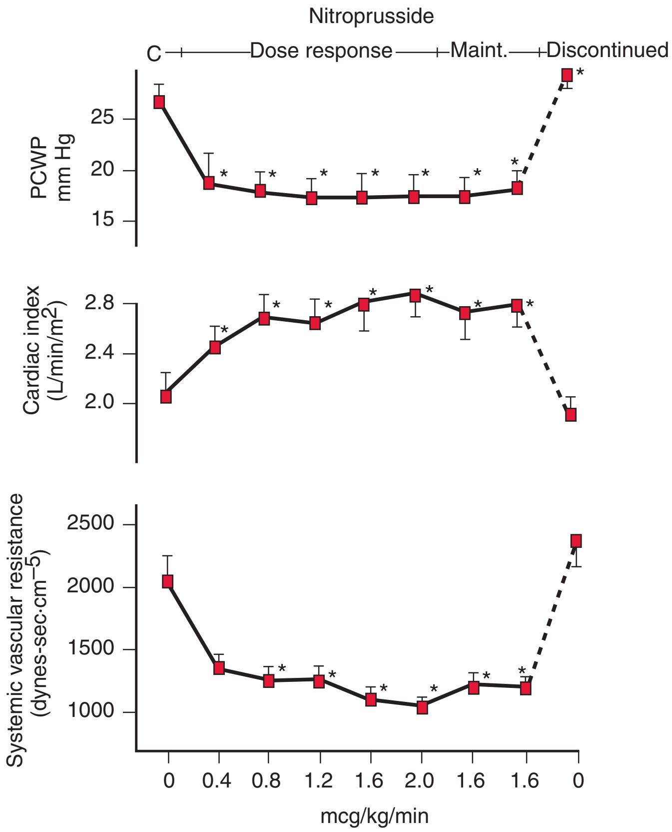

Figure 17–7 Hemodynamic rebound following discontinuation of nitroprusside in patients with moderate-to-severe heart failure. Graphs show changes in PCWP (*top panel*), cardiac index (*middle panel*) and systemic vascular resistance (*bottom panel*) during dose response, maintenance (Maint.) and discontinuation (Discontinued) of nitroprusside infusion. Thirty minutes following discontinuation, PCWP and systemic vascular resistance increased significantly above, and cardiac index decreased significantly below control values. (Adapted from Leier CV, Bambach D, Thompson MJ, et al: Central and regional hemodynamic effects of intravenous isosorbide dinitrate, nitroglycerin, and nitroprusside in patients with congestive heart failure. Am J Cardiol 1981;48:1115.)

SVR and left ventricular filling pressure to a greater extent than dobutamine. Conversely, for a comparable decrease in arterial blood pressure, milrinone increases cardiac output to a greater extent than nitroprusside.[125]

Milrinone may be useful for the treatment of refractory heart failure characterized by low cardiac output, high filling pressures and elevated or normal SVR. It may also be used as a bridge to cardiac transplant[126] or end of life,[127] especially in patients who develop tolerance to dobutamine, or to test pulmonary vasoreactivity in patients with secondary pulmonary hypertension being evaluated for cardiac transplant.[124] The positive inotropic effects of milrinone are additive to those of digoxin and may be synergistic with those of dobutamine.[128]

In patients with heart failure, milrinone is usually administered as a 25 to 50 mcg/kg intravenous bolus over 10 minutes followed by a constant infusion at 0.25 to 0.75 mcg/kg/minute, although an infusion may be initiated without a bolus. Although the pharmacologic half-life of milrinone is less than 1 hour in patients with heart failure, it is prolonged in the setting of renal dysfunction, and physiologic effects of discontinuation may not be fully apparent for over 12 hours. Thus, for patients undergoing cardiac surgery, it is recommended that milrinone be discontinued several hours before induction of anesthesia to avoid the development of vasoplegia. The major dose-limiting effects of milrinone are tachycardia and atrial or ventricular arrhythmias.[10] In addition, relatively volume-depleted patients may not tolerate the vasodilator effects of this agent and will experience hypotension requiring drug discontinuation. Other adverse effects of milrinone include liver function test abnormalities, fever, and nausea.

Table 17–9 Hemodynamic Effects of Positive Inotropic Agents

	+dP/dt	PCWP	SVR	CO
Dobutamine	↑↑	↓	↓	↑
Dopamine (low dose)	↔	↔	↓	↔↑
Dopamine (high dose)	↑↑	↑	↑↑	↑↔↓
Milrinone	↑	↓↓	↓↓	↑

CO, cardiac output; +dP/dt, maximum rate of rise of left ventricular systolic pressure; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance.

The occurrence of adverse events with short-term therapy has led clinicians to question the wisdom of using inotropes routinely in the management of decompensated heart failure. In a large study of patients admitted with an exacerbation of systolic heart failure, a 48-hour infusion of milrinone did not reduce the subsequent need for hospitalization and was associated with an increased risk of arrhythmias and sustained hypotension compared with placebo.[10] However, this study was criticized for enrolling patients who did not require inotropic therapy.

Dopamine

Dopamine is the immediate biosynthetic precursor of epinephrine and norepinephrine, and has both cardiac and vascular sites of action depending, in part, on the dose used.[129] At low doses (i.e., 1 to 3 mcg/kg/minute), dopamine directly activates dopaminergic receptors in the kidney, causing vasodilation. A small increase in cardiac output and decrease in SVR may also be observed (see Table 17–9). The resultant increase in renal blood flow leads to increased urine output and sodium excretion. At moderate doses (i.e., 3 to 8 mcg/kg/minute), dopamine is a weak partial agonist at myocardial β_1-receptors and exerts positive chronotropic and inotropic effects. In addition, increased release of norepinephrine from nerve terminals in the vasculature may result in stimulation of α-adrenergic receptors and a mild vasoconstrictor effect. At moderate-to-high doses (i.e., 5 to 20 mcg/kg/minute), peripheral α-adrenergic stimulation becomes apparent, resulting in vasoconstriction and increases in mean arterial pressure and systemic vascular resistance. As dopaminergic vasodilator effects in the kidney are overshadowed, renal blood flow decreases and urine output may decline.

In patients with acute decompensated heart failure, dopamine is occasionally used at low infusion rates to

improve renal function by increasing renal blood flow. Increased water and sodium excretion results in a decrease in cardiac filling pressures. To achieve clinical or hemodynamic goals, low-dose dopamine may be combined with other inotropic or vasodilator therapy.[121] In patients with significant hypotension or frank cardiogenic shock, higher doses of dopamine are used to increase SVR. When it is necessary to use vasoconstrictor doses of dopamine in the setting of myocardial failure, it is often useful to add dobutamine to augment the level of positive inotropic support beyond that provided by dopamine alone. If used alone at vasoconstrictor doses in patients with advanced heart failure, dopamine may increase both left and right heart filling pressures.[130] To counteract increased afterload and peripheral venoconstriction, high-dose dopamine may be combined with a vasodilator such as nitroglycerin.

As with dobutamine, the inotropic response to dopamine may be attenuated in patients with advanced heart failure[131] due to β-receptor downregulation and depletion of myocardial catecholamine stores.[132] Although generally well tolerated at low doses, higher infusion rates of dopamine may result in sinus tachycardia and supraventricular or ventricular arrhythmias. Other adverse effects of dopamine include digital gangrene in patients with peripheral arterial disease, tissue necrosis at sites of infiltration, and nausea at high doses.

Epinephrine and Norepinephrine

Epinephrine stimulates β_1- and β_2-adrenergic receptors in the myocardium, thereby causing marked positive chronotropic and inotropic responses. It also has potent agonist effects at vascular β-adrenergic receptors, causing increased arterial and venous constriction. Because of this latter effect, epinephrine (like high-dose dopamine) plays a minor role in the management of acute decompensated heart failure, except when complicated by severe hypotension. Epinephrine may be useful for the treatment of low cardiac output, with or without bradycardia, immediately following cardiopulmonary bypass or cardiac transplantation.[133] Continuous infusions may be started at a low dose, 0.5 to 1 mcg/minute, and titrated upward to 10 mcg/minute, as needed. The use of epinephrine may be limited by tachycardia, arrhythmias, ischemia due to increased myocardial oxygen consumption, and oliguria from renal vasoconstriction. In the setting of cardiac arrest, epinephrine may be used as per the Advanced Cardiovascular Life Support guidelines (1 mg intravenous push every 3 to 5 minutes) to manage ventricular fibrillation or pulseless ventricular tachycardia unresponsive to initial countershocks, asystole, or pulseless electrical activity.[134] Epinephrine infusion (2 to 10 mcg/minute) can also be used to treat patients with profound bradycardia while awaiting placement of an external or temporary transvenous pacemaker. An alternative agent to epinephrine for the treatment of shock-refractory ventricular fibrillation is vasopressin, which may be given once as a 40-unit intravenous push.[134]

The myocardial and peripheral vascular effects of norepinephrine are similar to those of epinephrine except that norepinephrine causes little stimulation of vascular β_2-adrenergic receptors and, therefore, causes more intense vasoconstriction. Norepinephrine may be used to provide temporary circulatory support in the setting of severe hypotension (e.g., following cardiac surgery or with cardiogenic shock complicating acute myocardial infarction).[135] Norepinephrine is infused at doses of 2 to 10 mcg/minute. As with epinephrine, the use of norepinephrine may be limited by arrhythmias, myocardial ischemia, and renal impairment.

Digoxin

Although digoxin can be given intravenously, it is seldom used as a positive inotropic agent in the management of acute or chronic decompensated heart failure. However, digoxin may occasionally be used to control heart rate in a patient with heart failure complicated by atrial fibrillation or atrial flutter with rapid ventricular response. In this setting, digoxin is given as a 0.5 to 1 mg intravenous load in divided doses over 12 to 24 hours. If the patient is markedly symptomatic with hemodynamic compromise, synchronized electrical cardioversion should be attempted. Less commonly, intravenous amiodarone or ibutilide may be tried for urgent chemical cardioversion[136] while the patient is supported with an inotrope, vasodilator, or both. Because there is a significant risk of proarrhythmia (torsades de pointes) with ibutilide administration, patients should be monitored closely on telemetry.

ADJUSTMENT OF ORAL MEDICATIONS

Renin-Angiotensin System Inhibitors

For patients without symptomatic hypotension or evidence of hypoperfusion, ACE inhibitors can often be initiated or increased empirically. However, in patients with hyponatremia or a resting systolic blood pressure of less than 90 mm Hg, marked hypotension may develop with the initial dose of an ACE inhibitor. In such patients, therapy should be initiated with low-dose captopril (e.g., 6.25 mg). For patients who have been stabilized on an intravenous vasodilator such as nesiritide or nitroprusside, ACE inhibitors should be titrated upward gradually as the intravenous vasodilator is weaned. With captopril, the dose can be increased every 6 to 8 hours until the desired level of vasodilation is achieved, while avoiding orthostatic vital signs. In patients for whom medication compliance has been suboptimal, switching over to a once-daily ACE inhibitor (e.g., lisinopril) at the time of discharge may be helpful. Not all patients, however, tolerate ACE inhibition. Approximately 25% of patients with advanced heart failure who were previously treated with an ACE inhibitor develop a circulatory or renal limitation (e.g., symptomatic hypotension, worsening renal function, or hyperkalemia) to continued use. ACE inhibitor intolerance identifies patients with severe heart failure and poor prognosis.[137]

An angiotensin receptor blocker (ARB) may be substituted for an ACE inhibitor in patients who develop a persistent and troublesome cough not due to heart failure or concomitant pulmonary disease (see Chapter 14). Updated ACC/AHA guidelines also suggest that although ACE inhibitors remain the first choice for inhibition of the renin-angiotensin system in heart failure, ARBs are a reasonable alternative.[3] Furthermore, addition of an ARB may be considered in persistently symptomatic patients with reduced ejection fraction already treated with an ACE inhibitor.[138]

Nitrates and Hydralazine

The addition of isosorbide dinitrate to captopril frequently reduces SVR and ventricular filling pressures more effectively than does captopril alone. In some patients who cannot tolerate captopril, isosorbide dinitrate may be used alone as an effective vasodilator.[139] Isosorbide dinitrate is typically initiated at a dose of 10 mg three times daily and may be increased up to a total daily dose of 180 to 240 mg. The development of nitrate tolerance may be minimized by use of a nitrate-free interval of 10 to 12 hours.[140] As with ACE inhibitors, compliance may be enhanced by switching to a once-daily formulation (e.g., isosorbide mononitrate) before discharge.

For patients in whom weaning from intravenous agents has been difficult, or in whom ACE inhibitors are not tolerated or do not adequately optimize clinical or hemodynamic status, hydralazine may be of value, often in combination with oral nitrates. The African-American Heart Failure Trial (A-HeFT) showed that adjunctive therapy with hydralazine and isosorbide dinitrate improves survival in blacks with advanced heart failure.[141] The usual starting dose of hydralazine is 10 to 25 mg, and the maximal dose is 75 to 100 mg three or four times daily. Side effects are common, and in A-HeFT included headache (48%), dizziness (29%), and nausea (10%); hydralazine-induced lupus is rare. Hydralazine may also precipitate ischemic events in patients with heart failure caused by ischemic cardiomyopathy (see Chapter 5).[142]

β-Blockers

As discussed in Chapter 14, all patients with heart failure and reduced ejection fraction should be treated with a β-blocker unless there is a contraindication (e.g., moderate-to-severe reactive airways disease) or documented intolerance to treatment. Although there are no studies demonstrating the long-term benefits of β-blockade in patients with heart failure and preserved systolic function, most patients with diastolic heart failure have another indication for anti-adrenergic therapy such as ischemic heart disease or hypertension. In the management of acute decompensated heart failure, a frequent question that arises at the time of hospital admission is what to do with background β-blocker therapy. At present, only empirical recommendations can be made based on the severity of presentation. If the patient is on a stable dose of β-blocker and presents with mild decompensated heart failure, the outpatient dose of β-blocker should be continued. If the acute decompensation is moderate in severity and/or precipitated by recent β-blocker titration, the dose should decreased by at least 50%. If the patient presents with severe heart failure with hemodynamic instability that is not due to tachyarrhythmias or uncontrolled hypertension, β-blocker should be withheld until clinical and hemodynamic stabilization has been achieved.

If treatment with a β-adrenergic agonist such as dobutamine is being considered, it is important to remember that chronic β-blocker therapy, especially with carvedilol, may attenuate the hemodynamic response[143] and, thus, should be discontinued. For patients with atrial or ventricular arrhythmias complicating severe decompensated heart failure, the hemodynamic effects of milrinone do not appear to be compromised by concomitant β-blocker therapy.[143] For stable patients with new onset heart failure who have not yet received a β-blocker, cautious initiation before discharge appears safe, does not increase length of stay, and improves the use of chronic β-blockade.[144]

Oral Diuretics

Once fluid balance has been restored, the selection of an oral diuretic dose is empiric, and further adjustment is usually required both in the hospital and after discharge. It should be noted that patients have a different salt and fluid intake at home than in the hospital. As a first approximation, the dose of intravenous diuretic that was effective may be given as an oral dose twice daily. Daily weights should be recorded along with fluid intake and output. Renal function and electrolytes should be monitored closely until discharge. Pre-discharge education regarding home weight monitoring and flexible diuretic dosing reduces the likelihood of a heart failure readmission.[145]

OTHER MANAGEMENT ISSUES

Sodium and Fluid Restriction

The majority of patients with advanced heart failure should receive a sodium-restricted diet (2 g/day) while in the hospital, except in rare cases in which oral nutrition is of overriding importance. In addition, education regarding sodium content of food may be enhanced during an admission.[146] Patients with intense neurohormonal activation, as indicated by a low serum sodium, may have marked thirst. Diuresis may intensify thirst initially, but this usually improves over 1 to 2 weeks as a lower volume status is maintained and the thirst mechanism "resets" itself. Restricting fluid intake to 2 liters per day is usually adequate for most hospitalized patients. In cases of severe or symptomatic hyponatremia, fluid should be restricted to 1 liter per day, and administration of oral salt or normal saline and diuretics may be necessary.

Oxygen Supplementation

In the absence of acute respiratory failure, concomitant pulmonary or pulmonary vascular disease, or significant right-to-left shunting, patients with chronic heart failure rarely exhibit arterial desaturation. In such patients, supplemental oxygen does not improve systemic oxygen delivery and has the drawbacks of causing airway irritation and limiting movement. The use of nasal oxygen is often empiric and may provide subjective benefit, perhaps through suppression of central dyspnea. In some patients, oxygen may decrease elevated pulmonary vascular resistance and improve right heart function, although 100% oxygen has been shown to depress cardiac output and increase PCWP in patients with moderate-to-severe heart failure.[147] Supplemental oxygen is recommended in patients with acute myocardial infarction complicated by heart failure, and alone or in combination with continuous positive airway pressure in patients with central or obstructive sleep apnea, respectively.[148,149]

Ventricular Arrhythmias

Premature ventricular contractions and nonsustained ventricular tachycardia may occur in up to 80% of patients

hospitalized with heart failure. Their appearance correlates with the severity of heart failure and all-cause mortality, but there is no evidence that suppression with antiarrhythmic agents improves prognosis. Ventricular arrhythmias that compromise perfusion or cause symptoms should be treated. Suppression with agents such as lidocaine is rarely necessary and is often complicated by toxicity. Amiodarone is the antiarrhythmic of choice in patients with decompensated heart failure, and can be given as an intravenous or oral load,[150] while monitoring closely for toxicity related to acute negative inotropic effects. Less efficacious alternatives include oral mexiletine or dofetilide. Patients with chronic ischemic or nonischemic cardiomyopathy with reasonable likelihood of 1-year survival should be considered for placement of an ICD based on primary prevention studies[151,152] and revised Centers for Medicare and Medicaid Services guidelines (see Chapter 15 and Appendix 2).

Anticoagulation

Although patients with a low ejection fraction and a dilated ventricle are at increased risk of thromboembolism, there are no prospective data to support the routine use of anticoagulation in chronic heart failure.[153] Anticoagulation is indicated for patients with additional risk factors such as atrial fibrillation, a history of an embolic event, or echocardiographic evidence of intracavitary thrombus. Consideration should also be given to anticoagulating patients with spontaneous echocontrast, apical akinesis or aneurysm, or acute heart failure due to peripartum cardiomyopathy or fulminant myocarditis. During hospitalization, such patients can be treated with intravenous unfractionated heparin, which can be discontinued for invasive procedures. Screening for venous thromboembolism is indicated when patients present with unilateral or asymmetric bilateral lower extremity edema, pleuritic chest pain, increased shortness of breath and/or presyncope. Hospitalized patients should receive low-molecular-weight heparin to avoid thromboembolic complications.

Comorbidities

A hospitalization for acute decompensated heart failure is an ideal time to assess for, and optimize treatment of, comorbidities such as diabetes, anemia, and sleep apnea (see Chapter 14). The long-term cardiovascular benefits of tight glycemic control with insulin have been well documented.[154] For patients treated with oral agents, it is important to recognize that thiazolidinediones, which have important ancillary effects on lipid metabolism and endothelial function,[155] may increase fluid retention and exacerbate heart failure, and that this effect is exacerbated by concomitant administration of insulin. In addition, metformin, another popular insulin sensitizer, is associated with a low risk of life-threatening lactic acidosis and is contraindicated in patients with heart failure. Anemia is also common in patients with advanced heart failure and is associated with increased morbidity and mortality rates.[156] Pilot studies suggest that correction of anemia with erythropoietic agents improves symptoms and functional status and may reduce readmission rates in heart failure.[157] However, definitive data on the balance of risks and benefits of anemia treatment await completion of large randomized trials.

Mechanical Cardiac Assist

For patients with severe hemodynamic compromise who do not respond to positive inotropic agents, urgent consideration should be given to support with an intra-aortic balloon pump or ventricular assist device. In the setting of cardiogenic shock complicating acute myocardial infarction, intra-aortic balloon counterpulsation (IABP) is commonly used to reduce ischemia and improve hemodynamics while awaiting more definitive treatment (e.g., percutaneous or surgical revascularization or repair of a mechanical complication such as papillary muscle rupture or ventricular septal defect). In addition, IABP may support a patient while waiting for spontaneous recovery of stunned myocardium. Absolute contraindications to intra-aortic balloon counterpulsation include aortic insufficiency and aortic dissection. Significant peripheral arterial disease involving the abdominal aorta or iliofemoral arteries is also a contraindication. For further discussion of the use of balloon counterpulsation in the setting of acute myocardial infarction, including insertion technique, monitoring, and complications, see Chapter 11 and Appendix 3.

In patients with advanced heart failure due to ischemic or nonischemic cardiomyopathy, IABP has also been used successively as a "bridge" to ventricular assist device or cardiac transplantation.[158] In this setting, systemic perfusion may be maintained and end-organ function preserved while awaiting a donor heart. However, given the increase in waiting list times in many regions, IABP is not a feasible method of providing prolonged support (i.e., weeks to months) and precludes pretransplant rehabilitation. Ventricular assist devices offer the best alternative for extended circulatory support, allowing for physical rehabilitation and reversal of renal and hepatic dysfunction before transplantation,[159] or rarely, myocardial recovery.[160] Ventricular assist devices have also been approved for permanent ("destination") therapy in select patients who are ineligible for cardiac transplant due to age or comorbidites.[161] General indications and surgical techniques for left ventricular (LVAD) or biventricular assist device (BIVAD) implantation, and perioperative care of VAD patients are discussed in Chapter 18 and Appendix 3. Decisions regarding the use of mechanical cardiac support should be made in consultation with a heart failure/transplant cardiologist and a VAD/transplant surgeon.

SPECIAL CONSIDERATIONS

Acute Heart Failure

The principles described earlier have been developed primarily to treat acute decompensation of chronic heart failure. Similar principles apply to acute heart failure, with some special considerations. Unlike the approach to an exacerbation of chronic heart failure, the primary goal of therapy for acute heart failure is temporary stabilization of the patient until definitive mechanical intervention or spontaneous recovery can occur. The design of an effective oral regimen for outpatient stabilization is not a major goal.

Heart failure in the setting of acute myocardial infarction can develop and progress rapidly, and the patient may suffer from intense precordial pain. Unless cardiogenic shock is present, arterial pressure is usually elevated due to adrener-

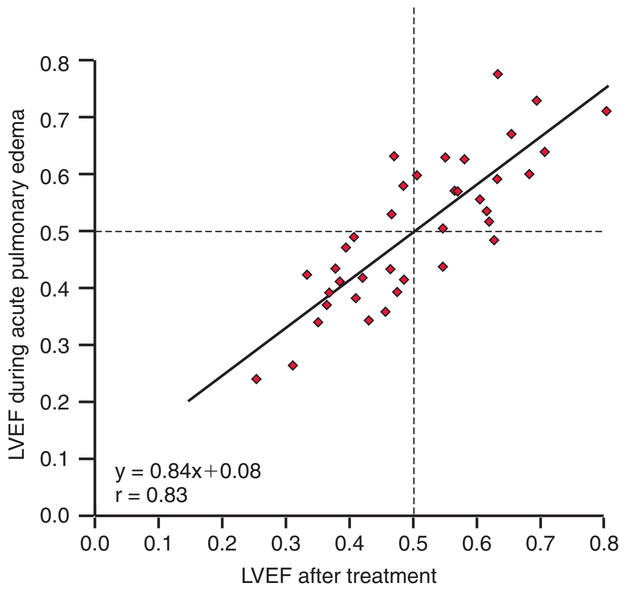

Figure 17–8 Relation between left ventricular ejection fraction (LVEF) during acute pulmonary edema and 1 to 3 days following treatment in 38 patients (14 men and 24 women, age 67 ± 13 years). *Dotted lines* indicate normal values for LVEF. (Adapted from Gandhi SK, Powers JC, Nomeir AM, et al: The pathogenesis of acute pulmonary edema associated with hypertension. N Engl J Med 2001;344:17.)

gically mediated vasoconstriction, and it may be suspected incorrectly that the pulmonary edema is due to hypertensive heart disease. However, hypertensive crises are now uncommon,[162] and funduscopic examination will usually indicate whether or not hypertensive heart disease is actually present. In addition, echocardiography may be useful in defining the pathogenesis of acute pulmonary edema. In most patients with hypertensive pulmonary edema and normal left ventricular function, the edema is due to an exacerbation of diastolic dysfunction, rather than to transient systolic dysfunction, myocardial ischemia, or severe mitral regurgitation (Fig. 17–8).[163]

Diagnosis of cardiogenic shock complicating acute myocardial infarction is occasionally delayed when blood pressure is maintained by sinus tachycardia. Intravenous inotropic support should not be postponed because of concern about increasing myocardial oxygen demand, which is also raised by increased ventricular filling pressures. Dobutamine can be initiated while a pulmonary artery catheter is being placed to monitor loading conditions and response to therapy. In contrast to the hemodynamic goals in the chronically dilated heart, low systemic blood pressure and reduced cardiac output may be less well tolerated in patients with previously normal hemodynamics, and higher filling pressures may be required to maximize cardiac output. In the setting of marked hypotension, dopamine should be initiated to support a systolic blood pressure >80 mm Hg.

Sublingual followed by intravenous nitroglycerin can be used to decrease ischemia and associated symptoms, and may also provide arterial vasodilation when the SVR is high. If symptoms are not immediately relieved with nitroglycerin, morphine sulfate given intravenously may be effective. Nitroprusside has the potential to cause a "coronary steal" in the setting of acute ischemia and should be avoided except in patients with severe hypertension. As total body volume status is usually normal, diuretics are infrequently needed during acute infarction except as initial therapy for pulmonary edema. IABP should be considered if cardiac output is markedly reduced, filling pres-sures are severely elevated, or there is evidence of ongoing ischemia. Evaluation for definitive intervention such as revascularization should not be delayed by prolonged attempts to stabilize a patient on pharmacologic therapy. In a landmark trial of cardiogenic shock complicating acute myocardial infarction, overall mortality at 30 days did not differ between patients randomized either to emergency revascularization or to initial medical stabilization; although 6-month mortality was lower in the revascularization group (50% versus 63%, $P = 0.027$).[164]

Patients with acute heart failure secondary to new mitral or aortic valve regurgitation (e.g., due to acute bacterial endocarditis) are exquisitely sensitive to afterload reduction. Arterial vasodilation with intravenous nitroprusside, followed by oral vasodilators, often improves forward flow markedly[165] and allows for elective consideration of valve replacement. Nitroprusside has also been used successfully to stabilize critically ill patients with severe aortic stenosis and left ventricular dysfunction (Fig. 17–9) while awaiting definitive aortic valve surgery.[166]

The evaluation and management of patients with acute myocarditis are discussed in Chapter 14. Lieberman and associates[167] classified myocarditis as fulminant, acute (nonfulminant), chronic active, or chronic persistent on the basis of clinicopathologic criteria. Patients with fulminant myocarditis display the least delay between initial viral symptoms and the onset of heart failure and present with severe hemodynamic compromise. However, they are more likely to recover left ventricular function and have an excellent long-term prognosis.[168] When this distinct clinical entity is suspected and confirmed by endomyocardial biopsy, aggressive hemodynamic support, including the use of inotropic agents and mechanical cardiac assist, is warranted to "bridge" patients to recovery. One exception is giant cell myocarditis in which patients are unlikely to recover even with adjuvant immunosuppressive therapy and should be considered for urgent cardiac transplantation.[169]

Heart Failure with Preserved Systolic Function

The pathophysiology of heart failure with preserved systolic function is discussed earlier, in Chapter 14, and other reviews.[18,19] Common precipitants of acute decompensation include ischemia, hypertension, and volume overload, all of which should be treated aggressively. Although cardiac output may be reduced, intravenous inotropic agents are seldom necessary to maintain vital organ perfusion and may exacerbate tachycardia or arrhythmias. Low-dose dopamine therapy (2 to 3 mcg/kg/minute) may help with diuresis in some cases. Systemic hypertension is a common target of therapy and vasodilators, often used in combination, can be adjusted without the need for hemodynamic monitoring. ACE inhibitors, angiotensin receptor blockers, and calcium channel

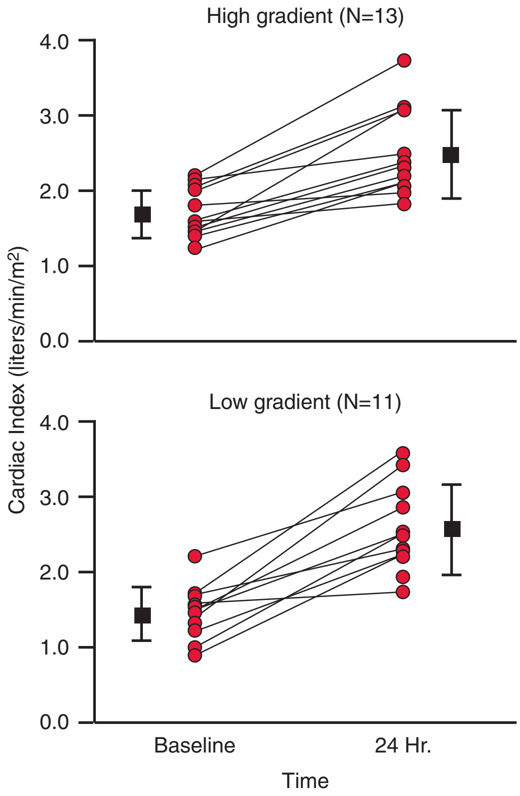

Figure 17–9 Change in cardiac index 24 hours after the start of nitroprusside infusion in subgroups of patients with left ventricular dysfunction and severe aortic stenosis according to the mean aortic-valve pressure gradient at baseline (≤30 mm Hg [low gradient] vs. >30 mm Hg [high gradient], *P* = 0.20). (Adapted from Khot UN, Novaro GM, Popovic ZB, et al: Nitroprusside in critically ill patients with left ventricular dysfunction and aortic stenosis. N Engl J Med 2003;348:1756.)

blockers can lower blood pressure and improve ventricular compliance. Oral, topical, or intravenous nitrates may be used to reduce ventricular filling pressures and improve exertional tolerance, as well as to treat myocardial ischemia. In some patients, however, postural hypotension may limit the use of nitrates or other vasodilators.

In addition to the management of blood pressure and fluid status, heart rate control is central to preventing or treating ischemia associated with diastolic heart failure. β-Blockers and calcium channel blockers are useful negative chronotropic agents. For patients who present with new onset atrial arrhythmias, restoration of sinus rhythm is important for achieving adequate cardiac output. While awaiting therapeutic anticoagulation, β-blockers, calcium channel blockers, or digoxin may be used to control the ventricular response. For patients with a contraindication to chronic anticoagulation, a transesophageal echocardiogram should be performed before cardioversion to assess for intracardiac thrombus.[136] Electrical or chemical cardioversion should also be considered for patients with chronic heart failure and atrial fibrillation in whom adequate rate control cannot be achieved. Alternatively, ablation of the atrioventricular junction with back-up ventricular pacing may be considered.

FUTURE DIRECTIONS

The most recently approved vasoactive agent for the treatment of acute decompensated heart failure was nesiritide in 2001; however, initial enthusiasm has been tempered by concerns for renal injury[91] and mortality,[170] which may be related to excess vasodilation at higher doses. Given the potential toxicity associated with positive inotropic agents[90] and the increased recognition of the cardiorenal syndrome contributing to adverse outcomes, clinical investigations have focused on the development of alternative vasodilators and renal protective agents.

As discussed earlier, plasma levels of arginine vasopressin are elevated in patients with chronic heart failure, and correlate with poor outcomes.[24] Adverse effects of vasopressin are mediated by V_{1a} receptors in the vasculature and myocardium causing vasoconstriction and positive inotropy, respectively, and V_2 receptors in the kidney causing water retention. Vasopressin receptor antagonists are a novel class of cardiovascular agents that are being developed to attenuate disease progression and improve survival in heart failure.[24,171] In patients with advanced heart failure, conivaptan, a combined V_{1a}/V_2-receptor antagonist reduced PCWP and right atrial pressure and caused a dose-dependent increase in urine output.[172] Tolvaptan is an oral selective V_2-receptor antagonist that has been shown to increase urine volume and decrease body weight compared with placebo in patients with acute decompensated heart failure, while increasing serum sodium concentrations in hyponatremic patients.[173] Whether this novel class of agents will offer additional clinical benefits with less adverse effects when compared with currently available drugs remains to be determined.

Another neurotransmitter that is activated in the kidney in patients with heart failure and may serve as a local target for therapy is adenosine. Adenosine stimulates A_1-receptors in afferent arterioles and proximal and distal tubules causing local constriction and sodium reabsorption, respectively. In addition, A_1-receptors in the macula densa mediate reduction in glomerular filtration rate via tubuloglomerular feedback. In patients with chronic heart failure, selective A_1-receptor antagonists enhance urine output and attenuate the decrease in glomerular filtration rate caused by loop diuretics.[174] Current studies are ongoing to test the safety and efficacy of adenosine receptor antagonists in patients with acute decompensated heart failure and diuretic resistance.

A limitation of most positive inotropic agents (e.g., dobutamine, milrinone) is that they act by increasing intracellular calcium in the myocyte, and may cause tachycardia and arrhythmias. Levosimendan is a pyridazinone-dinitrile derivative that enhances calcium sensitivity of myofilaments via calcium-dependent binding to troponin C.[175] Other pharmacologic actions include mild phosphodiesterase inhibition and activation of potassium channels. In patients with moderate-to-severe heart failure due to ischemic or nonischemic cardiomyopathy, a 6-hour infusion of levosimendan caused rapid, dose-dependent increases in stroke volume and cardiac index, and decreases in PCWP and right atrial pressure with only a modest increase in heart rate.[176] Levosimendan was well tolerated and appeared to improve symptoms without proarrhythmia. However, additional phase II data[177] and preliminary results of two large randomized studies[178] suggest that hypotension and tachyarrhythmias may

limit the use of levosimendan in patients with acute decompensated heart failure.

Chapter 18

Cardiac Transplantation and Circulatory Support Devices

Michael A. Mathier and Srinivas Murali

CHAPTER CONTENTS

Despite treatment with new drug regimens and high-risk cardiac surgery, many patients with heart failure (HF) progress to advanced stages characterized by marked symptomatic limitation and profound hemodynamic compromise. Cardiac transplantation is the first line therapy for select patients with end-stage HF. In the United States, there are 135 transplant centers performing approximately 2000 procedures annually. Unfortunately, the limited supply of donor hearts has restricted the growth of cardiac transplantation and has led to the search for alternative strategies such as mechanical circulatory support. The recent explosion in mechanical circulatory support technology offers the promise of a universally available therapy to decrease morbidity and mortality rates in all patients with end-stage HF.

CARDIAC TRANSPLANTATION

Human cardiac transplantation was first performed in 1967. Over the subsequent 4 decades, cardiac transplantation evolved into the gold standard therapy for many patients with end-stage HF. This evolution has been made possible by significant advances in every aspect of cardiac transplantation: recipient and donor selection and management, organ preservation, surgical technique, immunosuppression, and management of acute and chronic post-transplantation complications. Approximately 3000 cardiac transplantations are performed worldwide each year. The 1-, 5-, and 10-year survival rates post-cardiac transplantation are approximately 83%, 73%, and 68%, respectively. Long-term survival (more than 15 years) is not uncommon, largely as a result of more limited and targeted immunosuppression. The total number of cardiac transplantations performed annually has held steady for the past 20 years, largely owing to limited donor availability.[1,2]

During this same period, dramatic advances have been made in the medical and nontransplant surgical therapy of patients with advanced HF. Comprehensive pharmacotherapy has significantly delayed the progression of HF to its advanced stages. Biventricular pacemakers and implantable cardioverter-defibrillators have contributed importantly to reductions in the rates of HF morbidity and mortality. In addition, surgical advances have allowed the benefits of coronary revascularization and valvular repair to be extended to patients with poor ventricular function. Nevertheless, cardiac transplantation remains the best option for many patients with advanced HF.

Patient Selection

Although cardiac transplantation offers excellent patient outcomes, it has several important limitations. Among these are inadequate donor availability, significant perioperative risk, and substantial post-transplantation morbidity and mortality. Consequently, optimizing patient selection for the procedure is critical. The overriding principle is to select patients whose cardiac dysfunction substantially impairs their lifestyle and threatens their life span, but who do not have sufficient extracardiac comorbidities to importantly compromise post-transplant outcome. Individual transplant programs establish their own inclusion and exclusion criteria; a representative list of criteria is shown in Table 18–1.[3]

Cardiac transplantation is most commonly performed for chronic severe left ventricular systolic dysfunction, although it is occasionally used in patients with other advanced cardiac pathology (e.g., coronary artery disease, hypertrophic cardiomyopathy, restrictive cardiomyopathy, or others). A standard array of cardiac tests is generally performed to thoroughly assess each patient's cardiac status. The goals of cardiac testing are to determine that

1. The cardiac disease limits functional status or anticipated survival to a degree sufficient to warrant consideration of transplantation;
2. There are no acceptable alternative therapies (medical or surgical) for the cardiac disease;
3. Irreversible pulmonary hypertension is not present; and
4. Appropriate therapy is chosen to "bridge" the patient to transplantation.

Assessment of Cardiac Disease Severity

The assessment of the severity of the cardiac disease is based on anatomic, functional, and hemodynamic data. The functional assessment includes a determination of NYHA class, as well as more objective measures of exercise capacity such as peak oxygen consumption or 6-minute walk distance. Peak oxygen consumption ($\dot{V}O_2$) is measured by breath-to-breath respiratory gas analysis during either bicycle ergometry or

Table 18–1 Selection Criteria for Cardiac Transplantation Candidates

Inclusion Criteria

- Advanced heart failure with severe refractory symptoms and markedly shortened life expectancy
- Advanced coronary artery disease with refractory angina not amenable to revascularization
- Malignant ventricular arrhythmias unresponsive to standard therapies

Exclusion Criteria

- Advanced age
- Irreversible pulmonary hypertension
- Chronic noncardiac illness compromising survival and functional recovery
- Severe peripheral vascular disease
- Morbid obesity (BMI ≥ 40 kg/m^2)
- Active or recent malignancy
- Active infection (excluding chronic driveline infections of mechanical circulatory support devices)
- Human immunodeficiency virus seroconversion
- Drug, tobacco, or alcohol abuse within the past 6 months
- Psychiatric or psychosocial instability

BMI, body mass index.

graded treadmill exercise. In a seminal study, peak $\dot{V}O_2$ was found to predict mortality in patients with advanced HF (Fig. 18–1).[4] Based on this study, a peak $\dot{V}O_2 \leq 14$ mL/kg/min is commonly used as a threshold for listing the patient for cardiac transplantation. Studies have suggested that in patients with advanced HF who are treated with β-adrenergic antagonists, this threshold may be too high, and that a lower peak $\dot{V}O_2$ may be more appropriate for transplant listing.[5] Other parameters obtained during these studies, including minute ventilation-carbon dioxide ($\dot{V}E/\dot{V}CO_2$) slope (a measure of ventilatory efficiency), have been shown to predict outcome, and may be useful in the evaluation of a patient's candidacy for cardiac transplantation.[6]

The 6-minute walk distance has been shown to correlate well with peak $\dot{V}O_2$, suggesting that this simpler measure of functional capacity can be used in place of the more cumbersome oxygen consumption study.[7] A number of readily available clinical and laboratory parameters such as hyponatremia, azotemia, anemia, and cachexia, along with dependence on inotropic support, identify patients with a poor prognosis.[8] Calculation of a risk score based on clinical variables has been advocated by some as a more refined predictor of outcome in patients with advanced HF.[9]

Assessment of the Pulmonary Vasculature

An important determinant of candidacy for cardiac transplantation is the status of the pulmonary circulation. Patients with long-standing left HF frequently develop pulmonary hypertension, which may or may not reverse with acute or chronic vasodilator therapy. Agents commonly used to assess pulmonary vasoreactivity acutely include sodium nitroprusside, prostaglandin E_1 (PGE_1), milrinone, and inhaled nitric oxide. As shown in Figure 18–2, patients with reversible

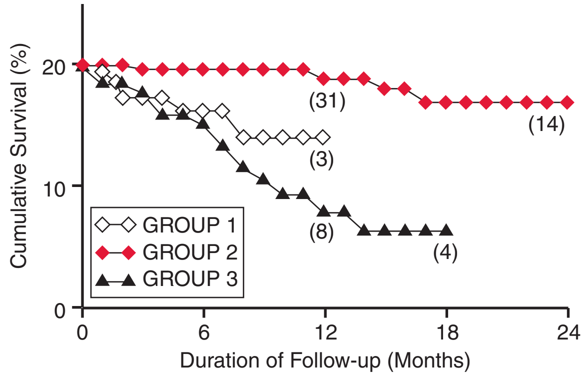

Figure 18–1 Survival curves for patients with $\dot{V}O_2$ of more than 14 mL/kg/min (group 2) and reduced $\dot{V}O_2$ (groups 1 and 3). (From Mancini D, Eisen H, Kussmaul W, et al: Value of peak exercise oxygen consumption for optimal timing of cardiac transplantation in ambulatory patients with heart failure. Circulation 1991;82:778-86).

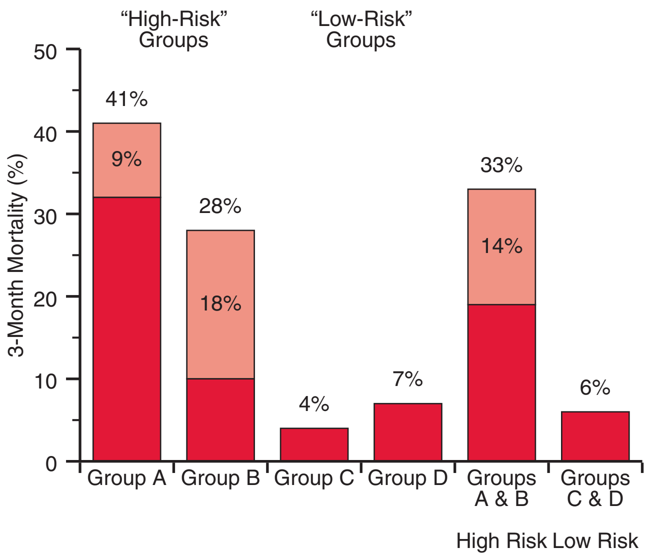

Figure 18–2 Three-month mortality after transplantation: Differentiation of low- and high-risk groups according to preoperative pulmonary hypertension. Group A = patients whose pulmonary vascular resistance could not be decreased to <2.5 Wood units (n = 32). Group B = patients whose pulmonary vascular resistance could be reduced to ≤ 2.5 Wood units at the expense of severe systemic hypotension (n = 40). Group C = patients whose pulmonary vascular resistance could be lowered to ≤2.5 Wood units without severe systemic hypotension (n = 78). Group D = patients whose pulmonary vascular resistance was <2.5 Wood units at baseline. *Light red bars,* deaths due to right heart failure and pulmonary hypertension. *Dark red bars,* deaths due to other causes. (Redrawn from Costard-Jackle A, Fowler MB: Influence of preoperative pulmonary artery pressure on mortality after heart transplantation: Testing of potential reversibility of pulmonary hypertension with nitroprusside is useful in defining a high-risk group. J Am Coll Cardiol 1992;19:48-54, with permission.)

pulmonary hypertension have post-transplant survival rates similar to those patients with normal pulmonary pressures prior to transplant. Patients with irreversible pulmonary hypertension have a significantly worse post-transplant survival, largely due to failure of the donor right ventricle.[10] For these patients, alternative strategies such as combined heart-lung transplantation or heterotopic heart transplantation (with retention of the native heart to take advantage of its "trained" right ventricle) may be considered.[11]

Other Cardiac Transplantation Candidacy Issues

Age

Most adult cardiac transplant programs establish an upper age cut-off of 65 years for transplant candidacy. Data from the International Society for Heart and Lung Transplantation (ISHLT) Registry have suggested that survival after cardiac transplantation declines with increasing recipient age after 50 years of age; this effect is most striking above 70 years of age.[1,2] Among the possible explanations for this association is the apparent increased risk of post-transplantation malignancy in older versus younger patients. Despite this, several reports of acceptable outcomes in an older patient population have emerged.[12,13]

Comorbidities

Many cardiac transplantation programs list significant irreversible noncardiac organ dysfunction as an exclusion criterion. Examples include intrinsic renal disease with a creatinine clearance of 40 mL/min or less, intrinsic pulmonary disease with spirometric values less than 50% of predicted, and biopsy-proven hepatic cirrhosis. There are, however, a number of reports of successful multiorgan transplantations, most commonly combined heart-kidney, heart-lung, and heart-liver transplants.[14,15] Similarly, significant noncardiac comorbidities (such as diabetes with end-organ dysfunction) may exclude patients from cardiac transplantation, although reports of acceptable outcomes in these populations exist.[16] Other relative contraindications to transplant include conditions that are likely to worsen with corticosteroid therapy—such as obesity and osteoporosis.

Table 18–2 United Network of Organ Sharing Organ Allocation System

Status	Definition
1A	Patient admitted to the listing center with: • Mechanical ventilation • Intra-aortic balloon pump • Extracorporeal membrane oxygenator • Mechanical ventricular assist device within a 30-day period or complicated by infection, thromboembolism or device malfunction • Single high-dose or multiple low-dose inotrope infusion with pulmonary artery catheter monitoring
1B	Patient on low-dose single inotrope or with uncomplicated mechanical ventricular assist device beyond 30-day period
2	Patient not meeting 1A or 1B criteria
7	Patient listed but temporarily unsuitable for cardiac transplantation

Immunologic Sensitization

Although rarely an exclusion for cardiac transplantation by itself, immunologic sensitization (the presence of antihuman leukocyte antigen [HLA] donor-specific antibodies) of potential transplant recipients can pose a significant challenge. All potential recipients undergo immunologic assessment, usually via a complement-dependent cytotoxicity assay (panel-reactive antibodies, or PRA). Because this technique is relatively insensitive, newer methods such as flow cytometry for antibody screening may be preferable.[17] Highly sensitized candidates commonly have a history of multiple pregnancies or prior transfusions, and they require careful donor selection and perioperative immunologic management as described subsequently.

Listing for Cardiac Transplantation

The United Network of Organ Sharing (UNOS) was created in 1986 by the United States Congress. UNOS oversees the allocation of organs on a nationwide basis to recipients who have been registered by transplant programs on regional waiting lists. Local Organ Procurement Organizations (OPOs) are nonprofit agencies responsible for evaluating the suitability of potential donor organs and for coordinating organ recovery, preservation, and transport to the transplant center. Organs are allocated according to ABO blood typing, size matching, duration on the waiting list, and severity of disease. In 1999, UNOS updated the criteria by which disease severity affects patient priority on the waiting list. Table 18–2 summarizes the current UNOS status criteria.

Improved success rates with cardiac transplantation have inevitably led to efforts to expand the procedure to previously excluded patient populations. One controversial strategy that has been used by some centers is the creation of a second or alternate list for those candidates deemed to be at higher risk.[18,19] Organs accepted for patients on this list are those judged to be marginal (e.g., from older donors or donors with single-vessel coronary disease), and therefore not acceptable for most candidates who meet standard listing criteria. Some have argued, however, that using suboptimal donor organs for higher risk candidates will lead to worse outcomes.

Pre-transplantation Patient Management

Patients deemed to be acceptable candidates for cardiac transplantation require careful management as they await the procedure. Standard pharmacologic (see Chapter 14) and device therapies for HF, as well as appropriate lifestyle modifications (see Chapter 13), are recommended for all patients. Patients with intractable signs and symptoms related to low cardiac output and end-organ hypoperfusion (renal or hepatic dysfunction or poor nutritional status) may require continuous inotropic therapy or mechanical cardiac support, both of which affect the priority status of the patient in the UNOS system. Patients managed with continuous intravenous inotropic therapy or mechanical cardiac support

require careful surveillance for, and aggressive therapy of, infection. Similarly, patients with evidence of pulmonary hypertension require careful follow-up of their pulmonary pressures. Chronic left ventricular unloading with mechanical circulatory support may prevent worsening of, or even reverse previously refractory, pulmonary hypertension and allow for successful transplantation.[20]

Patients found to be highly immunologically sensitized may benefit from immunomodulatory therapy before undergoing cardiac transplantation. Numerous protocols have been described in the literature, including those that use immunoglobulin and plasmapheresis.[21,22] These protocols aim to reduce the patient's burden of preformed antibodies to commonly encountered antigens, both to increase the possibility (and shorten the waiting time) of finding a donor with a negative prospective cross match, and to decrease the chance of rejection of the transplanted heart.

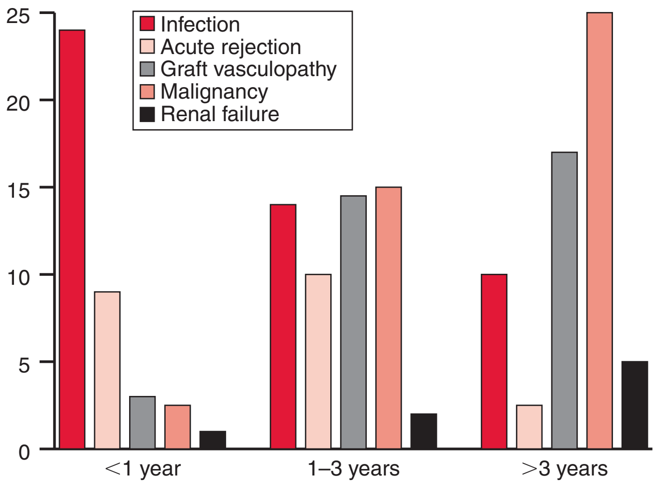

Figure 18–3 Frequency of various causes of death over time in patients following cardiac transplantation. (Redrawn from Mathier MA, McNamara DM: Management of the patient after heart transplant. Curr Treat Options Cardiovasc Med 6:459-69, 2004, with permission.)

Cardiac Transplantation Surgical Technique

The surgical technique for cardiac transplantation has remained fairly constant for the last 2 decades. One significant modification has been the adoption of a bicaval anastomotic technique in place of the standard biatrial anastomosis. With both techniques, the donor left atrium is anastomosed to a retained cuff of recipient left atrium with the pulmonary veins left intact. In the bicaval technique, the donor and recipient vena cavae are anastomosed after complete excision of the recipient right atrium. Studies indicate that the bicaval technique results in improved atrial function and decreased incidence of atrial arrhythmias.[23,24] A further modification, termed *total orthotopic cardiac transplantation*, combines a bicaval anastomosis with pulmonary vein anastomoses. This technique has not as yet been shown to offer significant benefit over biatrial or bicaval techniques.[25]

Advances have also been made in the area of organ preservation after harvest.[26] This may have contributed to the observation that outcomes with longer donor ischemic times are not markedly worse compared with those with shorter ischemic times.[27] In addition, immediate postoperative management has improved with the judicious use of inotropic agents, acute pulmonary vasodilators, and even temporary mechanical cardiac support for instances of transient allograft dysfunction related to ischemia, elevated pulmonary pressures, or both.[28-30]

Management of the Patient After Cardiac Transplantation

The management of the patient after cardiac transplantation involves three main strategies (1) optimization of immunosuppressive therapy; (2) prevention of allograft rejection and complications resulting from the transplant or the immunosuppressive agents; and (3) treatment of allograft rejection and associated complications when they arise. The relative impact of these various conditions on mortality rates varies over time after cardiac transplantation (Fig. 18–3).[31]

Acute cellular rejection is an important cause of morbidity and mortality in patients post-cardiac transplantation. Despite intensive investigation of potential noninvasive indicators of rejection, transvenous endomyocardial biopsy remains the diagnostic tool of choice, and revised ISHLT criteria have been published (Table 18–3).[32] Of note, however, a completed multicenter study suggested that peripheral blood gene expression profiling of circulating leukocytes may be able to identify patients for whom it is safe to defer endomyocardial biopsy.[33] The risk of acute cellular rejection is highest in the first year post-cardiac transplantation and declines significantly thereafter. This observation underlies the strategy of more intensive immunosuppression and surveillance for rejection early after transplant—with a gradual decrease in both over time (Table 18–4). The incidence of infection similarly is higher in the months following transplantation and declines thereafter. Accordingly, prophylaxis against opportunistic infections is of greatest usefulness early after transplantation, when the level of immunosuppression is highest.[34,35]

Over time, after cardiac transplantation, other conditions assume greater importance in determining patient outcome. Hypertension, diabetes, and dyslipidemia are quite common, occurring in 73%, 24%, and 50% of patients within the first year after cardiac transplantation, respectively.[1] The high incidence of these conditions reflects the fact that they are frequent comorbidities in patients who require transplantation and that immunosuppressive therapy can cause or exacerbate these conditions. Aggressive therapy of each is recommended, although data indicating that this improves outcomes in patients following cardiac transplantation are limited.[36] Among the important sequelae that may be prevented or delayed with such therapy are cardiac allograft vasculopathy (CAV) and renal insufficiency. Late mortality post-cardiac transplantation is predominantly related to CAV, renal failure, and malignancy.[2]

Prevention and Treatment of Cardiac Rejection

The primary management goal of immunosuppressive therapy is to limit episodes of acute rejection. To accomplish this in the perioperative period, some programs continue to

Table 18–3 ISHLT Standardized Cardiac Biopsy Grading: Acute Cellular Rejection*

2004		1990	
Grade 0 R†	No rejection	Grade 0	No rejection
Grade 1 R, mild	Interstitial and/or perivascular infiltrate with up to one focus of myocyte damage	Grade 1, mild A—Focal B—Diffuse	Focal perivascular and/or interstitial infiltrate without myocyte damage Diffuse infiltrate without myocyte damage
		Grade 2 moderate (focal)	One focus of infiltrate with associated myocyte damage
Grade 2 R, moderate	Two or more foci of infiltrate with associated myocyte damage	Grade 3, moderate A—Focal B—Diffuse	Multifocal infiltrate with myocyte damage Diffuse infiltrate with myocyte damage
Grade 3 R, severe	Diffuse infiltrate with multifocal myocyte damage ± edema, ± hemorrhage, ± vasculitis	Grade 4, severe	Diffuse, polymorphous infiltrate with extensive myocyte damage ± edema, ± hemorrhage + vasculitis

*The presence or absence of acute antibody-mediated rejection (AMR) may be recorded as AMR 0 or AMR 1, as required.
†Where "R" denotes revised grade to avoid confusion with 1990 scheme.

Table 18–4 Frequency of Follow-Up Evaluations Following Cardiac Transplantation

	Discharge to Week 4	Month 1 to Month 3	Month 4 to Year 1	Year 1 to Year 5	After Year 5
Office visit	q 1 week	q 2 weeks	q 1-2 months	q 3-6 months	q 6 months-1 year
Blood work	q 1 week	q 2 weeks	q 1-2 months	q 3 months	q 3 months
Right Heart Catheterization and Biopsy	q 1 week	q 2 weeks	q 1-2 months	q 3 months-1 year	As needed
Echocardiogram	As needed	At month 3	q 3 months	q 6 months-1 year	As needed
DSE	—	—	At year 1	q 1 year	q 1 year
Coronary Angiogram	—	—	At year 1	q 2 years	As needed

Blood work includes: serum chemistries; complete blood count; liver function testing; serum levels of calcineurin inhibitor and sirolimus; lipid profile, glycosylated hemoglobin; uric acid; thyroid studies less frequently.
DSE, dobutamine stress echocardiogram.
From Mathier MA, McNamara DM: Management of the patient after heart transplant. Curr Treat Options Cardiovasc Med 2004;6:459-69, with permission.

use induction immunosuppression with lymphocytolytic therapy or daclizumab, a humanized monoclonal antibody against the interleukin-2 (IL-2) receptor. This strategy may be effective,[37,38] but may carry increased risk of infection and malignancy.[39,40] Many U.S. transplantation programs avoid induction immunosuppression in most patients, relying instead on a standard three-drug regimen (calcineurin inhibitor, corticosteroid, and antimetabolite; see later) from the time of the transplantation. The risk of rejection is at its maximum during the initial period of exposure to the allograft, and consequently the level of immunosuppression is maintained at its highest level during the first 6 months post-transplant. For long-term survival, limiting the complications of immunosuppression is of primary importance and leads to a critical additional management goal: to limit rejection with the lowest level of immunosuppression possible.

Calcineurin Inhibitors

Cyclosporine, or cyclosporine A (CsA), is a cyclic polypeptide calcineurin inhibitor that decreases transcription and secretion of IL-2 and other cytokines, and prevents T helper cell activation. The introduction of CsA in the 1980s led to a marked reduction in acute rejection and significant improvement in survival after cardiac transplantation. Initial target trough levels are 200 to 300 ng/mL for the first 6 months post-transplant, and 100 to 250 ng/mL thereafter. The main side effects of CsA are hypertension, peripheral neuropathy, nephrotoxicity, hirsutism, and gingival hyperplasia. CsA is metabolized by the cytochrome P-450 system; numerous drugs that inhibit or induce this system are well known to increase (e.g., diltiazem, allopurinol, amiodarone) or decrease (e.g., nafcillin, phenobarbital, phenytoin) CsA levels. Target

levels are usually somewhat lower in older recipients given their more modest immune activation and greater risk of malignancies, renal dysfunction, and infection.

Tacrolimus (FK506) is a macrolide immunosuppressive agent that acts with a similar mechanism, but may be more potent than CsA. Although a randomized evaluation of CsA-versus tacrolimus-based regimens did not demonstrate a survival difference, tacrolimus appeared to have a potentially better side-effect profile, with less hypertension and dyslipidemia but more glucose intolerance.[41] Most centers still use a CsA-based regimen, reserving tacrolimus as alternative therapy for subjects with multiple rejection episodes on CsA, but others have opted for routine tacrolimus-based therapy. Initial target levels are 15 to 20 ng/mL for the first 6 months, and 10 to 12 ng/mL thereafter.

Corticosteroids

Corticosteroids remain a central part of immunosuppressive therapy during the first 12 to 24 months post-transplant and are the most commonly used agent for the therapy of acute rejection. Among the many mechanisms of action of corticosteroids are suppression of IL-1 and IL-2 synthesis and macrophage function. At most institutions, intravenous methylprednisolone (500 mg IV intraoperatively, then tapering to 20 mg IV twice a day over the first 5 post-operative days) is used initially, then converted to oral prednisone (20 to 30 mg PO every day), which is then slowly tapered over the subsequent 12 to 24 months. Each reduction in the prednisone dose is generally followed by a biopsy within 2 to 3 weeks to ensure the reduction has not resulted in cellular rejection. When acute cellular rejection occurs, an oral or intravenous "pulse" of corticosteroids (e.g., 1 gm IV every day for 3 days) is commonly used as primary therapy for the rejection episode. It is crucial that corticosteroid use be minimized to avoid long-term complications, including glucose intolerance, osteopenia, skeletal myopathy, hypertension, and cataracts. In light of this, there has been increasing interest in completely corticosteroid-free immunosuppressive regimens; however, the safety and efficacy of this strategy remain under investigation.[42]

Antimetabolites

Before the introduction of CsA in the 1980s, standard immunosuppressive therapy consisted of corticosteroids and azathioprine (2 to 3 mg/kg PO every day), an antimetabolite that inhibits purine biosynthesis and limits lymphocyte proliferation. Azathioprine is an important part of standard three-drug therapy in many centers, although its use has decreased with the advent of mycophenolate mofetil (MMF; generally given at 1000 to 1500 mg PO twice a day). Although MMF also inhibits purine synthesis, its selectivity for lymphocytes results in less frequent bone marrow suppression, although regular monitoring of white blood cell counts is necessary. In a randomized trial comparing the two agents in combination with a calcineurin inhibitor and corticosteroids, MMF was superior to azathioprine in decreasing both the frequency and severity of cardiac allograft rejection.[43] This led most centers to replace azathioprine with MMF for standard immunosuppressive therapy. Gastrointestinal side effects are common with MMF, often necessitating a dosage decrease.

Sirolimus

Sirolimus, or rapamycin, acts via the TOR (target of rapamycin) receptor to inhibit lymphocyte activation and proliferation in response to antigenic and cytokine stimulation. Its mechanism is distinct from other immunosuppressive agents. It has been shown to slow the progression of CAV in a single-center randomized trial when used in combination with a calcineurin inhibitor.[44] In native (nontransplant) coronary artery disease, sirolimus-eluting stents have been shown to have lower rates of restenosis, presumably by a similar antiproliferative mechanism (see Chapter 7). Sirolimus (2 to 5 mg PO every day, adjusted to achieve trough levels of 5 to 7 mg/mL) is sometimes used in place of calcineurin inhibitors as a renal sparing agent. Marked dyslipidemia may be seen with sirolimus therapy. Everolimus, a derivative of sirolimus with similar antiproliferative effects, may prevent the development of CAV.[45]

Lymphocytolytic Agents

Severe acute cardiac allograft rejection refractory to corticosteroids and intensification of standard immunosuppression may be treated with cytolytic agents. Examples include rabbit antithymocyte globulin or OKT3 (anti-CD3 monoclonal antibody). Cytolytic therapy produces profound immunosuppression via rapid depletion of circulating T lymphocytes. Patients who undergo such treatment must be monitored carefully for severe leukopenia and opportunistic infection and generally require supportive care to treat symptoms of a cytokine-release syndrome.

Prevention and Treatment of Post-transplant Complications

The major complications that occur following cardiac transplantation include infection, hypertension, diabetes, dyslipidemia, osteoporosis, CAV, renal insufficiency, and malignancy. Preventive efforts focus on infection (prophylactic anti-pneumocystis and antiviral therapy), osteoporosis (minimization of corticosteroid use and calcium supplementation), CAV (management of standard cardiac risk factors and minimization of rejection), renal insufficiency (minimization or alternative choice of immunosuppression), and malignancy (minimization of immunosuppression).

Opportunistic Infections

Opportunistic infections occur with the greatest frequency in the first several months after cardiac transplantation. The opportunistic infections targeted with prophylactic strategy in this period are herpesviruses, most notably cytomegalovirus (CMV), *Pneumocystis carinii* pneumonia, and oropharyngeal candidiasis.

The risk of viral opportunistic infection is related to the intensity and type of immunosuppression and the viral status of both the donor and the recipient. A recipient without prior CMV exposure who receives a heart from a CMV-positive donor has a 50% to 75% risk of developing CMV disease; a recipient with prior CMV exposure has a 10% to 15% chance, regardless of donor status.[46] Patients at high risk for CMV disease generally receive ganciclovir prophylaxis (typically

5 mg/kg IV twice daily for 14 days followed by 5 mg/kg IV every day for 14 more days or 1000 mg PO three times a day for 2 to 3 months). Those at lower risk can receive oral valacyclovir prophylaxis or rely on a preemptive treatment strategy without prophylaxis.[47,48] CMV disease is notorious for nonspecific symptoms and findings: the clinical presentation can range from a mild influenza-like illness to life-threatening pneumonitis or enteritis. Therefore, a high index of suspicion for CMV is required when evaluating constitutional, respiratory, or gastrointestinal complaints.

Pneumocystis carinii pneumonia is infrequently seen with current prophylactic strategies. The risk of this disease is greatest during the period of highest corticosteroid dosing, prompting the use of prophylactic trimethoprim-sulfamethoxazole (single-strength [80/400 mg] tablet PO every day) for the first 6 to 12 months, with less frequent dosing or discontinuation thereafter. This agent also appears to be effective against a variety of other pathogens, including toxoplasmosis, *Listeria*, and urinary tract pathogens.[47] Dapsone may be an acceptable alternative in patients with sulfa allergy, or who develop renal insufficiency or hyperkalemia on trimethoprim-sulfamethoxazole.

Nystatin liquid or mycostatin troches are usually effective in preventing oropharyngeal candidiasis. Although these represent the most common targets for antibiotic prophylaxis in patients following cardiac transplantation, many other opportunistic and nonopportunistic infections can occur.[47] A high index of suspicion for opportunistic infections is required. A full discussion of the therapy of established infections is beyond the scope of this chapter.[49]

Hypertension

Hypertension occurs frequently in cardiac transplant recipients; the incidence in long-term follow-up has been reported to be over 70% at 1 year and as much as 95% at 5 years. Hypertension after cardiac transplantation may have several etiologies, including preexisting essential hypertension, chronic use of calcineurin-inhibitors, chronic kidney disease, and alterations in renin-angiotensin-aldosterone system function.[50] Abnormalities in endothelial function have also been postulated to play a role; treatment of patients with omega-3 fatty acids preserves endothelial function and prevents increases in arterial pressure.[51]

Most standard antihypertensive agents are safe and are likely to be effective in patients following cardiac transplantation. A randomized comparison of diltiazem and lisinopril in hypertensive transplant patients found both agents to be safe, but neither to consistently provide adequate pressure control when used as monotherapy.[52] Diltiazem may have the ancillary benefits of raising CsA levels and, in one study, of slowing the development of CAV.[53] In practice, multidrug regimens for the control of hypertension are common, often including adrenergic antagonists such as β-blockers or clonidine. A thorough understanding of potential drug interactions is mandatory.

Diabetes

Cardiac transplantation in patients with diabetes at the time of surgery appears to offer a similar outcome as compared with patients without pretransplant diabetes.[54] In the first year after cardiac transplantation, however, preexisting diabetes frequently becomes much more difficult to treat. In addition, many patients will develop diabetes for the first time during this period, primarily as a result of corticosteroid therapy. Diabetes often requires therapy only during the period of corticosteroid administration. Either oral agents or insulin may be effective in the treatment of transplant-related diabetes.[55] Metformin is generally avoided because of concerns over renal dysfunction. Consensus guidelines for the management of diabetes in transplant recipients have been published.[56]

Dyslipidemia

Dyslipidemia develops in 50% of patients at 1 year and over 80% at 5 years. Dyslipidemia appears to be more severe in patients treated with CsA as compared with tacrolimus; fewer patients treated with tacrolimus require lipid-lowering therapy.[41,57] A small, randomized trial in patients with post-transplant dyslipidemia comparing simvastatin, gemfibrozil, and cholestyramine demonstrated superior total and LDL cholesterol-lowering effects for simvastatin. Gemfibrozil improved triglyceride levels.[58] A larger, longer-term randomized trial of simvastatin started early after heart transplantation versus dietary therapy alone revealed significant reduction in mortality, rates of CAV, and severe rejection without significant adverse effects in the simvastatin group.[59] This and other studies suggest that statins may have independent beneficial immunomodulatory effects. A head-to-head nonrandomized comparison of simvastatin and pravastatin suggested greater safety and efficacy of pravastatin.[60] Atorvastatin appears to be safe and effective in the treatment of dyslipidemia in the transplant patient.[61] Accordingly, pravastatin and atorvastatin are the generally preferred agents. There appears to be some increased risk of myositis and rhabdomyolysis with statin use in patients following cardiac transplantation, necessitating heightened clinical surveillance for such complications when using higher doses or combinations of agents.

Cardiac Allograft Vasculopathy

Cardiac allograft vasculopathy (CAV) is now the most common cause of late allograft dysfunction and death in patients following cardiac transplantation.[1] Risk factors for the development of CAV include frequency and severity of cellular rejection,[62] smoking, dyslipidemia, diabetes, antecedent coronary artery disease in either the recipient or donor, and older age of either the recipient or donor.[63] Studies indicate a potential role of systemic inflammation and infectious agents in the development of CAV.[64] CAV is associated with both worse functional status[65] and worse survival,[66,67] with late manifestations including refractory HF and sudden cardiac death. Most patients who have undergone cardiac transplantation lack an adequate anginal mechanism, necessitating a regular screening strategy. Intravascular ultrasound is the most sensitive diagnostic test for the detection of graft coronary disease. Standard coronary angiography, radionuclide perfusion imaging, and dobutamine stress echocardiography are frequently used (see Table 18–4). CAV may be a diffuse, concentric, and often distal process that is not amenable to percutaneous or surgical revascularization. On occasion, how-

ever, it may manifest as discrete, proximal stenoses treatable by standard revascularization techniques.

Medical therapy of CAV generally includes the use of diltiazem and a statin. Antioxidant vitamins may also delay early progression of CAV.[68] The mechanisms by which statins prevent the development and slow the progression of CAV are not fully understood. In addition to beneficial effects on serum lipid levels, statins preserve coronary endothelial function and modulate the elaboration of pro-inflammatory cytokines in the transplanted heart.[69] When combined with CsA, corticosteroids and statins, everolimus decreased the incidence of CAV within the first year after cardiac transplantation as compared with azathioprine added to the same combination.[45] In patients with established CAV, substituting sirolimus for azathioprine or MMF (in combination with corticosteroids and a calcineurin inhibitor) resulted in a significant decrease in disease progression.[44] Coronary angioplasty,[66,67] stenting,[70] and intracoronary brachytherapy[71] have all been used with acceptable results in the treatment of CAV. In addition, standard, off-pump[72] and minimally-invasive coronary artery bypass grafting[73] have been successfully performed in highly select patients who have undergone cardiac transplantation. Retransplantation for CAV appears to have greater success than when it is employed for acute graft failure or acute cellular rejection.[74] Although the rate of early mortality following re-transplantation for CAV is comparable with that of initial transplantation, long-term survival is worse.[75]

Renal Insufficiency

The risk of renal insufficiency is related to patient age, baseline renal function, and the development of hypertension.[76,77] Estimates of the incidence of end-stage renal disease postcardiac transplantation range from 5% to 8%,[78-80] and survival in patients experiencing renal failure is significantly worse than in patients with preserved renal function.[78,79] It is generally accepted that calcineurin inhibitor use increases the risk of renal insufficiency,[78] however, the relationship between dosing of these agents and the development of renal insufficiency is still uncertain.[80,81] The conversion of patients with renal insufficiency from a calcineurin inhibitor-based immunosuppressive regimen to one based on MMF and sirolimus appears to be safe and effective and is associated with an improvement in renal function.[82,83] Hemodialysis, peritoneal dialysis, and renal transplantation have all been reported to be acceptable therapies for end-stage renal disease in cardiac transplant patients.[84]

Malignancy

The final major cause of mortality in patients after cardiac transplantation is malignancy. Although careful vigilance should be maintained for all malignancies,[85] lymphomas (Epstein-Barr virus–associated post-transplant lymphoproliferative disease [PTLD]) and skin cancers in particular[86,87] occur with increased frequency. One large study of patients after heart transplantation found an overall incidence of PTLD of 6%, and an incidence among long-term survivors of 15%.[88] In general, the risk of malignancy appears to correlate with the intensity and duration of immunosuppression. Patients exposed to induction therapy or who receive OKT3 for treatment of severe rejection are at particularly high risk. Although younger recipients of cardiac transplants may be at higher risk for PTLD,[88] older patients at the time of transplantation appear to be at significantly increased risk for non-PTLD cancers.[89] PTLD often responds to a decrease in the intensity of immunosuppression, with or without concomitant antineoplastic therapy. Disease progression can often be monitored with serial PET or CT scanning. An anti-CD20 monoclonal antibody (rituximab) has been reported to be of benefit in select cases.[90] Skin cancers developing in transplant recipients, particularly squamous or basal cell carcinomas, generally respond well to local excision; recurrence is common, however.

Future Directions

The last several decades have seen significant improvements in the management of patients before and after cardiac transplantation. One challenge for the future will be to extend the life expectancy of patients following transplantation. This will depend on our ability to prevent and treat the long-term complications of transplantation, including many of the adverse consequences of immunosuppression. Toward this end, extensive investigation is underway into possible strategies for the induction of selective immune tolerance to the allograft. If successful, such strategies would likely yield an optimal post-transplant outcome. Ongoing investigation in the field of xenotransplantation may offer the possibility of an unlimited supply of donor organs and allow for expansion of transplantation to increasing numbers of patients.

CIRCULATORY SUPPORT DEVICES

The development of circulatory assist devices began in 1964 under the direction of the Artificial Heart Program at the National Heart, Lung, and Blood Institute. Initially, these devices were used exclusively for post-cardiotomy shock. In 1978, a left ventricular assist device (LVAD) was first used as a bridge to cardiac transplantation and in 2002, the U.S. Food and Drug Administration (FDA) approved the use of an LVAD for chronic, destination mechanical circulatory support in advanced HF.[91,92] As experience has grown, it has also been recognized that in select patients, implantation of an LVAD can promote recovery of myocardial function. Newer devices are smaller, more efficient, durable, and easier to implant surgically, and in some cases, percutaneously. With this evolution in technology, the promise of circulatory support as a viable option for many, if not all, patients with end-stage HF looks bright.

Candidate Selection

Failure of optimal medical therapy is the primary indication for circulatory assist device support. In acute HF, circulatory assist is needed in patients with postcardiotomy shock who are unable to be successfully weaned from cardiopulmonary bypass. It may also be necessary in the setting of persistent cardiogenic shock complicating an acute myocardial infarction or fulminant myocarditis. In chronic HF patients, circulatory assist is needed for patients who are failing medical therapy. These are generally stage D patients with end-stage

Table 18–5 Guidelines for Candidate Selection for Circulatory Cardiac Assist Support

A.	**Hemodynamic Criteria (on optimal medical therapy including balloon counterpulsation)**
	Cardiac index <2 L/min/m^2
	Systolic blood pressure <80 mm Hg
	Pulmonary capillary wedge pressure >20 mm Hg
B.	**Clinical Criteria (on optimal medical therapy for at least 60 days)**
	Marked functional limitation (NYHA class IV)
	LV ejection fraction <25%
	Inotrope dependence
	Peak $\dot{V}O_2$ < 12 mL/min/kg
	Inability to tolerate ACEI and β-blockers due to hypotension or renal failure
	Severe right ventricular dysfunction (for LVAD support only)
C.	**Assessment of Comorbidities**
	Diabetes
	Peripheral vascular disease
	Cerebrovascular disease
	Life-limiting systemic illness
D.	**Risk Factors for Suboptimal Outcome**
	Mechanical ventilation
	Postcardiotomy shock
	Reoperation
	Right atrial pressure >16 mm Hg (for LVAD support only)
	Prothrombin time >16 sec
	White blood cell count >15,000/mm^3
	Urine output <30 mL/hr
	Temperature >101.5° F
E.	**Technical Considerations**
	Body surface area <1.5 m^2
	Significant valvular pathology
	Right-to-left shunt
	Prosthetic valves
	Left ventricular thrombus
F.	**Atrial and Ventricular Arrhythmias**
G.	**Psychosocial Considerations**
	Current alcohol or drug dependence
	Significant mental illness
	Inadequate or absence of social support

ACEI, angiotensin-converting enzyme inhibitor; LVAD, left ventricular assist device; NYHA, New York Heart Association; $\dot{V}O_2$, oxygen consumption.

HF who may be on the cardiac transplant waiting list or who are candidates for destination therapy. There are no universal criteria for candidate selection, which is a complex process requiring clinical judgment and many considerations.[93] According to the ACC/AHA HF guidelines, permanent mechanical circulatory support is a class IIA recommendation for stage D patients.[94] The generally accepted criteria that are helpful in candidate selection are shown in Table 18–5.

Hemodynamic and Clinical Considerations

Criteria that define persistent hemodynamic and clinical compromise on optimal medical therapy include inotrope-dependence or intra-aortic balloon pump counterpulsation, factors that portend suboptimal short- and long-term outcomes after device implantation, and technical and psychosocial considerations. The benefit of intra-aortic balloon counterpulsation is short-lived and clinically insignificant in patients with nonischemic HF. The risk of infection and vascular compromise also precludes the use of balloon counterpulsation for more than 7 to 10 days.[95] Given the long waiting list times, balloon counterpulsation is generally not feasible as a bridge strategy and, in fact, in some centers circulatory support devices are implanted without a trial of balloon pump support. These criteria should be present after at least 60 days of optimal medical therapy as defined by the ACC/AHA guidelines.

Right ventricular function should be evaluated particularly thoroughly because it is the most important determinant of perioperative outcome after LVAD implantation. Patients who develop right ventricular failure have a higher early mortality rate, greater length of stay in intensive care, higher risks of reoperation for bleeding and renal failure, and lower survival to transplantation.[96] Unfortunately, there is no consensus on how best to assess right ventricular function in severe HF. Because routine echocardiographic assessment of the right ventricle is subjective and prone to error, more sophisticated analysis of contractile reserve using right ventricular pressure-area relations may be needed to accurately quantify right ventricular function.[97] In practice, however, right ventricular function is frequently assessed by collectively weighing the clinical, hemodynamic, and echocardiographic data. If severe right ventricular failure is present, then biventricular support or total heart replacement should be considered. Patient characteristics that predict the development of severe right ventricular failure after LVAD insertion include female gender, nonischemic etiology, elevated intraoperative central venous pressure, and low pulmonary artery pressure and right ventricular stroke work index.[98]

Secondary pulmonary hypertension is frequently present in patients with severe HF.[99] Although significant pulmonary hypertension by itself is not a contraindication to device implantation, its presence should be taken into consideration. It is important to remember that the absence or presence of only mild pulmonary hypertension does not always mean a lower risk for right HF because pulmonary pressures may be lower owing to significant right ventricular dysfunction and the inability of the right ventricle to generate an adequate output. On the one hand, mild pulmonary hypertension in the setting of a low cardiac output may actually become worse after device implantation when cardiac output is restored to normal. On the other hand, patients with significant pulmonary hypertension, who have preserved right ventricular function, may, in fact, lower their pulmonary pressures and resistance appreciably after device support. This strategy has been used successfully to help reverse significant pulmonary hypertension in transplant candidates.[100]

Assessment of Comorbidities

If present, comorbidities require as careful an evaluation as is done when considering candidates for cardiac transplantation. These comorbidities include diabetes, peripheral arterial and cerebrovascular diseases, and systemic illnesses.[101,102] Diabetic patients have to be screened for end-organ dysfunc-

tion. After device support, clinical outcomes in selected diabetics are similar to those in nondiabetic patients. Significant peripheral arterial disease and abdominal aortic aneurysm are relative contraindications. Because of the risk of thromboembolism after device implantation, patients should be screened for cerebrovascular disease. Mental status should be assessed in all potential candidates, as neurologic impairment is frequently encountered in patients who are in cardiogenic shock. It is important to determine if the neurologic dysfunction is reversible after restoration of cerebral blood flow with device support. Persistent neurologic dysfunction after device support precludes adequate physical rehabilitation that leads to poor long-term outcomes. Eligible candidates must not have a systemic illness, such as an active malignancy, that will limit life expectancy to 2 years or less.

Predicting Outcomes

The best outcomes are achieved in patients who undergo implantation of a circulatory assist device under elective conditions. Emergency device implantation is associated with a higher risk of death. Risk factors associated with poor outcome include significant right ventricular failure, mechanical ventilation, reoperation, laboratory parameters indicating end-organ dysfunction, and active infection. Previous sternotomy may be associated with increased postoperative bleeding. Reoperation to replace a temporary device such as an extracorporeal membrane oxygenator with a long-term circulatory assist device is also a risk factor.

The degree and number of organs affected by HF should be evaluated. Imaging studies are frequently needed if the laboratory parameters are abnormal. Many patients have mild-to-moderate renal impairment that requires temporary ultrafiltration or dialysis following device implantation. Hepatic dysfunction frequently resolves after device support, but it is critical that the coagulation profile be normalized before surgery. Liver dysfunction may be a risk factor for vasoplegia or excessive vasodilation on circulatory support. Device implantation should be postponed if active infection is present.[103]

In a retrospective analysis of 134 device implants in a single institution, preoperative creatinine clearance of less than 70 mL/minute, requirement for more than 1 inotrope, need for intra-aortic balloon for greater than 3 days, ischemic etiology for HF, diabetes, prior sternotomy, and absence of an internal cardioverter-defibrillator were independent univariate predictors of mortality after VAD placement. The presence of three or more of these risk factors was associated with a significantly shorter survival time on VAD support.[104] Other investigators have proposed a scoring system for risk assessment also based on the number of risk factors present at the time of device implantation. Although clinically useful, such a scoring system has not been prospectively validated.[105]

Technical Considerations

A small body surface area may preclude the use of currently approved intracorporeal devices. Extracorporeal support is needed for these patients. However, many of the newer devices are smaller and designed for use in pediatric and small adult patients. The presence of valvular disease must be taken into consideration.[106] Mitral stenosis, if severe, will require surgical correction at the time of device implantation to permit adequate filling of the device. Mitral regurgitation is encountered more frequently in advanced HF and is usually not a hemodynamic problem during device support. Typically, it improves acutely after device implantation due to decompression of the volume-overloaded left ventricle; this improvement is sustained during chronic device support. However, if myocardial recovery and device explantation are anticipated, mitral valve repair should be considered.

Aortic stenosis may not require surgical correction unless there is a possibility for recovery. Aortic regurgitation will limit the forward flow from the device and should be corrected by suturing the aortic leaflets together. If aortic valve replacement is considered, it is recommended that a bioprosthetic valve be used.

Tricuspid regurgitation, if severe, is frequently associated with significant right ventricular dysfunction. Lesser degrees of tricuspid regurgitation are often left alone because the experience with tricuspid valve repair during LVAD implantation is not very good. Immediately after device implantation, tricuspid regurgitation worsens because of volume loading of the right ventricle and shifting of the interventricular septum leftward. If the right ventricle can sustain this hemodynamic perturbation, over time there is no further worsening of tricuspid regurgitation. Experience with device implantation in patients with mechanical prostheses is limited.

An aortic prosthesis, in particular, can become thrombosed during device support related to blood stasis and inactivity of the prosthesis that remains in the closed position. Oversewing the valve and the use of a Dacron graft to occlude the outflow may reduce the risk of thromboembolism. A prosthesis in the mitral position is usually left alone with attention paid to chronic anticoagulation to reduce the risk of thromboembolism. Preoperatively, it is important to look for right-to-left shunting across a patent foramen ovale. Because of high left atrial pressures, these shunts are frequently not apparent until after device implantation and unloading of the left ventricle and atrium. Contrast echocardiography should be performed in the operating room after device implantation to look for a shunt that may require repair before separation from cardiopulmonary bypass.

Arrhythmias

Atrial arrhythmias may be important because they can impair adequate filling of the device. Ventricular arrhythmias are generally well tolerated in the absence of significant pulmonary hypertension that would prevent a passive Fontan-type circulation. In patients with recurrent ventricular arrhythmias and pulmonary hypertension, biventricular support is necessary. If there is a left ventricular apical mural thrombus, it should be removed at the time of device insertion, especially in a patient with acute myocardial infarction and cardiogenic shock.[107]

Psychosocial Factors

Psychosocial considerations are similar to those in transplant candidates. Current alcohol or drug dependence, lack of adequate social support, and significant mental illness that is difficult to treat are all risk factors for a poor long-term outcome.

Overview of Devices

It is extremely important to select the correct type of circulatory assist device in a given patient. A number of considerations influence this decision-making process, including emergency or elective implantation, body size, anticipated duration of support (bridge or destination), severity of right ventricular dysfunction, and the patient's eligibility for inclusion in a clinical trial. The menu for device selection continues to grow and, to date, there are no prospective data comparing one device with another.

The available devices can be categorized under extracorporeal devices, intracorporeal devices, axial flow pumps, centrifugal LVADs, total cardiac replacement devices, and percutaneous LVADs (Table 18–6; see also Appendix 3).

Extracorporeal Devices

These devices are outside the body and include the centrifugal pumps, the Abiomed BVS 5000, and the Thoratec (Pierce-Donachy) device.

Table 18–6 Overview of Circulatory Support Devices

Type	Name	Power Source	Type of Flow	FDA Approval	Anticoagulation	Patient Mobility	Duration of Use
Extracorporeal	ECMO	Electrical	Continuous	No	Yes	Limited	48-72 hrs
Extracorporeal	Abiomed BVS 5000	Pneumatic	Pulsatile	Yes (PCS)	Yes	Limited	7-10 days
Extracorporeal	Thoratec VAD	Pneumatic	Pulsatile	Yes (PCS, BTT)	Yes	Fair	Intermediate-term
Intracorporeal	Thoratec IVAD	Pneumatic	Pulsatile	Yes (BTT)	Yes	Good	Intermediate-term
Intracorporeal	HeartMate LVAS	Electrical (VE), Pneumatic (IP)	Pulsatile	Yes (BTT, DT)	No	Good	Long-term
Intracorporeal	Novacor LVAS	Electrical	Pulsatile	Yes (BTT)	Yes	Good	Long-term
Intracorporeal	LionHeart LVD 2000	Electrical	Pulsatile	No (DT*)	Yes	Good	Long-term
Axial Flow	HeartMate II	Electrical	Continuous	No (BTT*, DT*)	Yes	Good	Long-term
Axial Flow	Micromed DeBakey VAD	Electrical	Continuous	No (BTT*, DT*)	Yes	Good	Long-term
Axial Flow	Jarvik 2000	Electrical	Continuous	No (BTT*)	Yes	Good	Intermediate-term
Axial Flow	Incor LVAD	Electrical	Continuous	No (PCS*,BTT*)	Yes	Good	Short-term
Centrifugal	HeartMate III, Cor Aide, VentrAssist, Kriton, HeartQuest, DuraHeart	Electrical	Continuous	No	No	Good	Short-term
Total Cardiac Replacement	CardioWest TAH-t	Pneumatic	Pulsatile	Yes (BTT)	Yes	Fair	Intermediate-term
Total Cardiac Replacement	Abiocor	Electrical	Pulsatile	No (DT*)	Yes	Fair	Long-term
Percutaneous VAD	Tandem Heart PTVA	Electrical	Continuous	Yes (PCS)	Yes	Limited	7 days
Percutaneous VAD	Impella RS	Electrical	Continuous	No (PCS*)	Yes	Limited	7 days
Percutaneous VAD	Cancion CRS	Electrical	Continuous	No (HF exacerbation*)	Yes	Limited	7 days

See text for device abbreviation.
*Clinical trials underway.
BTT, bridge-to-transplantation; DT, destination therapy; PCS, postcardiotomy support.

Centrifugal Pumps

These are the devices used for cardiopulmonary bypass during cardiac surgery. They have an electrical power source and can be used to support right, left, or both ventricles. They use magnetic impeller cones with flow regulation by the rotation method and provide continuous flow. They cause less hemolysis than roller head pumps. Their implantation requires arterial, atrial, or ventricular cannulation. They are not FDA approved for circulatory support. Disadvantages of these pumps include the risk of coagulopathy, need for intravenous anticoagulation, only short duration of support (48 to 72 hours), the necessity for patients to remain in the intensive care unit, difficulty in closing the chest, and the need for bedside perfusion teams to run the system. A hollow fiber membrane oxygenator may be included in the system for extracorporeal membrane oxygenation (ECMO). In these patients, continuous monitoring of hematocrit and oxygen concentration in the pre- and postoxygenator circuits is needed. The use of ECMO for cardiopulmonary assist in adults has been disappointing. However, in patients with perioperative allograft failure following cardiac transplantation, an 84% weaning rate and a 52% survival rate were reported.[108-110]

Abiomed BVS 5000

This device is FDA approved for use in postcardiotomy shock. It is a pneumatic, pulsatile device that can be used to support the left, right, or both ventricles. The pump has two chambers, two polyurethane valves, and can achieve flows of up to 6 L/minute. It uses the left ventricle, left atrium, or right atrium for inflow cannulation. For left ventricular support, the outflow cannulation is into the ascending aorta, whereas it is into the pulmonary artery for right ventricular support. This device is self-regulating, fills via gravity, permits closure of the chest, and does not require a bedside perfusion team. Disadvantages of this device include the need for chronic anticoagulation with increased risk of bleeding, use for short to intermediate duration (7 to 10 days), and restricted patient mobility owing to the size of the console. Nevertheless, this is a device that can be used in community hospitals to stabilize patients before transfer to a specialized institution to await myocardial recovery or bridge to another longer-term device. Data from a worldwide registry indicate that this device has been used to support over 6000 patients (63% for postcardiotomy shock) with patient survival to explantation or transplantation approaching 50%.[111] A newer generation device (Abiomed AB 5000) that uses a smaller console is now available and this permits increased mobility and rehabilitation for supported patients.

Thoratec VAD

This ventricular assist device is a pulsatile, pneumatic, thromboresistant polyurethane-lined, pusher plate pump that can be used for right, left, or biventricular support (Fig. 18–4). The driver is connected via a pneumatic hose that delivers alternating pressure or vacuum inside the pump housing. With pressure, the blood sac collapses, resulting in ejection, whereas application of vacuum creates a pressure gradient that assists filling from the left ventricle. The dual drive console has two independent and identical drive modules for left and right ventricular support. It is FDA approved for both postcardiotomy shock and for use as a bridge to transplantation. Its placement is achieved via a median sternotomy on cardiopulmonary bypass.[112] For left-sided support, the inflow cannula is typically placed in the left ventricular apex and tunneled subcostally to the external pump. The outflow cannula is also subcostally tunneled and anastomosed to the ascending aorta. The left atrium can also be used for inflow cannulation, but this generally results in suboptimal flows. For right-sided support, the right atrium is used for inflow cannulation and the pulmonary artery for anastomosis of the outflow cannula. Unidirectional flow is maintained by Bjork-Shiley tilting disc prosthetic valves in the blood pump. The pump delivers a

Figure 18–4 Ventricular assist devices that are presently approved by the Food and Drug Administration in the United States. **A,** Novacor LVAS (electrical power, maximum flow 10 L/min). **B,** HeartMate XVE LVAD (electrical power, maximum flow 10 L/min). **C,** Thoratec VAD (pneumatic power, maximum flow 7.2 L/min). The Novacor LVAS and the Heartmate XVE are intracorporeal, whereas the Thoratec VAD is extracorporeal and can be used to assist both the right and the left ventricles.

maximum stroke volume of 65 mL, can achieve flows up to 7 L/minute, and can be operated in a fixed asynchronous mode or volume (full to empty) or synchronous (with R wave) mode.[113] This device is durable, versatile, and can be used in small adults and children. A compact and portable driver (TLC-II) is now available and when patients are ready to ambulate, they can be switched from the console driver to the TLC-II and discharged from the hospital.[114] According to the Thoratec VAD worldwide voluntary registry, more than 2800 patients have received these devices as of November 2004 with the longest duration of implantation being 566 days. Chronic anticoagulation is required with this device.

Table 18–7 Troubleshooting of the HeartMate LVAD in the Automode

Decreased LVAD rate	Increased LVAD rate
Filling slower = ↓ preload • Hypovolemia • Tamponade • RV dysfunction • Inflow cannula kink • LV function recovery	Filling faster = ↑ preload • Hypervolemia • Aortic insufficiency • Inflow valve regurgitation

Intracorporeal Devices

These implantable pulsatile devices include the Thoratec implantable ventricular assist device (IVAD), Thoratec HeartMate left ventricular assist system (LVAS), and the Novacor LVAS. All of these devices are implanted through a median sternotomy during cardiopulmonary bypass. The device is placed in a preperitoneal, subrectus pocket. Blood from the heart is channeled into the assist device through a tunneled inflow conduit that is attached to the apex of the left ventricle. The device, in turn, propels the blood in a pulsatile fashion through an outflow conduit that is tunneled and attached to the ascending aorta. Valves located in the inflow and outflow conduits ensure blood flow in only one direction. Precise placement of the inflow and outflow conduits and the routes by which they are tunneled are critical to prevent blood flow obstruction and erosive injury to the heart or the aorta. Inadequate de-airing of the LVAD may cause neurologic sequelae. A tunneled percutaneous driveline connects the device to its portable external driver. Design improvements to enhance patient comfort and mobility have resulted in smaller, lighter weight drivers with extended power packs for up to 6 hours. All of these devices enable patients to achieve full ambulation, resume all activities with the exception of swimming, and be discharged from the hospital.

Thoratec IVAD

The IVAD can be used as a bridge to transplantation or as a bridge to recovery in postcardiotomy shock patients.[115] It is the only FDA-approved implantable device that can be used for left, right, or biventricular support. The pump is made of a durable titanium alloy and has a smooth external profile. It accommodates a wide range of patient sizes and is connected to the portable TLC-II driver with a tunneled percutaneous driveline. The use of this device requires systemic anticoagulation. In the initial experience with this device, 68% of patients were successfully bridged to transplantation or recovery. The mean duration of IVAD support per patient was 82 days, with the longest duration of 298 days, without any unexpected adverse events or device failures.

Thoratec HeartMate LVAS

There are two approved versions of this device for left ventricular support only; the *Vented Electric (VE)* LVAD, which is powered by wearable batteries and the *Implantable Pneumatic (IP)* LVAD, which is powered by an external drive console.[116,117] Both are FDA-approved devices for use as a bridge to transplantation, and the VE LVAD is also approved for use as destination therapy (see Fig. 18–4). In both versions the pusher plate technology with a polyurethane diaphragm is used to propel blood in a pulsatile fashion. The inside of the device is coated with a textured blood contacting surface (composed of sintered titanium microspheres) that promotes adherence of blood elements leading to the development of a pseudointima that mimics the intimal lining of native blood vessels.[118] The inflow and outflow valves are both porcine xenografts. This unique design significantly reduces the risk of thromboembolism and avoids the need for systemic anticoagulation. This device can generate a stroke volume of 85 mL, with a maximum output of 10 L/minute. It can operate either in a fixed mode at a preset rate or an auto mode in which the device responds to changing physiologic flow demands of the patient (Table 18–7). If the activity level increases, requiring more blood flow, the increased flow through the heart triggers a similar increase in flow of the LVAD. Likewise, when flow demands decrease, flow through the device decreases as well. The device permits a fail-safe mechanism whereby in the event of pneumatic or electrical motor failure, it can be operated via a hand pump. As of November 2004, the HeartMate LVAS worldwide voluntary registry reported 1323 pneumatic and 2867 electrical LVAS implants. The average duration of the pneumatic implant was 97 days and the electrical implant 152 days; the maximum duration of pneumatic LVAD support was 805 days and the electrical LVAD support 1854 days.[119]

The Thoratec HeartMate XVE is an enhanced version of the VE LVAD that is now commercially available. The enhancements incorporated in this device include increased flexibility in the percutaneous lead, enhanced controller software to reduce wear of the valves and bearings, and a newly designed inflow valve that has greater durability.[120] Despite the design upgrade, durability remains an issue with this device, particularly when it is used for destination therapy. Device failure, which occurs at a rate of 15%, frequently involves inflow valvular regurgitation with recurrence of HF requiring elective replacement of the pump. Electrical power failure of the VE LVAD can sometimes be managed with the use of a pneumatic console, but may require emergency VAD replacement.

Novacor LVAS

This is an implantable, electrical, dual pusher plate, polyurethane-lined blood pump (see Fig. 18–4). It has two porcine-valved conduits. This device is known for its reliability and durability and was the first device used to bridge a patient to transplantation. It generates a stroke volume of 70 mL and can produce flows up to 10 L/minute. It is used only for left-sided support and is FDA approved as a bridge to transplantation.[121,122] Systemic anticoagulation is required,

and the thromboembolic risk with this device is high. Design changes (e.g., use of ePTFE inflow conduits) have however decreased this risk.[123] According to the Novacor LVAS worldwide registry, over 1100 implants have been performed with cumulative support of greater than 300 patient years, with only 0.7% requiring replacement. In the Novacor bridge to transplantation multicenter U.S. trial that enrolled 191 patients (156 device, 35 control), the mean duration of support was 80 days and the rate of survival to transplantation was 78%.[124]

Arrow LionHeart LVD 2000

This device is the first fully implantable LVAD for destination therapy. It is a pulsatile, volume displacement pump that uses energy from an external battery pack that is transmitted across the skin to power an implanted battery. Because there is no percutaneous driveline, infection rates on this device are much lower than other devices, and the patient can enjoy limited periods of untethered movements and activities. Initial experience in six patients at a single center in Europe demonstrated a 50% survival rate at 18 months with no device failures or device-related infections.[125] A U.S. feasibility trial is ongoing.

Axial Flow Pumps

The axial flow pumps are a new generation of nonpulsatile devices that are small, silent, easy to implant, and have simple mechanics with only one moving part and no valves (Fig. 18–5). Their small size and mechanical simplicity offer considerable advantage and benefits over the previously described first-generation pumps. An abdominal pocket is not needed and implantation can be done without cardioplegic arrest. A flexible inflow cannula is connected to the apex of the left ventricle and the outflow cannula is connected to the ascending or descending aorta. These pumps can generate flows between 8 and 10 L/minute. They are used to support only the left ventricle and their use requires systemic anticoagulation. Device failure is rare and causes severe aortic regurgitation requiring emergency replacement of the pump. There is, however, a risk of hemolysis. Although short-term nonpulsatile flow does not appear to affect organ function, the physiologic relevance of permanent loss of pulsatility is unknown at this time. The currently available axial flow pumps include the HeartMate II LVAS, Micromed DeBakey VAD, Jarvik 2000 Flowmaker, and the Incor (Berlin Heart) LVAD.[126-129] All of these devices are investigational in the United States.

HeartMate II LVAS

This device incorporates a textured surface similar to the HeartMate XVE that is resistant to thrombosis. A small percutaneous driveline connects to an external controller and power pack that share the same hardware platform and system components as the HeartMate XVE LVAS. A phase I pilot trial with this device was completed and a phase II pivotal trial is underway. This trial has two arms: one that will enroll 133 patients who are candidates for cardiac transplantation prospectively in a nonrandomized fashion, and another that will prospectively randomize 200 patients who are ineligible for transplantation in a 2:1 fashion to either the HeartMate II LVAS or the HeartMate XVE LVAS for destination therapy.

Micromed DeBakey VAD

This device is the size of a "C" battery, measures 1″ × 3″, and weighs only 4 ounces. More than 300 patients have been supported with this device worldwide and it is approved for use as a bridge to transplantation in Europe. In the United States, clinical trials are underway to evaluate its efficacy and safety both for bridge to transplantation and destination therapy in end-stage HF.

Jarvik 2000 Flowmaker

This device has been used to treat more than 100 patients in Europe and the United States. In 79% of patients, the device was used as a bridge to transplantation. In this group, survival to transplantation was 70%. The longest a patient has been supported with this device is 5 years. This device is approved in Europe for both bridge to transplantation and destination therapy. In the United States, clinical trials are currently underway to evaluate the safety and efficacy of this device as a bridge to transplantation.

Incor LVAD

In its first clinical experience, the Incor LVAD was evaluated in 15 patients with cardiogenic shock. One patient was weaned, five patients were bridged to transplantation, and three were on support at the time of the report. The overall survival rate was 60%.

A B C

Figure 18–5 The axial flow pumps that are presently under investigation. **A,** HeartMate II LVAS. **B,** Micromed DeBakey VAD. **C,** Jarvik 2000 Flowmaker.

Centrifugal LVADs

The centrifugal LVADs are investigational, third-generation pumps in which the rotating assembly is magnetically suspended and noncontacting and, therefore, has no mechanical wear with chronic use.[130] Potentially, these pumps can provide significantly longer periods of circulatory support than the previously described devices. No systemic anticoagulation is needed. The centrifugal LVADs currently in clinical development are the HeartMate III LVAS, CorAide pump, VentrAssist pump, Kriton pump, HeartQuest pump, and Dura Heart LVAS.

Total Cardiac Replacement

These devices are totally implantable and they orthotopically replace both ventricles and all four valves. They are particularly suited for those patients who have biventricular failure, cardiac arrhythmias, fixed pulmonary hypertension, interventricular shunts, intracardiac thrombus, and mechanical prosthesis and who are not candidates for a left ventricular assist device. Two devices that are currently available for total cardiac replacement include the CardioWest Temporary Total Artificial Heart (TAH-t), and the Abiocor replacement heart system. The American BioMed Baylor-TAH, the Cleveland Clinic Foundation Nimbus-TAH, and the MagScrew TAH are currently under investigation.

CardioWest TAH-t

This is the only FDA-approved total cardiac replacement device in the United States.[131] It evolved from the Jarvik-7 total artificial heart and is a pneumatic, pulsatile, biventricular blood pump lined with polyurethane. In the United States, the device is powered by a large console that prevents discharge from the hospital; whereas in Europe, portable drivers are used permitting discharge from the hospital. This device requires systemic anticoagulation. In a nonrandomized, prospective study, the safety and efficacy of this device were evaluated in transplant-eligible patients who had irreversible biventricular failure. Eighty-one patients were implanted with the device and the survival to transplantation was 79%. In 35 historical control patients who did not receive the device, the survival to transplantation was significantly lower at 46%. The one-year survival rate in patients receiving the device was 70%, which was significantly better than 31% in the control group.

Abiocor Replacement Heart System

This is an investigational, electrical, pulsatile device made of titanium and polyurethane plastic with fully implantable components.[132] These components include the pump, energy transfer device, internal battery, and controller. The pump is implanted in the thorax. The internal battery is continually recharged from an external battery pack using the energy transfer device called TET (transcutaneous energy transmission). The TET system consists of internal and external coils that transmit power across the skin without piercing the surface. Chronic anticoagulation is required with this device. The safety and efficacy of the Abiocor replacement heart system are currently being evaluated in an FDA-approved clinical trial. In the initial reported experience, seven patients received the Abiocor device, and there were five deaths during follow-up. The actual survival at 30 days was 71%, and at 60 days it was 43%. Predicted survival on medical therapy alone at 30 days was 13%. Total days on support with the Abiocor are 759 days. This multicenter trial is ongoing.

Percutaneous VADs

These magnetically levitated centrifugal pumps are electrically powered and can frequently be implanted without sternotomy or cardiopulmonary bypass. They are, therefore, ideally suited for circulatory support during high risk, percutaneous coronary intervention, for patients with cardiogenic or postcardiotomy shock, or for patients with acute HF exacerbation that is refractory to pharmacologic therapy. The percutaneous VADs currently available include the Tandem Heart PTVA system, Impella Recover system, and Cancion CRS therapy.[133-135] The Tandem Heart PTVA is approved by the FDA, whereas the other two devices are investigational. These pumps can generate up to 4 to 6 L of flow for 5 to 7 days and their use requires systemic anticoagulation.

Tandem Heart PTVA

This system pulls oxygenated blood from the left atrium and returns it to the systemic arterial circulation. An inflow cannula is advanced retrograde through the femoral vein transseptally into the left atrium. The outflow cannula is inserted into the femoral artery.

Impella Recover System

This is a microaxial pump that can be used to support either the right or the left ventricle. For left ventricular support, the device is inserted retrograde via the femoral artery and advanced into the left ventricle through the aortic valve. For right ventricular support, a sternotomy is needed and the pump with the suction chamber is implanted into the right atrium with the outflow cannula in the pulmonary artery.

Cancion CRS Therapy

This therapy increases blood flow in the descending aorta inducing vasodilation and increased renal blood flow. It uses two arterial cannulas: an inflow cannula in the femoral artery and an outflow cannula in the descending aorta. In a pilot study with 24 patients, continuous aortic flow augmentation with the Cancion CRS therapy achieved both hemodynamic improvement (increase in cardiac index and lowering of systemic vascular resistance) and ventricular unloading (decrease in pulmonary capillary wedge pressure) that persisted for 24 hours after device therapy was discontinued. In animal models of HF, this therapy has been shown to reverse neurohormonal and vascular signaling. The clinical and biologic effects of this therapy in end-stage HF that is inadequately responsive to medical therapy are currently being evaluated in a randomized, controlled trial.

Destination Therapy

Because short-term use of circulatory assist devices improves symptoms, normalizes hemodynamics, and restores quality of life with a relatively low incidence of adverse events, the suitability of these devices as permanent long-term therapy in end-stage HF patients was evaluated in the *Randomized*

*E*valuation of *M*echanical *A*ssistance for the *T*reatment of *C*ongestive *H*eart failure (REMATCH) trial.[92] This prospective trial randomized 129 patients who were ineligible for transplantation 1:1 to either optimal medical therapy or a HeartMate XVE LVAD. The inclusion criteria ensured that this was a truly end-stage study population (71% of patients were on inotropic support at the time of randomization) with a very high anticipated mortality. Kaplan-Meier survival curves demonstrated a 48% reduction (P = 0.003) in all-cause mortality in the LVAD group compared with the medical therapy group. The survival rate at 1 year was 52% in the device group and 25% in the medical therapy group (P = 0.002), and the survival rate at 2 years was 23% and 8%, respectively (P = 0.09). The patients enrolled in REMATCH were considerably sicker than the patients enrolled in pharmacologic studies in advanced HF (Table 18–8). The quality-of-life measures were significantly improved in the device group at 1 year. Terminal HF was the most frequent (93%) cause of death in the medical therapy group, whereas infection (41%) and device failure (17%) were the most common reasons for death in the LVAD group. The number of days in and out of the hospital was longer in the LVAD-supported patients.

Based on the results from the REMATCH trial, the FDA approved the HeartMate LVAD for destination therapy in end-stage HF patients who are transplant ineligible. Subsequent modification in device design and adoption of strict infection control guidelines have significantly improved outcomes on LVAD destination therapy. Data from the four highest volume destination therapy centers in the United States now demonstrate a 1-year survival rate of 61% in LVAD-supported patients, which is a 40% improvement over the REMATCH data (Fig. 18–6). Fatal device failure rate has been reduced to 15% and the fatal infection rate to 8%.[136] Because malnutrition is an important predisposing risk factor for infection, it is important to optimize nutrition before LVAD surgery. It is anticipated that continued enhancement in device design and greater experience with patient selection and management will lead to further improvements in outcomes for LVAD patients in the future, approaching those seen with cardiac transplantation. The eligibility criteria established by the U.S. Food and Drug Administration (FDA) for destination therapy were adopted by the Center for Medicare and Medicaid Services (CMS) in October, 2003 (Table 18–9).

The results of the *I*nvestigation of *N*on-*Tr*ansplant *E*ligible *P*atients who are *I*notrope-*D*ependent (INTrEPID) trial, which was a nonrandomized, multicenter study of the Novacor LVAS in 55 New York Heart Association (NYHA) functional class IV patients, who were not eligible for transplantation, were reported. As with the REMATCH trial, the 6-month and 1-year survival rates in the 37 patients who received the LVAS were significantly better than the control group of 18 patients (46% versus 22% at 6 months and 27% versus 11% at 1 year, respectively). Both infection and cerebrovascular events accounted for 16% of deaths in the LVAS group. The quality-of-life scores were better in the LVAS group and 85% of the device-supported patients improved to NYHA class I to II symptoms.

There are three destination therapy trials currently in progress, all of which are prospectively comparing another circulatory assist device with the HeartMate XVE LVAD in patients who are not transplant candidates. The *R*andomized *E*valuation of the Novacor *LVAS In A Non-Transplant* population (RELIANT) trial is randomizing patients in a 2:1 ratio to the Novacor LVAS and the HeartMate XVE, whereas the *D*estination *E*valuation *L*ong-*T*erm *A*ssist (DELTA) trial is using a 2:1 ratio to the Micromed DeBakey VAD and the HeartMate XVE. A third trial is randomizing patients in a 2:1 fashion to the HeartMate II LVAS and HeartMate XVE. With the successful completion of these trials, several devices will likely become available for destination therapy and physicians will have the opportunity to match the appropriate device to

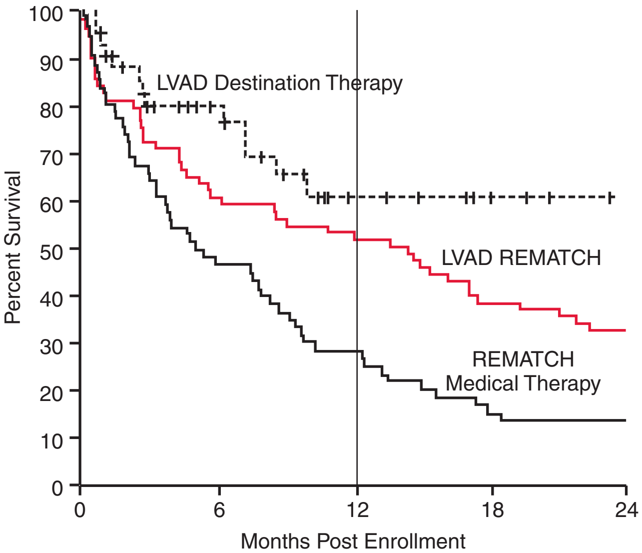

Figure 18–6 Long-term survival with HeartMate XVE LVAD destination therapy: Comparison with REMATCH results. (Redrawn from Long JW, Kfoury AG, Slaughter MS, et al: Long-term destination therapy with the HeartMate XVE left ventricular assist device: Improved outcomes since REMATCH study. Congest Heart Fail 2005;11:133-8, with permission.)

any given patient based on objective criteria so that long-term outcome on destination therapy is optimal.

Management of Patients on VAD

Although patient selection is a critical determinant for a good outcome after LVAD support, proper management of patients on support is also important for a successful outcome. A team approach to care is needed, and the key members of the team frequently include a nurse coordinator, engineer, cardiologist, and surgeon. Education of the patient and caregiver is vital to successful VAD management, as it is with any complex therapy. It is also important to ensure that paramedics and health care workers in fire departments and emergency rooms close to the patient's home are educated so that they can participate in the care of emergency issues.

Acute Management

Following LVAD insertion, the acute management issues include bleeding, right ventricular failure, and atrial and ventricular arrhythmias. However, selecting the proper patient and the proper device may minimize the risk of bleeding and right ventricular failure.

Bleeding

If there is significant mediastinal bleeding, reoperation is necessary to avoid tamponade. The risk of bleeding is greater with earlier sternotomy, hepatic dysfunction, and implantation of pulsatile intra- and extracorporeal devices and total cardiac replacement devices rather than the axial flow pumps. Bleeding that requires multiple transfusions of blood products can overburden the right ventricle causing right ventricular failure. Multiple transfusions can also cause noncardiogenic pulmonary edema leading to respiratory failure.

Right Ventricular Failure

Right ventricular dysfunction can be treated with inhaled nitric oxide to reduce pulmonary vascular resistance or intravenous milrinone to augment contractility in addition to causing pulmonary vasodilation. Among patients who stabilize, intravenous therapy may be needed for several days. Persistent, severe right ventricular failure with LVAD under filling and low flows requires insertion of a right ventricular assist device (RVAD). In general, when RVAD is needed following LVAD placement the outcome is poorer when compared with a priori biventricular support. Therefore, recognizing who is at risk for needing an RVAD preoperatively is important so that biventricular support or total cardiac replacement can be considered in these high-risk patients. Emergency device implantation, elevated serum creatinine and prothrombin time, mechanical ventilation, and low pulmonary artery pressure or cardiac index, or right ventricular stroke work index are all risk factors that predict the need for biventricular support.[137]

Arrhythmias

Both atrial fibrillation and serious ventricular arrhythmias can develop postoperatively and limit LVAD filling. Prompt restoration of normal rhythm either with pharmacologic or electrical cardioversion is critical. Serious ventricular arrhythmias are more frequent in patients with ischemic heart disease and if present early (within the first week) portend a poor outcome. Patients who do not respond to drug therapy frequently require RVAD insertion.

Chronic Management

According to the ISHLT Mechanical Circulatory Support Database (MCSD) analysis of 655 device patients (78% bridge to transplant) from 66 centers worldwide, the 6-month survival rate was 67% and the 1-year survival was 50%.[138] The major causes of death were multiorgan failure (35%), bleeding (15%), cardiovascular (12%), cerebrovascular accident (10%), and infection (8%). Right ventricular failure with need for RVAD, older age, female gender, ventilator support at the time of device implant, diabetes, and elevated creatinine and white cell count were risk factors for death after device implant. Freedom from device malfunction was 84% at 6 months and 66% at 1 year.

The chronic management issues of device support include anticoagulation, risk of thromboembolic complications, local (driveline) or systemic infection, systemic hypertension, arrhythmias, device failure, and HF. In addition, management of any coexistent noncardiac conditions such as diabetes, thyroid disease, and anemia is important—just as in other HF patients. Chronic care of the patient needs to be coordinated between the VAD team and the local physicians.

Anticoagulation

Thromboembolic transient ischemic attacks and strokes remain dreaded complications of device therapy and careful monitoring of anticoagulation is imperative. Over-anticoagulation with systemic, gastrointestinal, or intracranial bleeding is also of concern, and the INR needs to be monitored at least monthly. All VADs except for the HeartMate LVAS and the investigational centrifugal pumps require chronic warfarin therapy with a targeted INR of 3.0 to 3.5. The textured surface of the HeartMate LVAS permits the development of a pseudointima that reduces the risk of thromboembolism and the need for chronic anticoagulation. However, in the REMATCH trial, neurologic events were common with 44% of patients in the device group sustaining at least one event and 16% having either an ischemic or hemorrhagic stroke.[139] Certain devices such as the Novacor LVAS have been associated with a higher risk (23%) of fatal thromboembolic and cerebrovascular events than others such as the HeartMate XVE, although with recent design improvements (use of ePTFE inflow conduits) the risk of such events on Novacor

LVAS support has decreased significantly. The risk of a neurologic thromboembolic event decreases with increasing duration of support. All anticoagulation protocols combine warfarin and aspirin, and some also include dipyridamole or clopidogrel, or both.

Infection

Continued surveillance against driveline, pocket, and systemic infections is critical to optimizing outcome on device support. Older patients and patients with diabetes or renal dysfunction may be particularly prone to infectious complications. Obese individuals receiving intracorporeal devices may be predisposed to pocket infections. Antibiotic prophylaxis before dental, urologic, gastrointestinal, or gynecologic procedures is recommended.

Systemic Hypertension

Systemic hypertension has been noted in patients on chronic support with pulsatile LVADs. The incidence may be as high as 69%, and this can be detected as early as 7 days after LVAD insertion. There are no predisposing risk factors and this tends to occur both in chronic dilated and ischemic cardiomyopathy as well as acute cardiomyopathy and myocardial infarction patients. The cause is unclear and potential mechanisms include elevated vasomotor tone, malfunction of the cardiorenal axis, and neurohormonal activation. The incidence of hypertension correlates with device flow and its presence is associated with a higher incidence of neurologic events. The majority of patients respond to a single antihypertensive agent such as an ACE inhibitor, although resistant hypertension requiring multiple drugs has been noted.

Arrhythmias

Chronic atrial fibrillation, if present, should be treated by usual methods aimed at rhythm and rate control. Persistent rapid atrial fibrillation can impair filling and reduce LVAD flow. Sustained ventricular tachycardia or ventricular fibrillation during chronic LVAD support has been noted in 22% of patients. The arrhythmias are more prevalent in patients with ischemic HF and can be treated with either antiarrhythmic drug therapy or radiofrequency ablation. If an internal cardioverter-defibrillator (ICD) is present before implantation, it should remain activated. Patients receiving biventricular support may have their ICD removed after device implantation. There have been no reported incidents of LVAD-ICD interaction.

Device Failure

In the REMATCH trial, the probability of device failure at 2 years was 35%, and 10 patients (out of 67) required device replacement.[140] In a recent report, the rate of device failure was 15% with the use of the Thoratec HeartMate XVE for destination therapy. No device failures were reported in the INTrEPID trial with the Novacor LVAS. Inflow valve regurgitation and inflow cannula obstruction in the LVAD can result in recurrence of HF. This can be diagnosed by cardiac catheterization and requires device replacement.

Heart Failure

Patients on LVAD support require drug therapy for chronic HF. Treatment with ACE inhibitors and β-blockers should be continued because many patients have chronic right ventricular dysfunction and continued use of such therapy may aid in myocardial recovery. HF therapy is not needed during biventricular or TAH support. Cardiac resynchronization therapy (CRT), if present before implantation, can be turned off following LVAD insertion.

Myocardial Recovery on Circulatory Support

The progression of ventricular dysfunction in HF patients is characterized by cellular, molecular, structural, and functional changes that involve all components of the myocardium leading to alterations in myocardial architecture and geometry that is referred to as cardiac remodeling.[141,142] This progressive remodeling in turn leads to the hemodynamic alterations that are characteristic of HF. The exact mechanisms for these changes are unclear but mechanical stretch of myocytes, activation of neurohormonal, cytokine, and inflammatory pathways, and increased expression of matrix metalloproteinases may all be involved. There is considerable evidence to suggest that chronic unloading with a ventricular assist device not only restores normal hemodynamics and function, but also reverses, at least partially, the histologic, biologic, cellular, and molecular changes associated with HF (Table 18–10). Despite this, the number of patients who exhibit clinical recovery that results in successful VAD explantation remains variable and rather small—possibly because partial or complete normalization of HF-associated transcriptional responses occurs only in a small number of VAD-supported patients.[143,144]

In one series of 111 implants only five patients (4.5%) were explanted for myocardial recovery.[145] In another series of 131 VAD insertions in dilated cardiomyopathy patients, 32 patients (24.4%) were weaned successfully. The recovered patients had a 5-year survival rate of 78%. Left ventricular end-diastolic dimension greater than 55 mm and/or ejection fraction less than 45% before LVAD removal, as well as history of HF for 5 years or more before LVAD implantation, were risk factors for recurrence of HF after device explantation. Almost all patients demonstrating recovery had positive anti-β_1-adrenoceptor autoantibody titers.[146,147] In a third series of 154 patients who underwent device implants, there were 10 patients who exhibited recovery that allowed explantation. Patients demonstrating recovery underwent VAD implantation either for postcardiotomy shock or for severe HF from dilated cardiomyopathy. The incidence of recovery allowing explantation was 11% in the dilated cardiomyopathy group. No patient with chronic ischemic cardiomyopathy demonstrated recovery. The 1-year transplant-free survival in the explanted group was 80%.[148] Patients demonstrating recovery were younger women with a shorter duration of HF before VAD implantation. Based on these observations, it appears that sustained myocardial recovery after VAD explantation can be expected only in young patients with recent-onset dilated cardiomyopathy. Evidence for recovery peaks at around 60 days of support.

There is no consensus as to how the potential for myocardial recovery should be clinically evaluated in a VAD-supported patient. Echocardiographic assessment on and off pump is a good screening test in clinically stable, ambulatory patients. Patients whose clinical profile favors recovery on VAD support should have a resting echocardiogram on and

Table 18–10 Effects of Chronic Unloading with VAD

A. Hemodynamic and Functional Effects
Increased cardiac index
Decreased pulmonary capillary wedge pressure
Decreased pulmonary vascular resistance
Normalization of end-diastolic pressure-volume relation
Decreased cardiothoracic ratio
Decreased left ventricular dimensions
Decreased left ventricular mass
Decreased left atrial size
B. Histologic Effects
Decreased wavy band fibers
Decreased contraction band necrosis
Decreased myocytolysis
Decreased collagen deposition
Increased fibrosis
C. Biologic Effects
Decreased plasma renin activity
Decreased angiotensin II
Decreased epinephrine
Decreased norepinephrine
Decreased arginine vasopressin
Decreased interleukin-6
D. Cellular Effects
Decreased myocyte size and volume
Regression of myocyte hypertrophy
Improved contractility
Increased inotropic response to β-adrenergic stimulation
E. Molecular Effects
Upregulation of *Fas*
Downregulation of TNFα
Normalization of ANP, BNP immunoreactivity
Downregulation of MMPs
Improved cytosolic Ca^{2+} transients
Upregulation of SERCA
Changes in cytoskeletal proteins (sarcomeric, nonsarcomeric, and membrane-associated)
Improved myocardial mitochondrial function

ANP, atrial natriuretic peptide; BNP, B-type natriuretic peptide; MMP, matrix metalloproteinase; SERCA, sarcoplasmic reticulum calcium ATPase; TNF, tumor necrosis factor.

off pump monthly after device implantation. If the left ventricular end-diastolic dimension is less than 55 mm, and ejection fraction is greater than 45%, hemodynamic testing and maximal exercise with gas exchange analysis should be done at minimal support, to further establish functional recovery. The resting hemodynamics must be near normal and the maximal exercise oxygen consumption achieved should be similar to that seen in an NYHA class II patient (greater than or equal to 14 mL/kg/minute). In addition, there should be reductions in both QRS and corrected QT intervals from the pre-implantation ECG and a reduction in serum BNP levels. On-line quantitative echocardiography is another useful tool to ascertain recovery because it measures load-independent variables of cardiac function.[149] Increased stroke area, greater than 40% increase in fractional area change, or preload adjusted maximal power greater than 4.0 mW/cm^4 at low device flow (e.g., 1 to 2 L/minute) is often associated with successful device explantation. This technique is not widely available and can be used alone or in combination with maximal exercise testing and gas exchange analysis.

Combining pharmacologic therapy specifically aimed at reversing remodeling may increase the likelihood of myocardial recovery on VAD support.[150] Clenbuterol is a β_2-adrenergic receptor agonist that induces physiologic cardiac hypertrophy and reverses many of the adverse cellular and molecular changes in pressure-overloaded animal models of hypertrophy and HF. In a pilot series of 15 patients with dilated cardiomyopathy, clenbuterol therapy starting with 40 mcg twice a day with up titration to 700 mcg three times a day, in addition to ACE inhibitors, β-blockers, and aldosterone antagonists enabled successful device explantation in 12 patients (80%). Clenbuterol induced an increase in the myocardial expression of insulin-like growth factor (IGF)-1, which is an atrophy and apoptosis-limiting protein that also promotes regeneration. IGF-I expression returned to normal 1 year after LVAD explantation in this study.[151] These results are encouraging and a multicenter clinical trial is presently exploring the benefit of this promising strategy.

Future Directions

In the continuum of HF care, the role of circulatory assist devices continues to be redefined. From its initial application for short-term circulatory support as a last resort in cardiogenic shock, considerable progress over the years has resulted in the current use of these devices for destination therapy in chronic HF. During this period of evolution, the devices have become smaller, increasingly durable, and reliable—which has, in turn, enhanced the confidence in this therapy among health care providers. Further, chronic ventricular unloading with circulatory assist devices appears to result in partial or complete myocardial structural, functional, and molecular recovery. This recovery may be augmented by pharmacologic induction of cellular hypertrophy or myogenesis using cell therapy. In the future, application of circulatory support devices may not be only for temporary support of the failing circulation in end-stage HF patients awaiting transplantation, but also for induction of myocardial recovery of structure and function in patients with lesser degrees of HF.

With the anticipated increase in demand for devices in HF, special attention needs to be paid to the cost of circulatory assist device therapy. The cost burden of HF care in the United States is not only enormous and amounts to $24 billion annually, which is approximately 2% of the national health care budget, but also continues to escalate. In the REMATCH trial, the average cost of care among patients receiving the LVAD and surviving to discharge was $160,000, whereas it was $315,000 among the nonsurvivors.[152,153] The economic impact of an unfavorable outcome with an LVAD is, therefore, substantial. The median payment from CMS for an LVAD implant today is $128,000. In contrast, the cost of care for advanced HF patients on continuous inotropic therapy is between $40,000 and $130,000 annually, with no hope for increased survival. The challenge to clinicians in the future is not only to recognize the correct HF patients for circulatory assist device therapy, but also to appropriately time the implantation to maximize cost-effective prolongation of survival.

SECTION 4

Arrhythmias/Conduction Disturbances

Chapter 19

Clinical Pharmacology of Antiarrhythmic Drugs

Raymond L. Woosley and Farshad Shirazi

CHAPTER CONTENTS

Antiarrhythmic drugs have been developed with the expectation that they would extend and improve life for many patients with cardiovascular disease and for those with a history of life-threatening arrhythmias. Their usefulness, however, has been limited by ineffectiveness and/or toxicity. In mortality trials, benefit has not been clearly demonstrated, and worsened mortality rates have been observed with several drugs. Care must be taken, therefore, in deciding the mode of treatment, or in fact whether or not to treat at all. The use of antiarrhythmic drugs has been dramatically altered by the findings of the Cardiac Arrhythmia Suppression Trial (CAST).[1] This landmark study was designed to test the hypothesis that suppression of asymptomatic ventricular arrhythmias in patients with recent myocardial infarction would reduce mortality rates from cardiac arrest and/or arrhythmic sudden death. In 1989, the CAST was interrupted by the Data Safety and Monitoring Committee, and encainide and flecainide arms were removed because they had been found to increase mortality rates by two- to threefold. With the loss of confidence in sodium-channel blocking drugs, attention turned to drugs such as amiodarone that prolong cardiac refractorinesss. Although these drugs are effective in controlling symptomatic arrhythmias, their effects on mortality rates have been unclear but are probably neutral.[2,3] The other development in the treatment of serious ventricular arrhythmias has been the automated internal cardioverter-defibrillator. The trial that compared antiarrhythmic drugs with such devices, Antiarrhythmics Versus Implantable Defibrillators (AVID), found the device to have a greater improvement in mortality rates.[4,5] However, many patients with the devices continue to require treatment with antiarrhythmic drugs, and interactions (both desirable and undesirable) between the drugs and devices have been documented. Generally, drugs that block sodium channels can increase pacing and defibrillation thresholds, and drugs that prolong refractoriness, potassium-channel blocking drugs, lower the defibrillation threshold.[6,7]

Antiarrhythmic drugs are often classified according to their electrophysiologic effects.[8] The scheme most often used was originally proposed by Vaughan Williams as a classification of drug actions that should be antiarrhythmic.[8] Because of the limitations of the Vaughan Williams classification, another approach has been proposed,[9] termed the *Sicilian gambit*. This classification system is based on the differential effects of antiarrhythmic drugs on (1) channels, (2) receptors, and (3) transmembrane pumps. The grouping is based primarily on the predominant action of drugs but also considers the other ancillary actions that may be clinically relevant. Figure 19–1 is a combination of the Sicilian gambit and the Vaughan Williams classification, and it includes a comparison of their clinical effects and ECG changes. For example, quinidine, a class IA drug, is a sodium channel antagonist with abilities to block potassium channels and antagonize acetylcholine and catecholamines at cholinergic and α-adrenergic receptors, respectively. When this information is combined with an understanding of the electrophysiologic role of these actions, one can predict the effects that are likely to occur in vivo. In this case, one would expect conduction slowing, increased

ANTIARRHYTHMIC DRUG ACTIONS

Vaughn-Williams Class	DRUG	CHANNELS			RECEPTORS				Clinical Effects				ECG Changes
		Na	Ca	K	α	β	ACh	Ado	Pro-Arrhy	LV FX	Heart Rate	Extra Cardiac

Antagonist relative potency	
L = Low M = Moderate H = High	△ = Agonist ▲ = Agonist / Antagonist

Figure 19–1 (*See also Color Plate 19–1).* This is a modification of the Sicilian Gambit drug classification system and includes designation by the Vaughan Williams system. The sodium channel blockers are subdivided into the A, B, and C subgroups based on their relative potency. The targets of antiarrhythmic drugs are listed across the top in columns. These targets are the ion channels—sodium, calcium, and potassium—and the receptors—α-adrenergic, β-adrenergic, cholinergic (ACh), and adenosinergic (Ado). The next columns show a comparison of the clinical actions of the drugs, including proarrhythmic potential (Proarrhy), effect on left ventricular function (LV FX), effects on heart rate (Heart Rate), and potential for extra cardiac side effects (Extra Cardiac). The electrocardiographic tracings indicate the changes (*in color*) that are caused by usual dosages of the drug: PR interval (*blue*), QRS interval (*red*), and QT interval (*green*). The drugs are listed in rows with their brand names shown in parentheses. The symbols in the table indicate the relative potency of the drugs as agonists or antagonists. The *solid triangle* indicates the biphasic effects of bretylium to initially release norepinephrine and act as an agonist and subsequently to block further release and to act as an antagonist of adrenergic tone. The *number of arrows* and their directions indicate the magnitude and direction, respectively, of the effect of the drugs on heart rate and left ventricular function (i.e., inotropy).

action potential duration (APD) (and refractoriness), and vasodilation to result from these three actions of quinidine.

This chapter reviews the clinical pharmacology of the currently available antiarrhythmic drugs, excluding digoxin, β-receptor antagonists, and calcium channel blockers, which are addressed in other chapters. The drugs reappear in the same order as listed in Figure 19–1, a modified version of the Sicilian gambit classification. An understanding of clinical pharmacologic principles is essential when prescribing drugs that have narrow therapeutic indices, such as antiarrhythmic drugs (see Appendix 1 for a discussion of clinical pharmacology and tabular summaries of the pharmacokinetics, dosing, and plasma concentrations of the antiarrhythmic agents reviewed in this chapter). Individualization of dosage and plasma level monitoring have become standard with these drugs, but it is important to emphasize that there are many factors, such as chiral clearance and active metabolites, that create variability in the relationship between plasma concentrations and drug action.[10] This variability results in the need for clinicians to monitor clinical response whenever possible and not to place undue reliance on reaching the "therapeutic range" because it may not be therapeutic.

QUINIDINE

The effective dosage of quinidine varies among individuals because of several factors. Although quinidine sulfate is usually administered every 6 hours, there are wide interindividual differences in its elimination half-life, which ranges from 3 to 19 hours.[11] Plasma protein binding also varies widely, ranging from 50% to 95%.[11] Oral bioavailability is approxi-

mately 70%, and clearance after oral administration ranges from 200 to 400 mL/minute. Quinidine is inactivated or eliminated by both hepatic metabolism (50% to 90%) and renal elimination (10% to 30%). Several potentially active metabolites are formed in amounts that vary among individuals,[12] but for most, their clinical role has not been determined. One of the metabolites of quinidine, 3-hydroxyquinidine, has been shown to possess antiarrhythmic activity when administered to humans.[12] Experimental data indicate some contribution by metabolites of quinidine to its antiarrhythmic action.[13-15]

Marked prolongation of the QT interval has been seen in some patients receiving low or usual dosages of quinidine, and the risk of torsades de pointes is markedly increased. This arrhythmia may be responsible for most cases of quinidine syncope, which occurs in as many as 5% to 10% of patients within the first days of quinidine treatment, and for quinidine-induced sudden death.[16] Torsades de pointes usually occurs in patients (females more than males) with low serum concentrations of quinidine, hypokalemia, poor ventricular function, and bradycardia.[16,17] In a study by Drici and colleagues, dihydrotestosterone reduced the sensitivity to the effects of quinidine on the QT interval in animals.[18] This study[18] and subsequent studies,[19,20] in which women were shown to be more sensitive to the effects of quinidine on the QT interval, provide evidence that sex hormones have direct effects on cardiac tissue that may be responsible for the difference in baseline QT interval[21] and the incidence of torsades de pointes in men and women.[17,22]

For patients who develop torsades de pointes, treatment with pacing or isoproterenol is very effective. Magnesium sulfate injection (2 g IV bolus with 2 to 4 g repeated once, if necessary) is often recommended as initial therapy for torsades de pointes, although controlled trials are not available. These measures should also include correction of hypokalemia (to levels >4.0 mEq/L). Clinically, it is essential to distinguish torsades de pointes from polymorphic ventricular tachycardia occurring in the setting of a normal QT interval, because the latter should be treated with local anesthetic antiarrhythmic drugs and may be worsened by the above treatment for torsades de pointes.

Because quinidine acts via α-adrenergic blockade to produce vasodilatation,[23] hypotension may occur, especially in patients concomitantly receiving nitrates or other vasodilators. Other adverse effects include a high incidence of diarrhea and vomiting, tinnitus at high plasma levels, rare thrombocytopenia,[24] and, in unusual cases, conduction block in patients with existing conduction system disease.[25] In patients treated with quinidine for atrial flutter without prior atrioventricular (AV) nodal blockade by digitalis, there have been reports of sudden increases in AV conduction and rapid ventricular rates.[23] This results from a slight reduction of the flutter rate and enhanced AV nodal conduction due to the anticholinergic effects of quinidine. This permits 1:1 conduction through the AV node, often at 200 to 250 beats per minute. This may be of particular concern for patients receiving other drugs that increase conduction time through the AV node, such as β-adrenergic agonists.

Individualization of Dosage

Quinidine therapy (as the sulfate) is usually initiated with an oral dosage of 200 mg every 6 hours, and the dosage is titrated every 3 or more days. Elderly patients often require lower dosages of quinidine because of both reduced clearance and volume of distribution.

Quinidine is available commercially in at least three different forms: quinidine sulfate, gluconate, and polygalacturonate. Because the quinidine content varies among these at 83%, 62%, and 60%, respectively, the need for dosage adjustment should be considered if one form is substituted for another. The usually effective dosage of quinidine sulfate ranges from 800 to 2400 mg/day, with the maximum recommended single dose being 600 mg. Because the half-life varies from 3 to 19 hours, one should wait 4 days between dosage increases to prevent unexpected drug accumulation. The range of therapeutic plasma concentrations measured using assays that differentiate quinidine from its metabolites is 0.7 to 5.5 mcg/mL.[26,27] Rapid escalation in quinidine dosage has been used to convert atrial fibrillation, but this therapy is no longer recommended because of unacceptable toxicity.

Intravenous therapy with quinidine is usually avoided if alternatives are feasible. Vasodilation and hypotension result from quinidine-induced α-adrenergic blockade. If quinidine is administered intravenously (as quinidine gluconate), the patient's blood pressure should be monitored and the infusion rate should be no greater than 16 mg/minute. The infusion should be discontinued if hypotension is observed or the QRS is prolonged by more than 30%.

Modification of Dosage in Disease States

No adjustment in initial dosage is usually needed for patients with renal or hepatic disease,[28,29] although due to decreased protein binding in patients with hepatic failure, lower-than-usual total plasma concentration can produce toxicity.[30] Slower dose titration is advisable to permit attainment of steady state and complete accumulation of active metabolites; however, because the usual range of effective dosages is wide, dosage for these patients is not markedly different. Patients with rapid quinidine elimination may require higher dosages (up to 600 mg every 6 hours). This is often due to induction of hepatic metabolism caused by other drugs.

Patients with congenital long-QT syndrome, hypokalemia, or a history of torsades de pointes[31] should not be administered quinidine because of their increased risk for this form of proarrhythmic event. For patients with congestive heart failure, problems associated with use of quinidine are proarrhythmia and digitalis (either digitoxin or digoxin) toxicity. Prudent use of quinidine in individuals taking digitalis requires that (1) titration begin at a reduced dosage; (2) dosage of any cardiac glycoside being administered concomitantly be reduced; and (3) plasma electrolyte levels, especially potassium, be maintained above 4 mEq/L.

Although quinidine does possess some direct negative inotropic effects, these are usually counteracted by its vasodilatory effect; therefore, oral quinidine is well tolerated hemodynamically when administered at dosages producing usual plasma concentrations, even in patients with reduced ventricular function.[32] In a study of more than 650 patients, of whom 35% had congestive heart failure, quinidine therapy resulted in no induction or worsening of congestive heart failure.[25] On the other hand, a significant problem for patients with congestive heart failure receiving quinidine therapy is proarrhythmia, with quinidine-induced torsades de pointes

being potentiated in the setting of bradycardia and low serum levels of magnesium or potassium.[33,34]

Drug Interactions

Quinidine metabolism is inhibited by cimetidine[35] and induced by phenytoin, phenobarbital,[36] and rifampicin,[24] with the latter agents leading to reduced, often subtherapeutic, quinidine concentrations. Clinical digoxin toxicity has been described in 20% to 40% of patients receiving quinidine and digoxin concurrently.[35] The magnitude of this interaction is dependent on quinidine dosage, and in some patients it may not appear until the dosage is increased to higher levels.[37,38] The rise in digoxin levels appears with the first dose of quinidine; therefore, it is suggested that digoxin dosage be halved when quinidine therapy is initiated. A similar interaction has been reported for quinidine and digitoxin.

Quinidine is a potent inhibitor of the hepatic cytochrome P450 (CYP) specific for debrisoquine metabolism (CYP2D6),[39,40] although it is not metabolized by this specific CYP isozyme.[41,42] Thus, it may interfere with the biotransformation and actions of pharmacologic agents that are dependent on this cytochrome for their metabolism, which include propafenone, mexiletine, flecainide, metoprolol, timolol, sparteine, and bufuralol.[43] Quinidine worsens neuromuscular blockade in patients with myasthenia gravis[44] and may prolong the effects of succinylcholine.[45]

PROCAINAMIDE

Procainamide is rapidly absorbed and 100% orally bioavailable. About 15% of procainamide is bound to serum proteins. The short half-life of elimination of procainamide of 2 to 4 hours in patients with normal renal function necessitates dosing every 3 to 6 hours. Dosing every 6, 8, or 12 hours is possible with sustained-release preparations, and the frequency depends on the formulation. The varied formulations and their very different dosing requirements often create confusion and can lead to dangerous mistakes in dosing.

Slightly more than one half of the general population are phenotypic rapid acetylators of procainamide and quickly convert it to *N*-acetylprocainamide (NAPA), a metabolite with pure class III antiarrhythmic action.[46] As would be expected, however, the response to one agent does not predict response to the other. When each is administered as the sole agent, the usually effective plasma concentration is 4 to 8 mcg/mL for procainamide and 7 to 15 mcg/mL for NAPA.[46] During oral procainamide therapy, both agents are present in variable amounts, and there is no way to determine readily the contribution of NAPA to arrhythmia suppression under these conditions. Consequently, the usefulness of measuring plasma levels of procainamide during chronic therapy is limited because of this variable hepatic conversion to NAPA. Monitoring plasma concentrations for determination of compliance or prevention of toxicity is feasible and recommended (see later).

Individualization of Dosage

Procainamide is available for either intravenous or oral use. With normal renal and cardiac function, the initial recommended oral maintenance dose is 50 mg/kg/day. Frequent administration is required for oral procainamide, which is inconvenient and makes compliance difficult. Sustained-release forms of procainamide are available, which permit dosing every 6, 8, or 12 hours, depending on the formulation. During chronic therapy, levels of NAPA may accumulate to effective or toxic levels in some individuals, resulting in achievement of maximum pharmacologic effect long after the time procainamide has reached steady state.[46,47] Therefore, the elimination half-life of 2 to 4 hours for procainamide may be misleading as a predictor of time to the occurrence of stable pharmacologic action. Thus, dosage should be initiated at conservative levels, and the patient should be monitored carefully until both procainamide and its metabolite have reached steady state. Patients with ventricular tachycardia may need higher dosages[46] for the prevention of arrhythmia induction by programmed stimulation,[48] although such dosages often lead to adverse effects. Because the electrophysiologic effects of procainamide and NAPA are quite different, monitoring of patients receiving procainamide should at some point include measurement of plasma concentrations of both agents to determine their relative concentrations. Patients who are rapid acetylators or who have impaired renal function usually have plasma concentrations of NAPA higher than procainamide at steady state. These individuals should be monitored for excessive accumulation of NAPA during dose titration to maintain plasma levels of NAPA below 20 mcg/mL. The practice of using the sum of the plasma concentration of procainamide and NAPA is not recommended.

When administered intravenously, procainamide can be administered as a constant 25-minute loading infusion of 275 mcg/min/kg of body weight or in a series of doses (100 mg delivered over 3 minutes) given every 5 minutes, up to a total dose of 1 g.[49,50] If the loading infusion is well tolerated with no hypotension and less than 25% QRS or QT widening, a maintenance intravenous infusion of 20 to 60 mcg/kg/min can then be administered. Larger and more rapid loading infusions of 1 g over 15 to 20 minutes have been administered in the electrophysiology laboratory to prevent induction of ventricular tachycardia by programmed ventricular stimulation. A second loading infusion of 0.5 to 1 g has been administered in some instances where an initial loading infusion was well tolerated but ineffective. These large dosages are accompanied by a higher incidence of hypotension and conduction disturbance and often result in attainment of an unacceptably high plasma concentration.

Modification of Dosage in Disease States

With renal dysfunction or a low cardiac output, both procainamide and NAPA in usual doses may accumulate to potentially toxic levels and the dose should be reduced.[51] Increased plasma levels of procainamide and/or NAPA may occur with congestive heart failure because of decreased urinary excretion and hydrolysis of procainamide.[52] On the other hand, one study of procainamide pharmacokinetics following a single intravenous bolus revealed no difference in volume of distribution, clearance, elimination half-life, unbound drug fraction, and peak procainamide concentrations between patients with congestive heart failure and normal individuals.[53] Although intravenous procainamide does depress myocardial

contractility and lower blood pressure, worsening of heart failure is uncommon during oral therapy when the usual dosages and plasma concentrations are maintained.

Drug Interactions

Unlike quinidine, procainamide does not cause an increase in digoxin levels. There are few reports of interactions between procainamide and other drugs. Its clearance is reduced 30% to 50% by cimetidine, which blocks the renal tubular secretion of procainamide.[54,55] A similar competition has been found between procainamide and its predominant metabolite, NAPA.[56] Ranitidine affects procainamide pharmacokinetics by reducing both its renal clearance and its absorption, the former by 14% to 23% and the latter by 10% to 24%, depending on the dose.[57]

DISOPYRAMIDE

The oral bioavailability of disopyramide is 80% to 90%.[58] Its half-life of elimination, usually 6 to 8 hours, is lengthened to as much as 15 hours in cardiac patients.[59] About one half of the compound is eliminated by the kidneys unchanged, and the remainder as an active metabolite, resulting from hepatic *N*-dealkylation.[60] Protein binding of disopyramide is complex, with 20% to 50% of disopyramide being bound to plasma proteins. For most drugs, the percentage bound to plasma protein is a constant over the usual range of therapeutic concentrations. The saturation of disopyramide-binding sites on plasma proteins at usual doses means that there are disproportionate increases in levels of free drug in plasma compared with the magnitude of dosage increment.[61]

Individualization of Dosage

Loading doses are not recommended with disopyramide because of saturable protein binding. The usually effective dosage for disopyramide is 100 to 400 mg three to four times daily, to a maximal dose of 800 mg daily. Therapy should be titrated, beginning with low doses (100 mg three times daily) and allowing ample time (2 to 4 days) for achievement of steady-state equilibrium.

Although rapid fluctuations in plasma concentration are undesirable, they are difficult to avoid because of the saturable protein binding of disopyramide. The controlled-release form of disopyramide may be useful in reducing adverse effects by decreasing fluctuations in the concentration of free disopyramide in plasma.[62] Because of saturable protein binding,[63] the generally accepted therapeutic range for total disopyramide in plasma of 2 to 5 mcg/mL should not be strictly relied on. Although monitoring of the plasma concentrations of free disopyramide has been recommended,[64] the range of concentrations associated with arrhythmia suppression has not been clearly delineated and overlaps with that causing adverse effects.

Modification of Dosage in Disease States

Patient response to disopyramide should be monitored especially closely after acute myocardial infarction because both the absorption and elimination of disopyramide are decreased at this time.[65] In fact, in view of the negative inotropic actions and changes in levels of binding proteins in plasma after a myocardial infarction associated with disopyramide, other antiarrhythmic agents should be considered first. Disopyramide is contraindicated in patients with uncompensated heart failure because it can worsen failure.[66] The initial dosage of disopyramide should be reduced to 50 to 100 mg every 12 hours in patients with renal insufficiency[67] or decreased hepatic function.[68]

Drug Interactions

Disopyramide does not increase digoxin levels,[69] and the effects of warfarin are not potentiated by disopyramide.[70] Phenytoin, rifampicin, and phenobarbital induce hepatic metabolism (CYP3A4 mediated)[71] of disopyramide, thus increasing its elimination and potentially leading to loss of the antiarrhythmic effect.[72] Significant depression of myocardial contractility may result from the combined administration of disopyramide with β-adrenergic or calcium channel antagonists and should be avoided in patients with impairment of ventricular function.[73]

LIDOCAINE

Orally administered lidocaine is well absorbed, but it has poor oral bioavailability because it undergoes extensive first-pass hepatic metabolism. Lidocaine clearance is well approximated by measurement of the liver blood flow.[74,75] The two desethyl metabolites, which are excreted by the kidneys, have less antiarrhythmic potency than the parent drug and may contribute to the production of central nervous system side effects occurring with lidocaine.[76,77] After intravenous administration, the biphasic disposition of lidocaine is well represented by a two-compartment pharmacokinetic model.[78] Because antiarrhythmic activity is correlated with the concentration of lidocaine in the central compartment and because the half-life of distribution out of this compartment is rapid (8 minutes), regimens that include a series of multiple loading doses and a maintenance infusion should be used to achieve and maintain a therapeutic concentration in plasma and myocardial tissue (see later).

Regardless of the initial regimen used, during prolonged constant infusion, the lidocaine concentration eventually reaches steady state—dependent on drug infusion rate and the clearance of lidocaine. The time required to reach steady-state conditions is approximately 8 to 10 hours in normal individuals and up to 20 to 24 hours in some patients with heart failure and/or liver disease. This is longer than often anticipated because of the failure to recognize the relatively long elimination half-life (1.5 to 2 hours in normal subjects and longer in patients with heart failure or hepatic disease).

Individualization of Dosage

The primary use of lidocaine is for acute rapid suppression of highly symptomatic ventricular arrhythmias. Single intravenous boluses will achieve only transient therapeutic effects because the drug is rapidly distributed out of the plasma and myocardium; therefore, multiple loading doses should be used

to rapidly achieve more sustained therapeutic plasma levels of lidocaine. Based on pharmacokinetic models validated in clinical studies, several regimens have been designed to maintain a relatively constant therapeutic level. For a stable patient, a total loading dose of lidocaine should be approximately 3 to 4 mg/kg body weight administered over 20 to 30 minutes. After injection of an initial dose of 1 mg/kg over 2 minutes, a series of three loading ''boluses'' can be administered slowly (approximately 50 mg each over 2 minutes) at 8 to 10 minutes apart, while the patient is continuously observed for the development of side effects. Loading should be stopped should the transient, usually mild, central nervous system side effects persist or serious unwanted effects occur.

Another effective and well-tolerated loading regimen was suggested by Wyman and coworkers.[79] For a 75-kg person, an initial bolus of 75 mg is recommended, followed by 50 mg every 5 minutes repeated three times to a total dose of 225 mg. This regimen usually achieves and maintains plasma concentrations within usual therapeutic guidelines (1.5 to 5 mcg/mL). A priming dose of 75 mg followed by a loading infusion of 150 mg over 18 minutes has also been used successfully.[80] At the time of initiation of the loading regimen, a maintenance infusion, designed to replace ongoing losses due to drug elimination, should be started. This may be calculated as the product of the desired plasma concentration (about 3 mcg/mL) and the expected clearance. This calculation usually yields a dosage in the range of 20 to 60 mcg/kg/min.

Even in normal individuals, there is great variability in the peak plasma concentration and, consequently, in the calculated size of the central compartment for lidocaine. Therefore, during loading, the patient's electrocardiogram, blood pressure, and mental status should be monitored; the process should be stopped at the first sign of lidocaine excess. When symptomatic arrhythmias persist in the presence of documented adequate dosage, defined by side effects or plasma concentration in excess of 5 to 7 mcg/mL, another agent should be used.

If the maintenance infusion has reached steady state but the concentration is below the level needed to prevent recurrence and the arrhythmia reappears while side effects are absent, the appropriate actions are as follows:

1. Obtain a plasma sample for measurement of the lidocaine concentration for future reference.
2. Administer a small bolus of lidocaine (25 to 50 mg over 2 minutes).
3. Increase the maintenance infusion rate proportionally.

The plasma concentration can be used to estimate clearance for calculation of the final maintenance infusion (i.e., maintenance dosage equals clearance multiplied by the desired plasma concentration, and clearance equals infusion rate divided by the plasma concentration measured at steady state). Little therapeutic effect is evident at lidocaine plasma concentrations below 1.5 mcg/mL, whereas the risk of toxicity increases above 5 mcg/mL. In some patients, however, concentrations in the range of 5 to 9 mcg/mL may be required for arrhythmia suppression and can safely be achieved with cautious drug administration (e.g., monitoring for signs of neurologic toxicity from lidocaine).[81]

Once steady-state conditions have been achieved, simply terminating a lidocaine infusion will result in a gradual decline in plasma levels over the next 8 to 10 hours as elimination occurs. Not only is there no reason to taper lidocaine infusions, but also it may be dangerous if oral antiarrhythmic therapy is initiated too early because unpredictable additive effects may occur between lidocaine and newly started oral therapy. If a patient has reached steady-state equilibrium, it is possible to estimate when the plasma lidocaine concentration will fall below usually therapeutic levels. The plasma lidocaine concentration should be determined at the time the infusion is terminated, and the number of half-lives needed for that level to reach approximately 1.5 mcg/mL can be estimated. The half-life of lidocaine for an individual patient can be estimated from the following equation:

$$t_{1/2} = \frac{\text{plasma concentration} \times V_D \times 0.693}{\text{infusion rate}}$$

where V_D is the final volume of distribution. The measured plasma concentration and the infusion rate are known components of the equation. V_D is usually 1.1 L/kg but may be reduced by 50% or more in patients with heart failure.

Modification of Dosage in Disease States

Initial loading regimens require no adjustment in patients with renal or liver disease[78]; however, maintenance infusions must be decreased in liver disease and heart failure to compensate for decreased clearance. Because clearance alone is altered in liver disease with little change in the volume of distribution, the half-life of elimination is prolonged greatly (as much as 5 hours) and steady-state conditions may not be achieved until 20 to 25 hours after the institution of an intravenous infusion. Despite the fact that lidocaine metabolites are excreted by the kidneys, renal disease has not been reported to exert any significant effect on lidocaine dosing regimens. With mechanical ventilation, there is often a decrease in cardiac output and hepatic blood flow, and a decrease in lidocaine dosage may be required.[82] Patients with congestive heart failure achieve lidocaine levels that are almost double those in normal individuals who are administered the same dose.[78] Because the central volume of distribution is generally halved in heart failure, loading doses should be reduced by 50%. Because clearance is also approximately halved, maintenance doses should be reduced proportionately from an infusion rate of 30 mcg/kg/min used for usual patients to about one half that figure. The time required to achieve steady-state conditions after the institution of a maintenance infusion is still 8 to 10 hours in many patients with heart failure because of concomitant changes in V_D and clearance, resulting in a half-life similar to that seen in patients without heart failure.

General recommendations for initial lidocaine dosage selection should be adjusted for each patient based on clinical presentation, clinical response, and the results of plasma level monitoring. Some patients with congestive heart failure may experience toxicity when given an infusion as low as 0.5 mg/mL, so blood level monitoring is essential for proper dosage adjustment. In postmyocardial infarction patients receiving lidocaine infusions for longer than 24 hours, plasma lidocaine levels can increase and the elimination phase half-life can increase up to 50%.[83] This increase is due, in part, to

changes occurring in protein binding of lidocaine during the first few days of therapy. Assays for plasma lidocaine measure the sum of both protein-bound and free lidocaine as total lidocaine and, thus, do not give a true picture of the amount of free drug available. An increase in plasma lidocaine occurring at this time often reflects an elevation in plasma levels of alpha-1-acid glycoprotein (AAG), to which it binds,[84] and does not always indicate an increase in free, active drug. In this case, the lidocaine dosage should not be reduced to compensate for the higher total plasma concentration—as long as the patient displays no adverse effects. Subsequent decreases in AAG concentrations will result in an apparent decrease in plasma lidocaine, which may reflect a drop in only that fraction bound to AAG.

Drug Interactions

An additive or synergistic depression of myocardial function or conduction may occur when using lidocaine combined with other antiarrhythmic agents,[85] especially during conversion from lidocaine to another antiarrhythmic agent. A pharmacokinetic drug interaction between propranolol and lidocaine has been described experimentally and in humans in which β-adrenergic blockade caused decreases in cardiac output and liver blood flow with a resultant decrease in lidocaine clearance.[86] Cimetidine has been reported to decrease the volume of distribution of lidocaine, to decrease splanchnic (and hence liver) blood flow, and to inhibit the enzymes responsible for lidocaine metabolism. CYP1A2 and CYP3A4 are responsible for most of the hepatic metabolism of lidocaine.[87] This may raise lidocaine plasma concentrations and both loading and maintenance dosages may require downward adjustment by 25% in patients who are receiving cimetidine.[88]

MEXILETINE

The systemic bioavailability of mexiletine approximates 90%,[89] with a large volume of distribution (5.5 to 9.5 L/kg), reflecting extensive tissue uptake. About 1% of total body content of mexiletine is in the plasma compartment, with approximately 70% of this bound to serum proteins. Mexiletine has little first-pass metabolism but is eliminated primarily by hepatic metabolism, with only 10% to 15% being excreted unchanged in the urine. Its half-life of elimination is between 8 and 20 hours (9 and 12 hours for healthy subjects), with the time needed to reach steady state ranging from 1 to 3 days.[90] Mexiletine undergoes extensive hepatic metabolism by CYP2D6,[91-93] and, consequently, clearance is extremely variable (see later).[94]

Individualization of Dosage

Mexiletine therapy should be initiated with a low dosage, which is increased at 2- to 3-day intervals until efficacy or intolerable side effects such as tremor or other central nervous system symptoms develop. With normal renal function, the recommended initial oral mexiletine dosage is 200 mg every 8 hours. As with most drugs having extensive liver metabolism, clearance will be widely variable within the population. This is especially true for mexiletine because CYP2D6, responsible for its metabolism, is absent in 7% of the white population. Also, consideration of dosage adjustment to compensate for the action of agents (discussed later) that induce or inhibit hepatic mexiletine metabolism is required.

Modification of Dosage in Disease States

Patients with renal failure who also inherit a deficiency of hepatic CYP2D6 are likely to have extremely slow elimination for mexiletine,[95] and for this reason, all renal failure patients should be administered low initial doses. Elimination half-life and clearance may be prolonged by overt congestive heart failure[96] and hepatic failure,[97] and dosage reduction by 50% is required.

Drug Interactions

The hepatic metabolism of mexiletine can be increased by phenobarbital, phenytoin, or rifampicin, which reduce the half-life of mexiletine, possibly changing an effective dose to an ineffective one. [90,98,99] Conversely, if treatment with an inducing agent is stopped, an effective dose may become toxic.

In one study, mexiletine decreased the clearance and increased the plasma concentrations of theophylline.[100] Quinidine inhibits the CYP2D6 enzyme primarily responsible for metabolic clearance of mexiletine, and the plasma concentration of mexiletine may increase in those individuals who express the enzyme (93% of whites).

PROPAFENONE

Propafenone has a marked structural similarity to propranolol, and studies have shown that propafenone can accumulate during continued administration to levels capable of producing clinically significant β-adrenergic inhibition.[101] Propafenone, like mexiletine and flecainide, is eliminated by a metabolic pathway that has a polymorphic pattern of inheritance. Patients deficient in CYP2D6 activity have very slow elimination of propafenone and fail to form measurable quantities of the potentially active metabolite 5-hydroxypropafenone.[102,103] The accumulation of high concentrations of propafenone leads to significant β-receptor antagonism at both low and high dosages in poor metabolizers of propafenone but only at high dosages in extensive metabolizers.[104] Although metabolic phenotype does not seem to dramatically influence the antiarrhythmic response to propafenone in many patients,[102] it clearly influences the degree of β-blockade occurring during therapy.

Individualization of Dosage

Effective dosages range from 300 to 900 mg daily in two to four divided doses. To prevent unexpected accumulation of pharmacologic action, propafenone dosage should not be changed more frequently than every 3 days; there is slow elimination of the parent drug in poor metabolizers, and there is slow accumulation of the metabolites in extensive metabolizers. Patients with reduced ventricular function, especially those receiving propafenone, should be carefully monitored

for deterioration in ventricular function, which may result from β-adrenergic receptor antagonism and/or the direct negative inotropic effect.[105]

Modification of Dosage in Disease States

Reduced dosages are recommended for patients with hepatic dysfunction but dosage reductions are not required for patients with renal insufficiency.

Drug Interactions

It is very likely that there will be drug interactions between propafenone and other agents that use or inhibit cytochrome CYP2D6 for their metabolism. Such an interaction has been documented already between propafenone and metoprolol[106] and should be expected with timolol, many antidepressants, many neuroleptics, and perhaps other agents. Quinidine, which inhibits this cytochrome, inhibits the formation of 5-hydroxypropafenone in extensive metabolizers[107]; however, the clinical consequence of such inhibition is unknown and difficult to predict. Greater β-blockade occurs after combining quinidine with propafenone therapy because of the resulting higher propafenone concentrations.[108]

FLECAINIDE

The systemic bioavailability of oral flecainide is 90% to 95%,[109] and most of flecainide is metabolized in the liver to compounds that are not pharmacologically active at the concentrations usually found in plasma.[110] Flecainide, like many other antiarrhythmic agents, is metabolized by CYP2D6.[111] Because flecainide is also eliminated by the kidneys to a considerable extent, the enzyme deficiency has little effect on the pharmacokinetics of flecainide. If, however, patients without the enzyme develop renal insufficiency or if renal failure patients are administered a drug that blocks the metabolism of flecainide, extremely high plasma concentrations are likely to occur.[112] A potential advantage of flecainide is its very slow elimination, with a half-life ranging from 7 to 23 hours in normal individuals and tending to be even longer (14 to 26 hours) in patients with cardiac disease, even in the absence of heart failure.[109,113]

Individualization of Dosage

The usual dosage of flecainide for ventricular arrhythmias is 100 to 150 mg every 12 hours in patients without cardiac or renal failure. A total daily dosage of more than 400 mg may sometimes be used under close medical monitoring (see later). It is recommended that patients with supraventricular tachycardia receive 50 mg every 12 hours as a starting dose. The range of therapeutic plasma concentrations of flecainide is reported to be between 200 and 1000 ng/mL, although adverse effects may occur in some patients at concentrations within this range,[114,115] and many patients tolerate concentrations well above this range. To reduce the incidence of adverse effects, flecainide therapy should start with a low dosage that is maintained until steady state has been reached (at least 4 days) and altered relative to clinical response.

Modification of Dosage in Disease States

With cardiac failure, the usual initial dose is 50 to 100 mg every 12 hours. Because 7% of white patients with renal failure will not have the CYP2D6 enzyme and because flecainide is usually eliminated via both metabolism and renal excretion, all patients with renal failure should be administered very low dosages and titrated. Plasma concentration monitoring is essential in patients with renal disease or cardiac or hepatic dysfunction. Any significant reduction in ejection fraction should be expected to lengthen elimination half-life and, hence, the time needed to attain steady-state equilibrium, whereas reductions in clearance may occur in renal or hepatic dysfunction and lead to higher plasma concentrations at steady state.

Drug Interactions

Cimetidine reduces flecainide clearance and prolongs flecainide elimination half-life.[116] Studies in normal volunteers have demonstrated an increase in the plasma concentrations of digoxin and propranolol when flecainide is coadministered.[117,118] Not unexpectedly, propranolol and flecainide have been found to have additive negative inotropic effects. An interaction with amiodarone, resulting in elevation of the plasma flecainide concentration and necessitating reduction of the flecainide dosage, has been described.[119]

SOTALOL

Sotalol blocks cardiac potassium channels (class III antiarrhythmic activity) and also possesses β-adrenergic antagonist activity. Oral bioavailability of sotalol is greater than 90%, and peak concentrations are seen 2.5 to 4 hours after a dose. It is not bound to plasma proteins and is eliminated by the kidneys unchanged, with an elimination half-life of approximately 12 hours. Because of the relatively long half-life and twice-daily dosing regimen, it is recommended that testing for efficacy be conducted near the end of the dosing interval at steady state. Age per se does not influence the pharmacokinetics of sotalol other than that due to the natural decline in renal function that occurs with age.

Individualization of Dosage

Sotalol is available only in oral form in the United States. The recommended initial oral dose of sotalol is 80 mg every 12 hours. In patients with relatively normal renal function, steady state is reached in 2 to 3 days. If evaluation at this dosage indicates a lack of response without evidence of excessive effects on repolarization (QT below 500 milliseconds), the dosage may be increased to 160 mg twice daily and, if necessary, to 240 mg twice daily. Some patients with life-threatening arrhythmias have required dosages of 640 mg daily. Accelerated titration regimens have been used with close monitoring without apparent increased adverse events.[120]

Modification of Dosage in Disease States

Because sotalol is mainly eliminated unchanged in the urine, the dosage must be adjusted for altered renal function.

For patients with a creatinine clearance of greater than 60 mL/minute, the usual dosing interval is every 12 hours. If the creatinine clearance (Cr Cl) is between 30 and 60 mL/minute, the recommended interval between doses is 24 hours. For patients with Cr Cl between 10 and 30 mL/minute, the interval should be every 36 to 48 hours or the usual dose halved and administered every 24 hours. The dosage for patients with Cr Cl below 10 mL/minute should be individualized. Because of the increased risk of proarrhythmia and congestive heart failure, patients with reduced cardiac output should be administered lower doses and monitored for excessive QT prolongation or worsening heart failure carefully.

Drug Interactions

Concomitant use of sotalol with agents that prolong repolarization has the potential to increase the likelihood of torsades de pointes. No pharmacokinetic interactions have been seen with sotalol and/or warfarin, digoxin, cholestyramine, or hydrochlorothiazide. Because of the β-blocking actions of sotalol, it is likely that there would be increased pharmacologic effect if the drug is combined with amiodarone, calcium channel blockers, antihypertensive agents, or antiarrhythmic agents.

AMIODARONE

Amiodarone blocks potassium, sodium and calcium channels and blocks α- and β-adrenergic receptors. It is a highly lipid-soluble compound with extremely variable and complex pharmacokinetics. It is slowly absorbed from the gastrointestinal tract, and bioavailability varies over a fourfold range.[121] Amiodarone is extensively metabolized to desethylamiodarone by CYP3A4,[122] and little, if any, is excreted unchanged in the urine. Concentrations of desethylamiodarone DEA in plasma vary from 0.4 to 2.0 times those of amiodarone during chronic therapy.[123] This metabolite has antiarrhythmic potency equal to or greater than that of amiodarone in in vitro and animal models.[124] Amiodarone is rapidly concentrated in some tissues, including myocardium, but accumulates more slowly in others, such as adipose tissue. It redistributes out of myocardial tissue while still accumulating in adipose and other tissues.[123,125] Until all tissues are saturated, rapid redistribution out of the myocardium may be responsible for early recurrence of arrhythmias after the discontinuation of therapy or rapid reduction of dosage. Because of drug accumulation in tissues, the volume of distribution for amiodarone is very large, 20 to 200 L/kg.[125] After intravenous administration, the measured half-life in plasma is from 4.8 to 68.2 hours,[126] with tissue uptake being the primary factor responsible for the decline in plasma concentration. As tissues become saturated, however, the decline in plasma levels is slow, reflecting mainly elimination and slow redistribution of drug out of adipose and muscle tissues. This leads to slow and extremely variable elimination from plasma, with half-lives ranging from 13 to 103 days at steady state.[125] It is also possible that amiodarone inhibits its own elimination after chronic therapy, contributing to the differences between half-life early in therapy to those after prolonged therapy.

Individualization of Dosage

Without a loading dose regimen, amiodarone requires several weeks to months before producing its antiarrhythmic action. Large intravenous dosages or oral loading dosages can hasten the onset of therapeutic effects. From small prospective studies, loading dosages have varied from 600 to 1400 mg daily for 2 to 21 days.[127] Large clinical trials have used a lower loading dose of 600 to 800 mg daily for 14 days.[128,129] Because of relatively rapid redistribution out of myocardial tissue, the dosage should be tapered over a period of several weeks. The usual maintenance dose varies from 200 to 600 mg daily, and because of the severe nature of adverse reactions, the lowest effective dosage should be prescribed. Patients with supraventricular arrhythmias may respond to lower dosages than those with ventricular arrhythmias, but there are many exceptions. Because of the variable pharmacokinetics and oral bioavailability, generalizations such as this may be unreliable. Some patients with extensive absorption (about 80% to 90% bioavailability) of even low doses may have the same drug exposure as a person with limited bioavailability given a high dose.

For intravenous administration, the manufacturer recommends a three-phase infusion over the first 24 hours: 150 mg over 10 minutes, followed by 360 mg over the next 6 hours, followed by 0.5 mg/minute. The drug can be continued at this rate, but monitoring of plasma concentrations is recommended. An additional 150 mg can be infused over 10 minutes for those patients who continue to have recurrent ventricular tachycardia or fibrillation or whose arrhythmia recurs during downward titration of the infusion. Concentrations of drug greater than 3 mg/mL should be infused through a central catheter to prevent phlebitis. Also, the surfactant properties of the drug alter the size of a drop of infusate, and pumps that count drops will give approximately 30% less drug than intended.

Amiodarone concentrations are usually between 1 and 2 mcg/mL during effective oral therapy.[130,131] Similar concentrations of desethylamiodarone accumulate during therapy and, although this is not proved, they are likely to contribute to antiarrhythmic efficacy. Because of extensive overlap between the range of concentrations required for arrhythmia suppression and those associated with toxicity, monitoring of plasma concentrations is of limited value. Clearly, levels of amiodarone above 3 to 4 mcg/mL for prolonged periods of time are associated with a higher incidence of adverse effects.[132]

Modification of Dosage in Disease States

Long-term oral therapy with amiodarone appears to be well tolerated hemodynamically in patients with congestive heart failure. In the Veteran's Administration trial cited, amiodarone failed to prolong life for congestive heart failure patients with arrhythmias but was associated with improved ventricular function as measured by radionuclide ejection fraction.[128]

Drug Interactions

Amiodarone interferes with the clearance of many drugs. This may involve the formation of a metabolically inactive CYP Fe (II)/metabolite complex, which has been described in animals treated with amiodarone,[133] and may explain the

reduced metabolism and unexpected accumulation of warfarin,[134] quinidine, procainamide, disopyramide, mexiletine, and propafenone[135] and the resulting bleeding, heart block, or torsades de pointes.[122,136] It does not, however, explain interaction with drugs eliminated predominantly by the kidneys, such as digoxin.[137] The elimination of other drugs may be impaired by amiodarone, and the lowest effective dosage should be sought.

IBUTILIDE

Ibutilide is available only for intravenous administration. When given over 10 minutes, it distributes rapidly in a multiexponential fashion, with the relevant component having a half-life of 2 to 12 hours (mean of 6 hours). The plasma concentration and pharmacokinetics are highly variable, and dosing is recommended on the basis of weight. The drug is mainly eliminated by oxidative hepatic metabolism, and systemic clearance is rapid (about 29 mL/minute/kg). Because formal drug interaction studies have not been performed, it is not possible to anticipate which enzymes are likely responsible for its elimination.

Individualization of Dosage

Ibutilide is administered undiluted or diluted in saline as an infusion over 10 minutes. The recommended dose is 1 mg for a patient of more than 60 kg and 0.01 mg/kg for a patient less than 60 kg. For patients whose arrhythmias have not converted by 10 minutes after completion of the first dose, a second dose of equal size can be administered. Because conversion of the arrhythmias is usually associated with peak levels, slower infusion rates are not likely to be as effective.

Because of a relatively high risk of torsades de pointes, it is essential that patients who receive ibutilide are treated in a carefully monitored environment during and at least 4 hours subsequent to treatment. The U.S. Food and Drug Administration-approved labeling recommends that skilled personnel, facilities, and medication for defibrillation or resuscitation must be readily available. Although well-controlled studies are not available, retrospective analyses indicate that pretreatment with magnesium sulfate can reduce the 3% to 4% incidence of torsades de pointes by 20% to 30%.[138]

Modification of Dosage in Disease States

Although specific studies with heart failure and renal or hepatic disease have not been conducted, current information does not indicate that any dosage adjustments should be necessary in these conditions. Patients with severe left ventricular dysfunction, however, have a higher risk of developing ventricular arrhythmias, including torsades de pointes. Because the duration of drug effect is determined by distribution, it is possible that patients with severe congestive heart failure will have decreased volumes of distribution and, hence, an exaggerated and prolonged duration of effect.

Drug Interactions

No specific drug interaction studies have been performed. Concomitant β-receptor or calcium channel antagonists apparently do not interact, although data are limited. The manufacturer's labeling warns against combining ibutilide with other drugs that prolong the QT interval. During the development of ibutilide, these drugs were discontinued for at least five half-lives prior to administration of ibutilide and were not allowed until at least 4 hours after administration.

DOFETILIDE

Dofetilide is well absorbed after oral administration and is partially metabolized by CYP3A4[139] to inactive metabolites and excreted predominantly in urine. In most patients, the elimination half-life ranges from 8 to 10 hours, but in patients with renal failure, the elimination half-life is prolonged and clearance is reduced. Dofetilide is susceptible to several drug interactions because it is metabolized by CYP3A4 (see later). It is likely that these interactions increase the risk of torsades de pointes.

Individualization of Dosage

The recommended dosage of dofetilide is 0.5 mg twice daily. Lower dosages are recommended for patients who develop excessive corrected QT interval prolongation on 0.5 mg twice daily. In the largest clinical trial, "excessive" was defined as longer than 550 milliseconds or more than 20% longer than baseline.

Modification of Dosage in Disease States

Dosage should be reduced in patients with renal disease (0.25 mg twice daily for creatinine clearance 60 to 40 mL/minute and 0.25 mg daily for creatinine clearance 40 to 20 mL/minute). Data are not available for adjustment of dosage in patients with liver disease. It is not clear whether the greater risk of torsades de pointes in women is influenced by a pharmacokinetic difference between the sexes.

Drug Interactions

The concomitant administration of dofetilide with verapamil, ketoconazole, or cimetidine (but not ranitidine) results in increased plasma concentrations of dofetilide, especially in patients with reduced renal function.[136,140] Because it is known to be a substrate for CYP3A4, there may be other important interactions with erythromycin, other macrolides, or antifungals. No interactions have been seen between dofetilide and digoxin or warfarin.

ADENOSINE

After intravenous injection, adenosine is rapidly transported into red blood cells and endothelial cells. A half-life of elimination has ranged from 1.5 to 10 seconds. The drug is rapidly metabolized in the plasma and in cells to form inosine and adenosine monophosphate. Maximal pharmacologic effects are seen within 30 seconds after injection into a peripheral intravenous line but occur within 10 to 20 seconds when administered into a central line.

Individualization of Dosage

Adenosine should be injected intravenously into a proximal tubing site and flushed quickly with saline. For adults, the initial dose is 6 mg injected over 1 to 2 seconds. If the arrhythmia persists, a 12-mg dose can be injected 1 to 2 minutes later. This can be repeated, but doses larger than 12 mg are not recommended by the manufacturer. A dosage regimen based on body weight has been proposed, with an initial dose of 50 mcg/kg incremented by 50 mcg/kg until the PSVT is terminated or side effects become intolerable.[141] Higher doses may be required for patients who have received caffeine or theophylline because of their antagonistic effects at α_1-receptors. Lower doses are recommended if the patients are receiving dipyridamole or carbamazepine.

Modification of Dosage in Disease States

Although the pharmacokinetics of adenosine are unlikely to be altered in patients with renal or hepatic disease, these patients often have electrolyte imbalances that could alter the clinical response. Although patients with congestive heart failure have not been reported to respond abnormally, heart transplant recipients appear to require one third to one fifth of the usual dose due to denervation hypersensitivity.[142]

Drug Interactions

There are several proven interactions that can increase or decrease the activity of adenosine. Dipyridamole pretreatment increases the potency of adenosine, probably because it blocks cellular uptake of adenosine.[143] Caffeine and theophylline antagonize the actions of adenosine.[144] The manufacturer cautions that carbamazepine may potentiate the actions of adenosine.

Chapter 20

Nonpharmacologic Treatment of Tachyarrhythmias

David J. Callans and Jason T. Jacobson

CHAPTER CONTENTS

The primacy of antiarrhythmic drug therapy for the treatment of many types of tachyarrhythmias has been challenged on several fronts. First, there is increasing fear of the potential for life-threatening complications of pharmacologic therapy, particularly in patients with structural heart disease. The Cardiac Arrhythmia Suppression Trial (CAST) showed that patients treated with flecainide and encainide encountered a threefold excess mortality risk compared with placebo, despite a reduction of ambient ectopy.[1] A nonrandomized, retrospective analysis of the Stroke Prevention in Atrial Fibrillation (SPAF) Trial[2] demonstrated that patients treated with antiarrhythmic agents for atrial fibrillation had a 2.6-fold increased risk of arrhythmic death; this excess risk was borne almost entirely by patients with a history of symptomatic heart failure. Although unusual (<1%), proarrhythmia in the form of torsades de pointes can complicate therapy with drugs that prolong cardiac repolarization, even in the absence of structural heart disease.[3] An analysis of case-specific mortality in the AFFIRM trial population showed an increased risk of noncardiovascular death (most notably pulmonary and cancer-related deaths) in patients treated with antiarrhythmic medications versus those in the rate-controlled group, despite similar rates of cardiovascular deaths in both groups.[4] Second, there is a growing appreciation for the "nuisance" side effects of pharmacologic therapy. For example, in the Electrophysiologic Study Versus Electrocardiographic Monitoring (ESVEM) Trial,[5] intolerable side effects resulting in termination of drug therapy ranged from 16% for sotalol to 43% for imipramine; additional patients developed side effects in long-term follow-up, which further limited successful therapy. These side effects add to the frustration felt by both physicians and patients. The requirement of chronic, daily therapy for a paroxysmal disorder is difficult to accept on a conceptual level. Third is the rapid development of nonpharmacologic techniques that have proved to be curative in some arrhythmia syndromes and superior to pharmacologic therapy in many others.

This chapter provides an arrhythmia-specific overview of the available techniques, current efficacy, procedural side effects, and future considerations of nonpharmacologic therapy. Although, broadly speaking, this topic could well include a discussion of surgical ablation and pacing therapy, the predominant focus is on catheter ablation. Discussion of the use of implantable electrical devices for the management of sudden cardiac death is found in Chapter 21.

CATHETER ABLATION FOR THE TREATMENT OF TACHYARRHYTHMIAS

The development of modern catheter-based ablative techniques during the 1980s and 1990s has had a remarkable effect on the treatment of many arrhythmia syndromes. Advances in these techniques have essentially eliminated the need for arrhythmia surgery (except for the treatment of atrial fibrillation), a field that was vigorous in the early 1990s. Still, as outlined later, the results of catheter ablation are syndrome specific. Although catheter ablation is first-line therapy for many paroxysmal supraventricular arrhythmias, it is largely palliative for ventricular tachycardia (VT) in the setting of structural heart disease and in evolution (albeit rapidly progressing) as a method for treatment of atrial fibrillation. Differential success rates, patient preference, and data regarding both the cost and the efficacy of ablation compared with drug therapy are important considerations in determination of the relative role of catheter ablation in specific arrhythmia syndromes.

PRACTICAL CONSIDERATIONS

The general focus of ablation therapy, either surgical or catheter based, involves selective destruction of a "vulnerable parameter" of the tachycardia circuit. Depending on the arrhythmia, this parameter can be identified electrophysiologically or anatomically. Catheter ablation requires positioning of a catheter on the basis of electrical recording and fluoroscopic, echocardiographic, or magnetic resonance imaging information (often in conjunction with three-dimensional electroanatomic mapping systems) to this critical area and the delivery of some form of energy to the tip of the catheter, resulting in focal destruction of the myocardium. Although any energy source could (theoretically) produce this lesion, catheter ablation was revolutionized with the introduction of radiofrequency energy. Catheter ablation was initially performed with direct current electrical energy, which resulted in

irregular, unpredictable lesions and significant side effects, presumably caused by barotrauma.[6]

Radiofrequency energy destroys tissue by resistive heating in the myocardium directly in contact with the distal catheter electrode.[7] Irreversible tissue death occurs at temperatures in excess of 50° C.[8] Radiofrequency lesions are homogeneous and precise, with necrotic centers 5 to 6 mm in diameter and 2 to 3 mm deep, surrounded by a hemorrhagic periphery (Fig. 20–1).[9] Two biophysical considerations fundamentally limit the size of radiofrequency lesions: (1) heat transmission diminishes by distance from the energy source to the fourth power and (2) temperatures at the catheter/myocardial surface interface >100° C lead to coagulum and gas bubble formation, preventing subsequent current delivery. Thus, the primary determinant of success is the ability to define the vulnerable parameter of the arrhythmia to an area smaller than the lesion volume possible with radiofrequency techniques. Although this is a fundamental limitation, the precision required to successfully perform catheter ablation provides an opportunity for greater understanding of the interplay of anatomic and electrophysiologic substrates for arrhythmia.[10] Nevertheless, the development of new energy sources (e.g., laser, microwave, cryoenergy, or focused ultrasound energy) or techniques (e.g., irrigated tip radiofrequency ablation) that allow the production of larger, deeper lesions could prove helpful in select applications, particularly for VT in the setting of healed myocardial infarction.

Figure 20–1 Histology of radiofrequency ablation lesion. The atrioventricular junction is seen (atrial wall is superior, coronary artery is seen in AV groove) with an ablation lesion (*arrow*) at the annulus. Note the homogeneous nature of the lesion. (From Morady F: Radio-frequency ablation as treatment for cardiac arrhythmias. N Engl J Med 1999;340:535.)

REVIEW OF THE SUCCESS OF CATHETER ABLATION BY SPECIFIC ARRHYTHMIA SYNDROME

Catheter ablation therapy is virtually always curative, with low complication rates and low cost for many supraventricular arrhythmias. Catheter-based techniques for other arrhythmias are less successful or are under development.

Catheter Ablation for Supraventricular Tachyarrhythmias

Accessory Pathway-Mediated Tachycardias

Accessory pathways are microscopic muscular bundles that connect the atrium and ventricle, providing a “bypass” of the normal conduction system (Tables 20–1 and 20–2). Manifest pathways (capable of antegrade conduction) are present in the Wolff-Parkinson-White (WPW) syndrome. Concealed pathways are not apparent on the surface electrocardiogram but can still mediate reentry. Most symptomatic arrhythmias in patients with bypass tracts are associated with a narrow QRS complex, that is, orthodromic supraventricular tachycardia (SVT)—conducted antegrade through the atrioventricular (AV) node, retrograde through the bypass tract. However, in patients with WPW syndrome, circus movement tachycardia conducting antegrade down the bypass tract and retrograde up the AV node can occur, as well as rapid accessory pathway conduction during atrial fibrillation, which may lead to cardiac arrest (estimated annual risk, 0.05% to 0.5%[11]).

The target for ablation in accessory pathway-mediated reentry is the accessory pathway itself (Fig. 20–2). The AV node is another vulnerable site, but its ablation may ultimately necessitate pacemaker therapy if antegrade bypass tract conduction fails, a phenomenon that can occur in up to 20% of patients. Accessory pathways can occur at any location around the AV rings except for the aortomitral continuity. Greater than one half of all accessory pathways are found at the left atrial free wall (62%)—the second most frequent location being the posteroseptal space (21%).[12] Right atrial free wall (13%) and anteroseptal (8%) accessory pathways are less frequently observed.[12] Right-sided pathways are ablated via a venous approach, typically at the atrial insertion of the pathway. Left-sided pathways are ablated either via a retro-

Table 20–1 Expected Success Rates for Catheter Ablation (at Referral Centers)

Tachyarrhythmia	Success (%)
Supraventricular Tachycardia	
Accessory pathway mediated	>90
Atrioventricular nodal reentry	>97
Atrial tachycardia	>80
Atrial flutter	>90
Atrial fibrillation	>75
Atrioventricular junction ablation	>97
Ventricular Tachycardia (VT)	
Idiopathic VT	>85
VT in structural heart disease	>70

Table 20–2 Indications for Catheter Ablation

First-Line Therapy in Symptomatic Patients	Potentially Helpful in Patients with Symptoms Despite Pharmacologic Therapy	Clinical Frontier Uses of Catheter Ablation
Accessory pathways	Atrial tachycardia	Polymorphic VT/VF
AV nodal reentry	Atrial fibrillation	Epicardial approach to ablation
Atrial flutter	VT in structural heart disease	
Idiopathic VT	Anatomic ablation of poorly tolerated VT	
	AV junction ablation for rate control of AF	
	Inappropriate sinus tachycardia	

AV, atrioventricular; AF, atrial fibrillation; VF, ventricular fibrillation; VT, ventricular tachycardia.

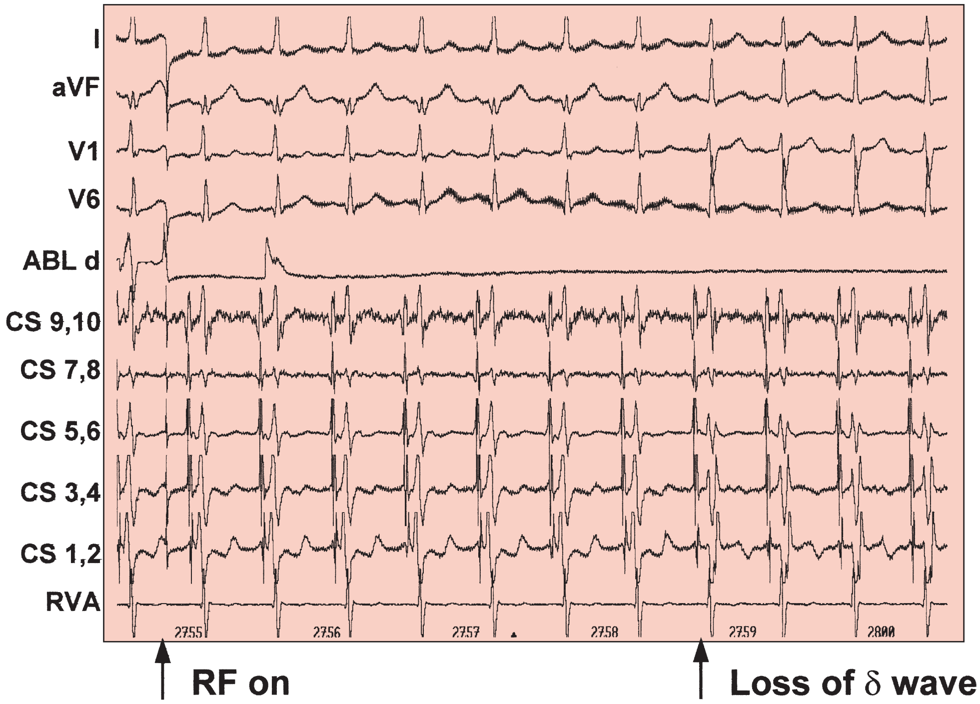

Figure 20–2 Surface ECG (I, aVF, V1, V6) and intracardiac electrograms during ablation of accessory pathway with antegrade conduction. Note the presence of preexcitation and short PR interval on the surface leads on left side of tracing (start of radiofrequency application). After 7 QRS complexes, the PR interval increases and preexcitation (δ wave) is lost. ABL d, distal ablation catheter; CS, coronary sinus catheter; RVA, RV apical catheter.

grade aortic approach or a transseptal approach to the left atrium.[13,14] A small percentage of posterior septal accessory pathways can be successfully ablated with a catheter positioned within the proximal coronary sinus, often within the middle cardiac vein or a venous malformation.[15]

Acute success rates in relatively large published series for accessory pathway ablation during the 1990s range from 71% to 100%.[13,14,16-23] Subsequent multicenter experience reports success rates independent of accessory pathway location of 93% in one study[24] and, in 1998 alone, rates of 97.7% for left-sided pathways and of 94.6% for right-sided pathways.[12] The location-dependent nature of ablation success seems to reflect differential blood flow and catheter/tissue interface contact (both of which influence lesion size),[25] as well as the anatomic complexities of the posteroseptal and anteroseptal regions. The risk of recurrence after acutely successful ablation ranges from 3% to 9%.[13,14,16-23] Recurrence after the initial loss of bypass tract function is believed to be due to temporary "stunning" caused by microvascular perfusion abnormalities in the tissue outside of the isotherm for permanent tissue death.[26] For unsuccessful attempts, the technique of epicardial mapping and ablation (see later) has been applied to persistent accessory pathways.[27] This has allowed for success with ablation from the endocardium, epicardium or both, with the aid of epicardial mapping. Complications of accessory pathway ablation are unusual and appear to be decreasing with operator experience. In the trials cited here, the incidence of major complications was 2.5%.[13,14,16-23] The most common serious complications are inadvertent AV block with paraseptal ablation and nonfatal cardiac tamponade. Thromboembolic stroke can occur with the ablation of left-sided accessory pathways, but the risk is quite low (0.1%) with procedural anticoagulation. Death has been reported with accessory pathway ablation procedures, although its incidence is approximately 0.1%.

Catheter ablation is considered appropriate first-line therapy in patients with symptomatic accessory pathway-mediated arrhythmias, particularly in young patients who want to avoid long-term pharmacologic therapy. The cost efficacy of ablation has been studied in WPW syndrome but not in the setting of concealed accessory pathways. Hogenhuis and coworkers[11] calculated a favorable marginal cost of $6600 per quality-adjusted life year gained for 20-year-old symptomatic patients.

Treatment of asymptomatic patients with incidentally detected accessory pathways is controversial. The lingering concern about the presence of a bypass tract is presentation with atrial fibrillation (which typically occurs following an episode of orthodromic tachycardia), with rapid conduction over the bypass tract causing induction of ventricular fibrillation. Viewed this way, the most important parameter is the anterograde refractory period of the bypass tract. Abrupt disappearance of preexcitation during exercise testing, or disappearance of preexcitation with type I antiarrhythmic drug infusion, identifies an accessory pathway as low risk for causing ventricular fibrillation.[28] If noninvasive testing is inconclusive, invasive testing and prophylactic ablation, if high risk characteristics are confirmed, may be appropriate in individual patients, at least in experienced laboratories.[28,29]

Atrioventricular Nodal Reentry

AV nodal reentry (AVNRT) is the most common paroxysmal supraventricular tachycardia (SVT), and the preferred vulnerable parameter is the slow pathway (Fig. 20–3). Since the development of selective slow pathway ablation strategies in the early 1990s, success rates in published series of ablation of AVNRT have ranged from 97% to 100%, with a risk of heart block of 0% to 1.5%.[22,24,30-32] The success rate in the 1998 North American Society of Pacing and Electrophysiology (NASPE) Registry was 96.2%.[12] The risk of recurrence ranges from 0% to 2%.

Although AVNRT does not cause life-threatening complications, it does cause significant symptoms in many patients. Catheter ablation is safe and highly effective therapy and is widely considered as first-line therapy in highly symptomatic patients. A cost analysis by Cheng and coworkers[33] demonstrated that catheter ablation improved quality-adjusted survival and resulted in cost savings over pharmacologic therapy in symptomatic patients with AVNRT. Alternatively, because this arrhythmia occurs most frequently in young patients, some experts suggest that ablation should be pursued only after the failure of relatively benign pharmacologic therapy such as digitalis or low-dose β-blockers rather than exposing them to a 1% risk of inadvertent heart block requiring life-long pacing therapy. In our experience, however, β-blocker therapy is often poorly tolerated in young patients.

Atrial Tachycardia

The ablation experience for atrial tachycardia is more limited due to the relative infrequency of this arrhythmia and the lack of consistent induction in the electrophysiology laboratory.[34] The vulnerable parameter for atrial tachycardia is the focal site of origin in the atrial myocardium, recognized by the site of earliest atrial activation during tachycardia. Although it was previously believed that atrial tachycardia arose consistently from the right atrium in adults, particularly along the crista terminalis,[34] the frequency and importance (e.g., as a source for focal atrial fibrillation, see later) of left atrial tachycardia are now recognized.

Contemporary series of atrial tachycardia ablation report acute success rates of 80% to 100% with rare complications and a recurrence risk of 0% to 25%.[35-39] The 1998 NASPE Registry reported a success rate of 70.2% and a complication rate of 2.99%.[12] These success rates may overpredict the true efficacy of catheter ablation in this setting for two reasons,

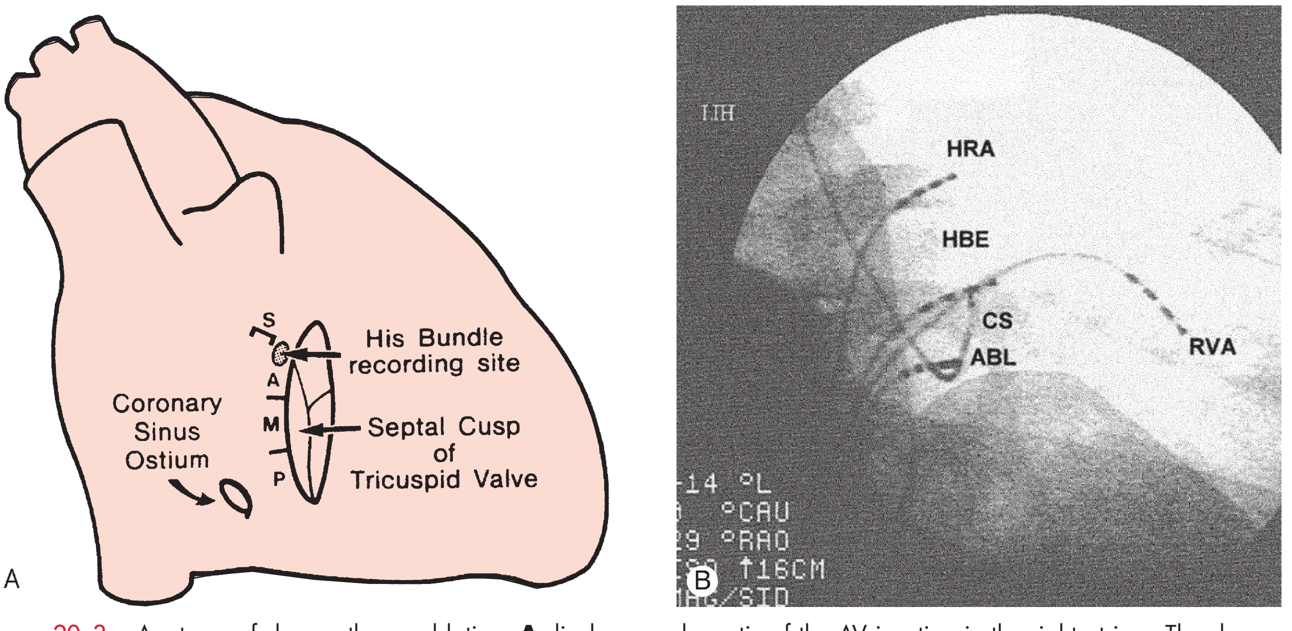

Figure 20–3 Anatomy of slow pathway ablation. **A** displays a schematic of the AV junction in the right atrium. The slow pathway is usually ablated just anterior to the CS ostium, at the posterior septal isthmus. **B** displays the right anterior oblique fluoroscopic view of ablation catheter location. A, anterior septal isthmus; ABL, ablation catheter; CS, coronary sinus catheter; HBE, His bundle catheter; HRA, high right atrial catheter; M, midseptal isthmus; P, posterior septal isthmus; RVA, right ventricular catheter; S, septum. (**A,** Redrawn from Jazayeri MR, Hempe SL, Sra JS, et al: Selective transcatheter ablation of the fast and slow pathways using radiofrequency energy in patients with atrioventricular nodal reentrant tachycardia. Circulation 1992;85:1318-28.)

however. First, these series report the success rate in patients who have uncomplicated diagnostic studies and reproducible atrial tachycardia that can be mapped. A true intention-to-treat analysis would probably show a lower success rate because mapping and ablation cannot be performed without either spontaneous or inducible sustained atrial tachycardia. Second, atrial tachycardia occurring in the setting of repaired congenital heart disease, often relating to the surgical incision, may be much more difficult to approach with catheter ablation. Nevertheless, Kalman and coworkers[40] reported success in 15 of 18 acute patients (21 of 26 tachycardias) with postsurgical "incisional" tachycardia.

Because of the unpredictable nature of atrial tachycardia and the lower degree of procedural efficacy, catheter ablation is typically performed only after pharmacologic therapy is unsuccessful. Primary ablation therapy does not apply to multifocal atrial tachycardia, but this arrhythmia is occasionally treated with AV node ablation (see later).

Inappropriate sinus tachycardia is a nonparoxysmal automatic tachycardia with a P wave consistent with sinus node origin and an exaggerated rate response to endogenous catecholamines.[41] There is limited published experience, which initially suggested that lesions delivered intentionally to the sinus node region may control symptoms in up to 90% of patients[42]; recurrent symptoms are common, however, and often unrelated to rhythm abnormalities. Complications of sinus node modification include symptomatic bradycardia that requires pacing in 10% of patients. Subsequent experience suggests that ablation guided by intracardiac echocardiography may improve safety and efficacy.[43,44]

Atrial Flutter

Typical atrial flutter is caused by macroreentry in the right atrium; the reentrant impulse is anatomically constrained to the narrow "isthmus" of tissue between the tricuspid annulus and the inferior vena cava. This isthmus forms the vulnerable parameter and the target for atrial flutter ablation.[45] Several studies have demonstrated the superiority of an anatomic approach to atrial flutter ablation, reducing recurrence rates from 25% to 5% to 10%.[46-48] In this approach, bidirectional isthmus conduction block is used as an endpoint rather than termination and subsequent inability to induce atrial flutter (Fig. 20–4). Acute success rates in these series were greater than 90%, and complications are rare. The 1998 NASPE Registry reported an acute success rate of 86% with a recurrence rate of 13%.[12] One limitation of ablation for atrial flutter is the high incidence of atrial fibrillation (up to 26%) after successful procedures,[49,50] raising suspicion about the potential proarrhythmic effect of ablation. However, Natale and colleagues[51] performed a randomized trial of primary ablation versus antiarrhythmic therapy for patients with atrial flutter without atrial fibrillation. The ablation strategy not only provided better arrhythmia control and cost less than the pharmacologic strategy, but also provided greater freedom from atrial fibrillation in follow-up. These observations, as well as the high-efficacy and low-risk profile of catheter ablation in this setting, argue that ablation is appropriate first-line therapy for symptomatic patients with atrial flutter.

Atypical atrial flutter (i.e., not cavotricuspid isthmus dependent; especially left atrial flutter) is an entity most

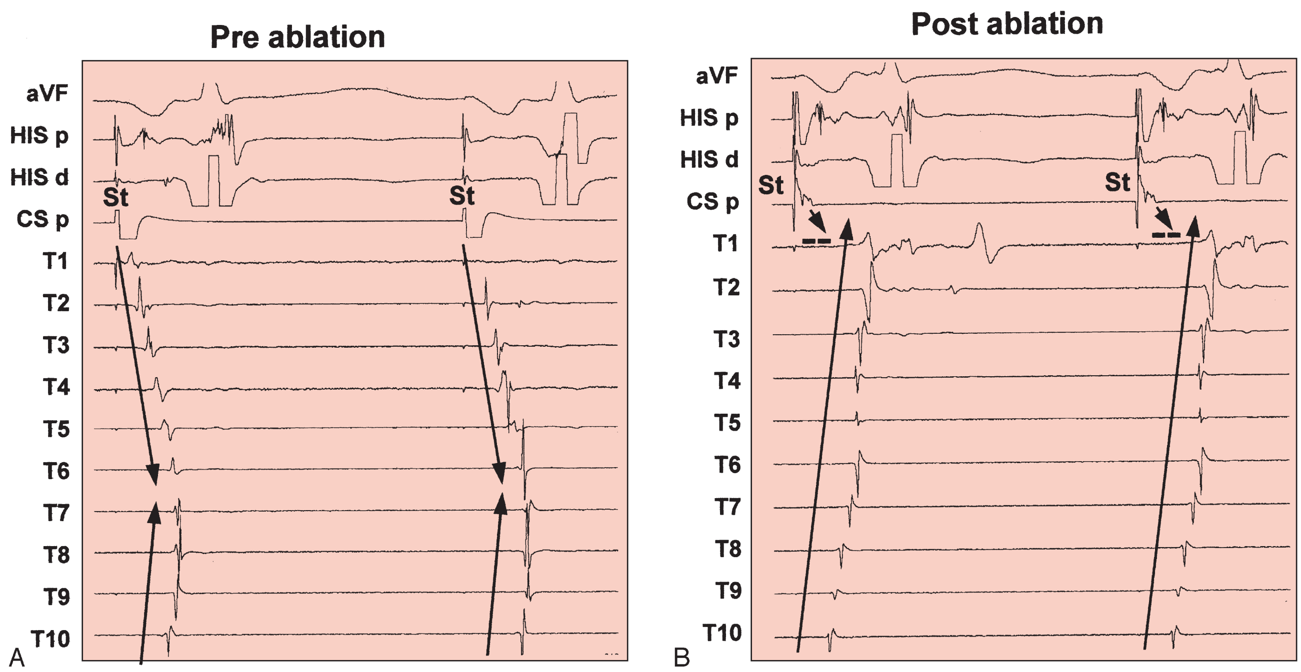

Figure 20–4 Activation sequence around the tricuspid annulus before and after cavotricuspid isthmus ablation for atrial flutter. A circular mapping catheter is placed on the atrial side of the tricuspid valve annulus. T10 is the proximal electrode that sits at the superior annulus; T1 is the distal electrode that sits at the inferolateral annulus. Part **A** shows that during pacing from the coronary sinus (CS) before ablation, activation spreads in two directions around the tricuspid valve (note the "Christmas tree" pattern of activation on the mapping catheter around the TV annulus). After ablation, activation is blocked **(B)** at the ablation line (which is just medial to T1) and spreads in a counterclockwise direction around the annulus (from T10 to T1). aVF, surface ECG lead; CS p, proximal coronary sinus catheter; HIS p and HIS d, proximal and distal His catheter.

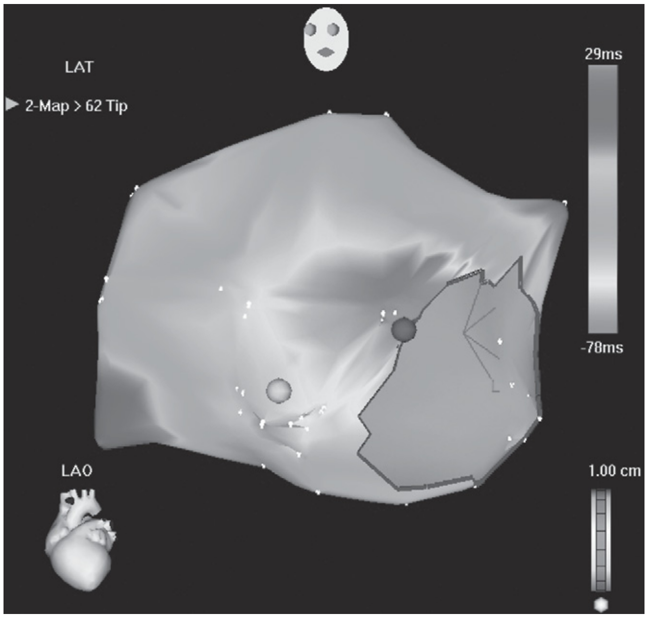

Figure 20–5 (*See also Color Plate 20–5.*) Three-dimensional electroanatomic activation map of atrial tachycardia originating from the mitral annulus. Right anterior oblique view of left atrial map. The earliest activation is indicated in *red*; latest in *purple*. Radiofrequency ablation terminated this tachycardia with one application (*red dot*). The *yellow dot* is the location of the His bundle in the right atrium.

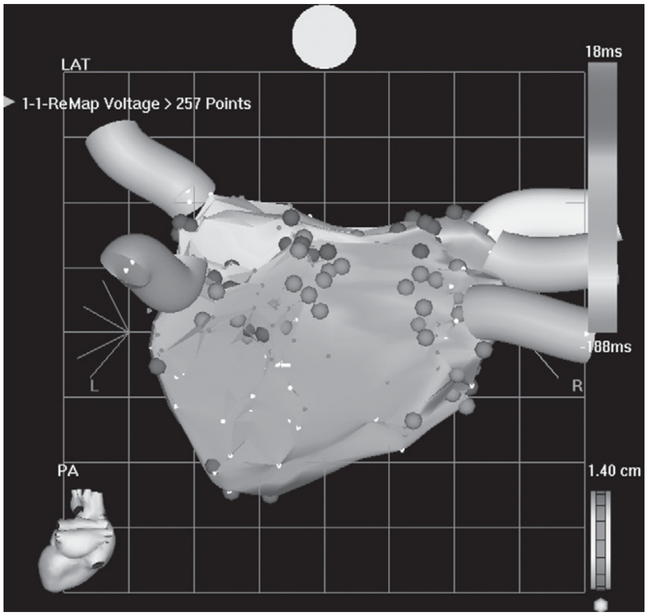

Figure 20–6 (*See also Color Plate 20–6.*) Segmental pulmonary vein isolation. An electroanatomic map of the left atrium is shown in a posteroanterior view. The left superior and inferior pulmonary veins are indicated in *purple and blue on the left;* the right superior, middle, and inferior pulmonary veins are indicated in *yellow, pink, and orange on the right.* The *red dots* indicate full power radiofrequency (RF) applications, whereas the *pink dots* indicate low power, short duration RF applications near the esophagus.

frequently seen in patients with atrial scarring, either due to coexisting structural heart disease or after cardiac surgery.[52] A more contemporary etiology of left atrial flutter is prior ablative therapy of atrial fibrillation (see later).[53-55] Using a transseptal approach and modern mapping systems (Fig. 20–5), many of these arrhythmias can be successfully ablated.[52,55]

Atrial Fibrillation

Since the realization that atrial fibrillation is often initiated by ectopic depolarizations originating in the pulmonary veins near their attachment with the left atrium,[56] the evolution of ablation for the treatment of this ubiquitous arrhythmia has been rapid and significant. Throughout the discovery process, a conceptual debate has raged over what the target of ablation should be.

"Trigger ablation" refers to the procedure that targets the atrial ectopic foci that fire during the atria's vulnerable period (i.e., heterogeneous repolarization), leading to atrial fibrillation. The entity of focal atrial fibrillation is a syndrome of frequent paroxysms of atrial fibrillation in young patients without structural heart disease; this syndrome is "triggered" by rapid but uniform atrial tachycardia.[57,58] Atrial triggers for focal atrial fibrillation are most often located within the pulmonary veins and have been successfully ablated there,[56,58] but other smooth left atrial sites, the crista terminalis, Eustachian ridge, and superior vena cava, have also been implicated. Pulmonary vein ablation has evolved from a technique aimed at ablating the site of focal discharge from within the vein to the electrical isolation of the vein just outside its ostium. This has been necessitated by the development of pulmonary vein stenosis after ablation within the vein and also by the conceptual risk of leaving behind potentially arrhythmic proximal pulmonary venous tissue.[59-61] Isolation of the veins is usually achieved by ablating a segment of the ostium (Fig. 20–6)[62,63] without totally encircling it, thereby minimizing the risk of stenosis. Ablation lesions are created encircling the pulmonary vein until it has been electrically isolated.

"Substrate ablation" refers to targeting the atrial muscle that is responsible for the maintenance of atrial fibrillation after initiation by an ectopic beat. The area felt to be most important as a substrate is the posterior left atrium, demarcated by the pulmonary vein ostia. The creation of wide, encircling RF lesions around the pulmonary veins (wide area catheter ablation) not only blocks the initiating ectopic beats but also appears to modify the substrate.[54,64,65] With this approach, electrical isolation of the pulmonary veins is not the goal and is not frequently achieved. Another approach aimed at modifying the substrate for AF has been proposed by Nadamanee and colleagues.[66] This technique involves mapping both atria in search of complex fractionated (multipeaked or continuous) electrograms that are believed to be the "anchor points" for the wavelets that drive AF. These investigators found these electrograms in nine areas throughout both atria and report a success rate comparable with both segmental pulmonary vein isolation and wide area catheter ablation. Finally, mapping of the intrinsic cardiac nervous system and targeting of ablation lesions to modify vagal effects on the atrium have also been suggested.[67,68]

Despite different approaches to the ablation of AF, success rates seem comparable among all techniques (85% to 91%

freedom from symptomatic AF with or without antiarrhythmic drugs)[59,65,66,69,70] and randomized comparisons of wide area catheter ablation and pulmonary vein isolation are few and somewhat conflicting.[54,71] Whereas AF ablation was initially reserved for patients with paroxysmal AF with structurally normal hearts, those with persistent AF and concomitant heart disease (e.g., cardiomyopathy, valvular disease, and so on) have also demonstrated benefit from the procedure,[69] although at decreased rates of success. Most patients are considered candidates after initial failure of antiarrhythmic drug therapy. In addition, various series have inconsistent approaches to the need for "adjuvant" antiarrhythmic drug therapy after less than completely successful ablation. It remains to be seen which approach will produce the most benefit for specific subsets of patients.

Results of many studies show efficacy of ablation for control of symptomatic AF, but caution must be exercised when interpreting the data. Most studies report a primary endpoint of symptomatic recurrence of AF and perform limited outpatient monitoring for arrhythmias after ablation. Although the population of patients included in these series are highly symptomatic, it is becoming clear with more intensive monitoring that even symptomatic patients can have frequent episodes of asymptomatic AF, both before and (more frequently) after catheter ablation.[72] This phenomenon was also found by Karch and coworkers[71] in a randomized comparison of pulmonary vein isolation and wide area catheter ablation for the treatment of AF. Despite a significant freedom from symptomatic recurrence in both groups (54% for wide area ablation and 82% for pulmonary vein isolation), 7-day Holter monitoring at 6 months showed atrial tachyarrhythmias in 58% and 34% of patients in each group, respectively. These results suggest that a patient's perception of AF may change after ablation. More importantly, these data caution against discontinuing anticoagulation after ablation in patients who have successful control of their symptoms without the use of extensive monitoring to confirm arrhythmia control.

Ablation in the left atrium carries some risk. In a world survey of AF ablation,[59] Cappato and associates found a 0.94% incidence of CVA/TIA and a 1.63% incidence of pulmonary vein stenosis (about one half of which cases were symptomatic). A dreaded complication first noted by cardiothoracic surgeons performing ablation for AF in the operating room[73] and most recently by electrophysiologists performing percutaneous AF ablation[74] is atrioesophageal fistula. This complication usually manifests 1 to 4 weeks after the procedure and can occur with symptoms of cryptogenic stroke, endocarditis, or hematemesis. Patients may develop systemic air emboli (especially if subjected to esophagoscopy), gastrointestinal bleeding, or mediastinitis. Although the phenomenon itself is extremely rare, the mortality rate is high (50%). Treatment hinges on immediate detection and surgical correction. New intraprocedural imaging techniques, such as intracardiac echocardiography and barium swallow, have been used to attempt to eliminate this complication.

Atrioventricular Junction Ablation for Ventricular Rate Control

There is growing evidence to suggest that uncontrolled ventricular rates during atrial fibrillation frequently cause tachycardia-related myopathy (see Chapter 24).[75] This is of special concern in the presence of preexisting structural heart disease because these patients are at high risk of complications from antiarrhythmic therapy and are less likely to tolerate the negative inotropic effects of AV node-blocking agents. Catheter ablation of the AV junction was the first routinely successful strategy using radiofrequency energy; even in early published series, acute success rates were 98% to 100%.[76,77] In the 1998 NASPE Registry, the acute success rate was 97.6% with a 3% risk of recurrence.[12] Randomized comparisons of ablation with medical therapy demonstrated better symptomatic control and improvement in left ventricular (LV) function in patients with severe symptoms.[78,79] Despite this success, there are two important limitations to AV junction ablation. The first involves the requisite pacemaker dependence for ventricular rate support and the potential complications that result from pacing system failure. In recent years, it has become clear that right ventricular (RV) pacing can be deleterious, especially in patients with compromised LV function. RV pacing produces dyssynchronous ventricular contraction analogous to that seen in patients with left bundle branch block. In response, the PAVE (ACC 2004) study investigated the prophylactic implantation of biventricular pacemakers in patients undergoing AV junction ablation. This study found that patients treated with a biventricular pacemaker performed better on a 6-minute walk test and that LV ejection fraction was preserved, as opposed to a 4.2% decrease in patients treated with RV pacing after ablation.

Catheter Ablation for Ventricular Tachyarrhythmias

Idiopathic Ventricular Tachycardia

There are several distinctive syndromes of VT that occur in patients without structural heart disease that are recognized by their electrocardiographic characteristics: right ventricular (RV) outflow tract VT and idiopathic LV (midseptal) tachycardia (see Tables 20–1 and 20–2). Less commonly, idiopathic VT can arise from other sites in the right or left ventricle. RV outflow tract tachycardia has a left bundle branch block morphology and inferior axis on the 12-lead surface ECG, and usually manifests as salvos of nonsustained VT precipitated by exercise or emotion. It is usually mapped to just below the pulmonary valve on the septal aspect of the RV outflow tract.[80] Series of catheter ablation have demonstrated acute success rates in excess of 85% with low rates of complications,[80-82] although procedure-related death has been reported.[82] One reason for lack of efficacy of RV ablation in some patients with this syndrome is a "mimic" VT with an inferior axis but earlier precordial transition (before V_3), which indicates an LV outflow tract[83] or epicardial origin.[84] LV midseptal VT is distinguished by its right bundle branch block, left superior axis ECG morphology. LV mapping localizes this tachycardia to the inferior aspect of the midseptum; often, Purkinje fiber activation precedes local ventricular activation at the site of origin both in sinus rhythm and during VT.[85] Although the published experience is limited by the relatively infrequent incidence of this arrhythmia, several studies have shown acute success rates of 85% to 100% without procedural complications.[83,84,86] Because of the efficacy of catheter ablation of the two predominant forms of idiopathic VT, as well as its relatively low risk, it is recommended for patients with persistent

symptoms despite drug therapy (typically β-blockers and calcium channel antagonists) or when the individual patient prefers ablation therapy to drug therapy. By extension, although without the support of published experience, catheter ablation may be effective in treating idiopathic VT that does not fit these well-described clinical syndromes.

Ventricular Tachycardia in Patients with Structural Heart Disease

Sustained, monomorphic VT can complicate several forms of heart disease, including coronary heart disease, nonischemic dilated cardiomyopathy, RV dysplasia/cardiomyopathy, and sarcoid heart disease. The most frequent and well-understood anatomic substrate for VT is healed myocardial infarction—in which slow, discontinuous conduction in the surviving border zone of the infarct allows the establishment of stable reentrant circuits.[87] Sites of arrhythmia origin are recognized by low-amplitude, fractionated endocardial electrograms, an electrophysiologic marker for the slow conduction necessary for reentry (Fig. 20–7).[88] Similar endocardial electrograms can guide catheter mapping in other forms of heart disease.[89,90] In RV cardiomyopathy, sarcoid-related cardiomyopathy and idiopathic dilated cardiomyopathy, electrogram abnormalities are typically localized to perivalvular areas; in dilated cardiomyopathy, epicardial electrogram abnormalities sometimes predominate.[91]

Radiofrequency catheter ablation has proved to be modestly effective in a minority of well-selected patients with VT in the setting of healed infarction.[92-94] Several factors limit the success of VT ablation in this setting.[10] First, although patients often have a "dominant," frequently occurring clinical morphology, the anatomic substrate for VT is such that many other morphologies are usually inducible or will develop over time. Even after the successful ablation of a dominant morphology, the VT substrate remains largely unaltered, and VT ablation is not viewed as a curative procedure. Second, the areas critical to the VT circuit are sometimes located deep within infarct scar; radiofrequency lesions are not able to penetrate deeply into scarred myocardium.[9] Newer technologies for energy delivery, such as irrigated radiofrequency, help to overcome this limitation.[95] Third, traditional methods for VT localization require prolonged mapping during VT, a condition that many patients with poor ventricular function cannot tolerate. Largely anatomically directed linear ablation lesion techniques (Fig. 20–8) have proved to be helpful in poorly tolerated, unmappable VT.[96] The prognosis for patients who present with sufficiently frequent VT episodes to be considered for ablation is dismal, most likely reflecting the advanced stage of ischemic cardiomyopathy. Data from ablation series range from 12% to 30% mortality at 36 to 40 months, to 51% at 5 years.[97-99]

With these limitations in mind, the efficacy reported in published trials for VT ablation ranges from 67% to 96%.[92-94,100-102] The 1998 NASPE Registry reported a disappointing success rate of 59%, with an incidence of complications of 3.8%.[12] It is important to remember the highly selected nature of the patient population, estimated at approximately 10% of the total population with sustained VT.[92] An intention-to-treat analysis demonstrated successful ablation of only 58% of patients suspected to be candidates for VT ablation; this success rate rose to 71% after the inclusion of multiple procedures.[94] The risk of these procedures is higher than that in other situations because of the left-sided approach (particularly in the setting of atherosclerotic

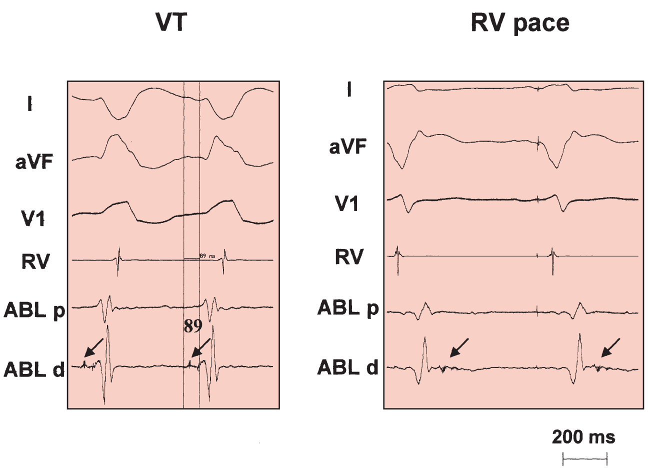

Figure 20–7 Electrogram (EGM) from area of slow conduction in VT circuit. *Left:* Recording during VT. The ablation catheter (ABL d) is in the left ventricle at the exit of the VT circuit. Note a low voltage presystolic deflection that is 89 msec before the onset of the surface QRS and before the larger component of the EGM. *Right:* The same recording site during right ventricular pacing. The larger component of the EGM now precedes the low-voltage deflection, indicating slow conduction into scar during RV pacing. ABL p and ABL d, proximal and distal ablation; EGM I, aVF, V1, surface ECG leads; RV, RV EGM.

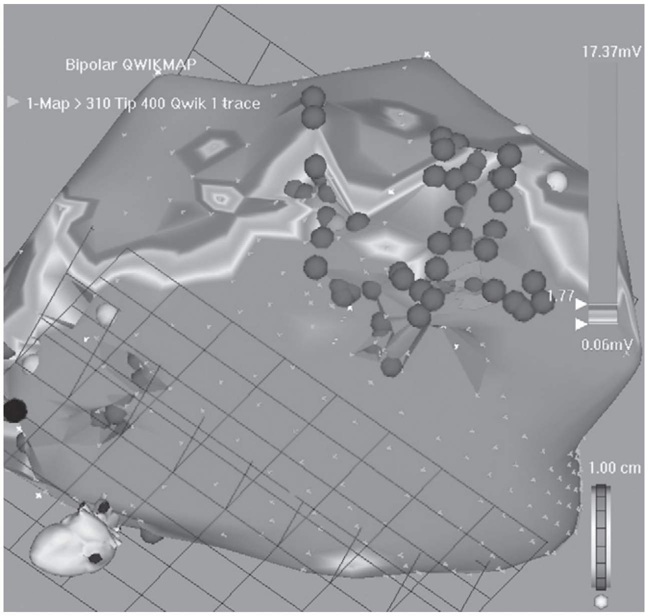

Figure 20–8 (*See also Color Plate 20–8.*) Linear ablation of scar-related ventricular tachycardia. Inferior view of left ventricle. Myocardial scar is displayed in *red* (low voltage). Normal myocardium is displayed in *purple* (normal voltage). Two lines of RF lesions (*red dots*) are seen at the base of the LV, extending from deep within the scar, across the border zone to normal myocardium.

disease) and the general condition of the patients. Serious complications occur in approximately 2% of patients and include stroke and death.[92-94,100-102] Although the VT that was targeted for ablation recurs in fewer than 10% of cases in follow-up, the occurrence of a new VT morphology is likely. For this reason, at present we recommend ICD back-up in all patients who undergo VT ablation.[103]

The patients who appear to benefit most from this procedure are those with incessant VT or who have received multiple defibrillator shocks for relatively slow VT that does not respond to adjuvant antiarrhythmic drug therapy or antitachycardia pacing. Analysis of this strategy showed that it significantly improved patients' quality of life.[104] Some investigators also apply VT ablation as primary therapy to patients who present with well-tolerated VT.[102] In our experience, however, presentation with well-tolerated VT does not predict that recurrent VT episodes will also be tolerated, particularly after ablation.[103,105]

Patients with nonischemic dilated cardiomyopathy and VT may also benefit from radiofrequency ablation.[91,106] Whereas most VT in these patients is reentrant in etiology, bundle branch/fascicular and focal VT may also occur.[91,107] Bundle branch reentrant (BBR) VT uses the left and the right bundle branches in a circuit that can be easily treated by ablation of the right bundle branch.[108] Although BBR VT is seen in patients with dilated cardiomyopathy, intramyocardial reentrant VT is the predominant form in this population. The methods of ablation used for patients with VT in the setting of healed infarction have been applied to VT in dilated cardiomyopathy with similar (albeit somewhat lower) success.[91,106] Some of these patients may have VT circuits or foci that are located on the epicardial surface of the heart, and with a technique recently described by Sosa and colleagues[109] to access the pericardium percutaneously, these VT may be successfully ablated in the electrophysiology laboratory.[91] Despite these advances, ablation is considered as adjuvant therapy to ICD therapy in patients with VT in the setting of structural heart disease.

Ventricular Fibrillation and Polymorphic Ventricular Tachycardia

Due in part to the success of ablation for atrial fibrillation, the trigger hypothesis of arrhythmia initiation has been applied to the treatment of ventricular fibrillation (VF) with ablative techniques. Selected patients with VF and polymorphic VT (PMVT) due to varied etiologies such as Brugada syndrome and long QT syndrome,[110] post-infarction,[111] and idiopathic VF[112] have achieved control of VF by mapping and ablation of the triggering premature ventricular beats that initiate their tachyarrhythmia. These premature beats most often originate from the Purkinje system, but may also arise from the right ventricular outflow tract.[110,111,112] The literature is limited to case reports and case series at this time and, therefore, ICD implantation remains the preferred therapy—whereas ablation can be considered in patients with frequent ICD shocks in the setting of uncontrolled arrhythmia.

SUMMARY

Developments in nonpharmacologic therapy have eclipsed the results possible with antiarrhythmic drugs in many arrhythmia syndromes. Catheter ablation therapy is highly effective in a variety of supraventricular arrhythmias. Extension of this success to the majority of patients with VT and VF, particularly in the setting of structural heart disease, awaits technologic enhancements as well as improvements in understanding of the arrhythmia substrate.

Chapter 21

The Role of Implantable Cardioverter-Defibrillators in Primary and Secondary Prevention of Sudden Cardiac Death

Rishi Arora, Daniel R. Frisch, and Alan H. Kadish

CHAPTER CONTENTS

SUDDEN CARDIAC DEATH—THE SCOPE OF THE PROBLEM

Sudden cardiac death (SCD) causes more than 400,000 deaths annually in the United States and accounts for more than one half of all deaths from coronary artery disease.[1] SCD has been defined as sudden, unexpected death from a cardiac cause within a short time period (≤1 hour) after the onset of cardiac symptoms, or as death from a cardiac cause occurring outside of a hospital, in an emergency department, or on arrival to a hospital. Approximately two thirds of these deaths occur in the out-of-hospital setting, with the vast majority of these deaths considered to be the result of a ventricular tachyarrhythmia.[2]

Of concern is the fact that despite a decline in overall cardiovascular disease mortality over the last decade, the proportion of cardiac deaths attributable to SCD continues to rise.[1] Such a trend is believed to, at least partially, reflect the increased prevalence of heart disease and its risk factors in the U.S. population and improvement in the care of other cardiac conditions. Given that SCD claims more lives every year than AIDS, breast cancer, lung cancer, and stroke combined, serious attempts have been made over the last 2 decades as part of a major public health initiative to identify and treat populations at risk for SCD. To date, attempts to reduce rates of SCD have focused primarily on patients with coronary heart disease (CHD) and left ventricular dysfunction because these patients are known to have high rates of arrhythmias and SCD. However, a major limitation of currently available high-risk markers of SCD (such as CHD and left ventricular dysfunction) is that they can be used to identify only a small percentage of at-risk patients. The majority of patients who succumb to SCD do not belong to any currently defined high-risk category (Fig. 21–1),[3] as defined by the presence of coronary artery disease, reduced left ventricular systolic function, congestive heart failure, or earlier cardiac arrest.

The survival of a patient with SCD due to ventricular fibrillation is critically dependent on the time to defibrillation,[4,5] with greatest survival rates being seen with successful defibrillation within the first 4 minutes of cardiac arrest. Despite dramatic improvements in emergency response services in the industrialized world over the last few decades, it is unfortunate that, depending on the arrhythmia at presentation (i.e., ventricular fibrillation, electromechanical dissociation, or asystole), only 1% to 25% of all patients with SCD survive to discharge after hospitalization.[4] These odds have made the implantable cardioverter-defibrillator (ICD) the preferred approach for secondary, as well as for primary, rescue therapy for SCD. This practice is supported by continued improvement in device technology and multiple clinical trials that demonstrate improved outcomes with an ICD as compared with pharmacologic therapy in patients at risk of sudden cardiac death. Although the ICD does not prevent malignant ventricular arrhythmias, it does reverse them promptly when they occur, with efficacy rates as high as 99%.

ADVANCES IN ICD TECHNOLOGY AND IMPLANTATION TECHNIQUES

ICD technology has come a long way since Mirowski reported the first implantation of an epicardial defibrillator via a thoracotomy in 1980. The majority of such epicardial implants were for high-risk survivors of sudden cardiac death. The introduction of endocardial implantation techniques and transvenous defibrillation leads in the early 1990s made more widespread prophylaxis a reality, as operative morbidity and mortality rates rapidly declined from a 3% mortality risk for epicardial implants to a less than 1% incidence of significant complications for the latest generation of transvenous ICDs.

ICD generators have also decreased significantly in size since the earlier models. First-generation ICD generators were large (160 to 190 cm^3) and heavy (>200 g), necessitating

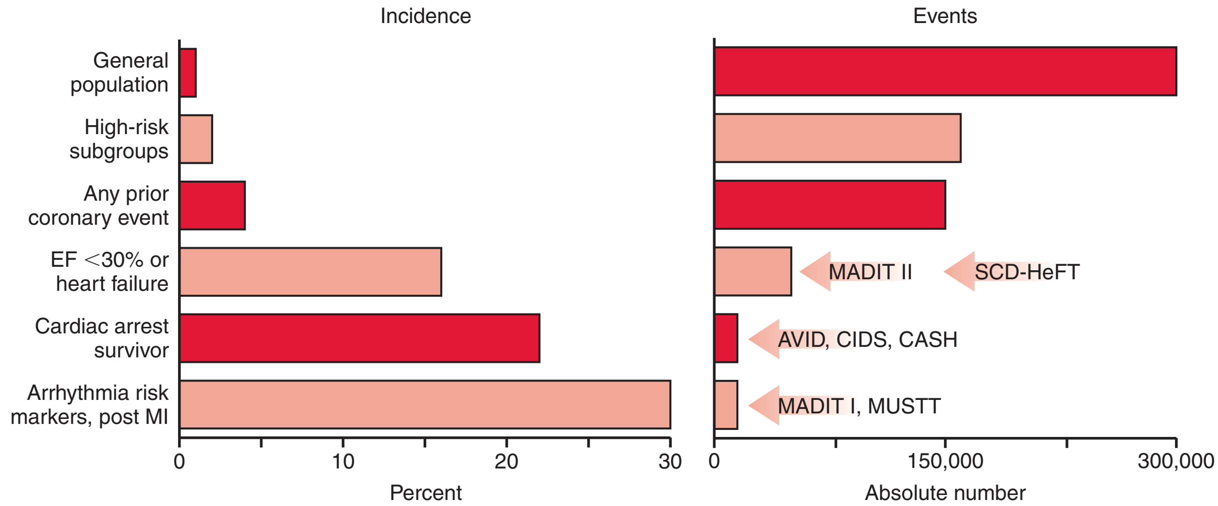

Figure 21–1 Relation between population and subsets, incidence of sudden cardiac death, and total population burden for each group. With increasing incidence, based on subgroup profiling, there is a decreasing proportion of the total sudden death burden. This relates to the population impact of the outcomes of implantable cardioverter-defibrillator (ICD) trials. (From Myerburg RJ, Interian A, Jr, Mitrani RM, et al: Frequency of sudden cardiac death and profiles of risk. Am J Cardiol 1997;80:10F-19).

implantation in the abdominal wall, either subcutaneously or under the rectus muscle. The current generation of devices averages 35 cm^3 and can be implanted in the prepectoral, subcutaneous fascia in most cases.

ICDs originally only delivered shocks to rescue from ventricular tachycardia or ventricular fibrillation. These devices also treat bradycardia with single- and dual-chambered rate-adaptive pacemakers. More contemporary devices also offer concomitant left ventricular pacing (resynchronization therapy). Newer generation devices have added capabilities for transtelephonic interrogation of detection criteria, therapy parameters, and other diagnostic information. Other relatively recent improvements include additional therapies specific for ventricular tachycardia, improved tachycardia discrimination algorithms, antitachycardia and bradycardia pacing, noninvasive programmed stimulation, storage of high rate counters or electrograms, and biphasic waveform shocks.

ICD USE IN SECONDARY PREVENTION OF SCD

The ICD is highly effective in terminating VT/VF and in aborting SCD. Initial uncontrolled studies suggested that an ICD reduced SCD rates to well below those seen in historical controls.[6] These initial uncontrolled observations provided the basis for performing more rigorous, randomized controlled trials to determine the true benefit of an ICD for ssecondary prevention.

Because the ICD would not be expected to reduce death from heart failure or noncardiac causes (but may in effect shift the cause of death from SCD to non-SCD) and because of the potential to misinterpret the mechanisms responsible for apparent sudden deaths, the only valid primary endpoint for such trials was believed to be total mortality. Nonetheless, sudden arrhythmic death remains an important secondary endpoint in such studies, especially because the ICD exerts its beneficial effects on mortality primarily by effective treatment of ventricular tachyarrhythmias.

Three randomized secondary prevention trials (Table 21–1) comparing ICDs with pharmacologic antiarrhythmic agents were reported from 1997 to 2000. There were subtle differences among the studies in the patient entry requirements and treatments assigned in each of these trials (discussed later).

In summary, a significant mortality benefit with an ICD was noted in the Antiarrhythmic Drug Versus Defibrillator (AVID) trial,[7] and nonsignificant trends toward reduced mortality rates with an ICD were noted in the Cardiac Arrest Survival in Hamburg (CASH) and the Canadian Implantable Defibrillator Study (CIDS) trials.[8,9] The latter two trials are believed to have been underpowered to detect a significant difference of the magnitude observed. However, both of these trials were found to have contributed to more deaths when a meta-analysis of all three studies was performed; this was, in part, due to longer follow-up in CASH and CIDS as compared with AVID.[10] Nonetheless, this meta-analysis found a significant 25% reduction in mortality rate with an ICD compared with amiodarone therapy (hazard ratio 0.75, 95% confidence interval [CI] 0.64 to 0.87) that was entirely due to a 50% reduction in sudden death (hazard ratio 0.50, 95% CI 0.34 to 0.62). The absolute reduction in all-cause mortality was 7% at 2 years, meaning that 15 patients needed to be treated to prevent one death. Importantly, subgroup analysis has suggested that some patients who have survived a cardiac arrest, such as those >65 years or with well-preserved left ventricular function, may not have so great a benefit from ICD therapy. Although the data suggesting lower mortality in patients who receive an ICD are clear, there are many patients who experience a cardiac arrest in whom less aggressive medical therapy may be appropriate because of an overall poor prognosis or comorbid conditions.[11]

Table 21–1 Secondary Prevention Trial Outcomes

Trial	Randomized to ICD w/Implant (%)	Receiving Amiodarone (%)	Follow-Up Duration (mo)	2-Yr Mortality Drug Rx (%)	2-Yr Mortality ICD (%)	Hazard Ratio (ICD)
AVID	98	85 (2 yr)*	18	24	15.8	0.73
CIDS	95	80 (3 yr)	36	20.97	14.75	0.70
CASH	100	90 (study duration)	57	22	12	0.61

In Zipes DP, Jalife J (eds): Cardiac Electrophysiology: From Cell to Bedside, 4th ed. Philadelphia, WB Saunders; 2004, pp 901-9).

ICD USE IN PRIMARY PREVENTION OF SUDDEN CARDIAC DEATH

Although ICD implantation for secondary prophylaxis has gained widespread acceptance in the medical community, indications continue to evolve for use of the ICD for primary prevention for SCD. Most of the large-scale studies that have been performed for primary prevention have been in patients with known coronary artery disease with abnormal left ventricular (LV) systolic function, although studies have begun to address patients with nonischemic dilated cardiomyopathy (NIDCM).

Patients with infarct-related cardiomyopathy (IRCM) have been targeted by ICD trials because of the known risk of SCD in this patient population. Acute, as well as chronic ischemic, states are known to be associated with an increased risk of SCD. Evidence for this comes, in part, from the Framingham cohort, in which a history of CHD was found to impart a 3- to 12-fold increase in risk of sudden death, with other conventional CHD risk factors also imparting varying degrees of risk. Beyond the presence of coronary artery disease, several additional risk factors have been used to stratify the likelihood of SCD. Three risk factors that deserve special mention include (1) reduced left ventricular ejection fraction (LVEF); (2) presence of nonsustained ventricular tachycardia (NSVT); and (3) inducibility of ventricular tachycardia/ventricular fibrillation (VT/VF) during electrophysiology study (EPS).

Left Ventricular Ejection Fraction

Left ventricular dysfunction, as measured by the left ventricular ejection fraction (LVEF), is one of the most powerful predictors of mortality at 6 months and 1 year (Fig. 21–2) after acute MI.[12] The higher rate of mortality includes an increase in SCD. Among patients receiving standard therapy, such as ACE inhibitors, the rate of SCD was 1.4% at 1 year in the GISSI-Prevention trial of patients who generally had an LVEF > 40%,[13] approximately 8% at 1 year in the TRACE trial of patients with an LVEF ≤ 35%,[14] and 9.4% at 20 months in the MADIT II trial of patients with an LVEF ≤ 30%.[15] In the ESVEM trial, LVEF was the single most important predictor of arrhythmic death or cardiac arrest in patients with life-threatening arrhythmias who were treated with antiarrhythmic drugs. Of the 486 patients enrolled over a 6-year follow-up, 285 had an arrhythmia recurrence. Patients with an LVEF >40% had a 5% risk of developing a malignant arrhythmia, whereas for each decrease of 5% in LVEF, the risk of cardiac arrest or arrhythmic death increased by 5%.[16] Left ventricular dysfunction has, therefore, been an entry criterion for every major clinical trial that has attempted to evaluate the efficacy of an ICD for primary prevention of SCD, in both the presence and absence of coronary artery disease (i.e., IRCM as well as NIDCM).

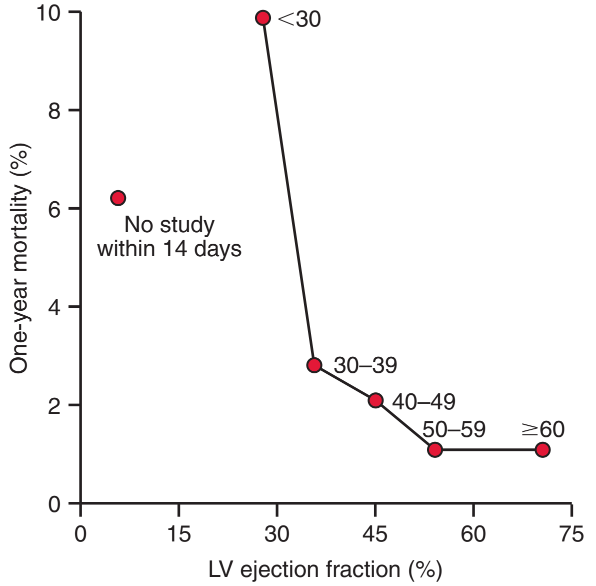

Figure 21–2 LVEF predicts 1-year mortality after MI. Among 3197 patients enrolled in the TIMI II trial, the 1-year mortality correlated with the resting left ventricular ejection fraction (LVEF) measured by radionuclide ventriculography obtained within 14 days of the event. The mortality was highest in patients with an LVEF < 30% (9.9%). Patients not undergoing study for any reason had an intermediate mortality of 6.6%. (Data from Zaret BL, Wackers FJ, Terrin ML, et al: Value of radionuclide rest and exercise left ventricular ejection fraction in assessing survival of patients after thrombolytic therapy for acute myocardial infarction: Results of Thrombolysis in Myocardial Infarction (TIMI) phase II study. The TIMI Study Group. J Am Coll Cardiol 1995;26:73).

Nonsustained Ventricular Tachycardia

Another risk factor for SCD that was used as a screening tool in some primary prevention trials was the presence of nonsustained ventricular tachycardia (NSVT).[16] After the first 24 hours post-infarction, NSVT is detected in approximately 5% to 10% of the patients, particularly during the first months, and has been considered to have adverse prognostic significance. Data from many sources, including the Multicenter Postinfarction Research Group, showed that NSVT detected on 24-hour ambulatory monitoring at 1 week or later post-MI carried at least a twofold increased risk of SCD.[17] The patients at greatest risk are those with diminished left ventricular systolic function, with NSVT appearing to have little prognostic significance if ejection fraction is preserved. Moreover, it seems that in the β-blocking era, all common arrhythmia risk variables, including NSVT, may have diminished predictive power in identifying post-infarction patients at risk of SCD. The incidence and prognostic significance of NSVT have also been shown to be diminished in patients who have undergone thrombolysis.[18] In addition, NSVT on Holter monitoring may have low reproducibility (50% overall in one study), especially in patients with infrequent NSVT episodes.[19]

In the Multicenter Unsustained Tachycardia Trial (MUSTT) and the Multicenter Automatic Defibrillator Implantation Trial (MADIT I), the role of an implantable cardioverter-defibrillator (ICD) was evaluated in patients with an earlier MI, and NSVT was used as one of the entry criteria. NSVT alone, however, was not considered sufficient to justify randomization in these studies; both required the additional criteria of LV dysfunction and inducible VT on EPS. In addition, patients were not enrolled sooner than 1 month in the MUSTT and 3 weeks in the MADIT I studies from their most recent MI.

Inducible VT/VF

Rates of inducibility of VT/VF at EPS differ based on the underlying substrate,[20] with inducibility rates being highest in the setting of coronary artery disease, especially in patients who have an underlying myocardial infarct/scar and in those who present with sustained monomorphic VT (SMVT; inducibility rates in the latter group exceed 90%). Inducibility rates are decreased in patients without coronary artery disease in those who present with cardiac arrest and those who present with nonsustained VT. The incidence of any inducible ventricular arrhythmia in cardiac arrest survivors varies in the literature from 46% to 85%. Only 37% of patients with nonsustained VT have inducible SMVT and 14% have sustained polymorphic VT/VF. Overall, the induction of SMVT at EPS in patients with an earlier myocardial infarction and NSVT is best predicted by the degree of LV dysfunction and the presence of regional wall abnormalities. A reduced rate of VT inducibility has been noted in patients with patent (as opposed to occluded) infarct-related arteries, despite comparable ventricular function between the two groups.[21] Induction of arrhythmia is less common in patients treated with a thrombolytic agent (15% to 20%).

In patients with no presenting arrhythmia, the prognostic value of EPS is controversial, although some studies suggest that the induction of sustained VT or VF in post-MI patients has strong predictive value for subsequent life-threatening arrhythmias.[22,23] In these studies, the induction of SMVT was strongly related to the degree of left ventricular dysfunction. The sensitivity of EPS in the post-MI setting is approximately 58% (specificity of 95%, positive predictive accuracy of 30% and a negative predictive accuracy of 98%). Despite the high negative predictive accuracy that was demonstrated in earlier studies, data from subsequent randomized trials (e.g., MUSTT) show that event rates are still substantial in patients who are noninducible; the high negative predictive accuracy of EPS noted in some studies is, therefore, believed to be related to the low incidence of events in this population versus the discriminant value of the test. In those patients who are inducible, SMVT is more specific than VF for predicting arrhythmic events and allows for the accurate identification of patients who may profit by prophylactic antiarrhythmic therapy.[24]

If one summarizes the results of multiple studies, approximately one third of post-MI patients had an arrhythmia induced during EPS; 18% of these patients (range 6% to 41%) had an arrhythmic event during a 1-year follow-up period. In contrast, the incidence of an arrhythmic event was only 7% (range 0% to 14%) in noninducible patients.

The predictive difference between patients with inducible and noninducible arrhythmias in the reperfusion era was evaluated in a registry of the MUSTT trial; all patients had an LVEF < 40% and NSVT. Patients who had inducible SMVT or VF and were untreated had significant increases in the rate of arrhythmic death or resuscitated SCD at 2 years (18% versus 12%) and five years (32% versus 24%) compared with those who did not have inducible SMVT or VF (Fig. 21–3).

Inducible sustained VT was used as an entry criterion, together with LV dysfunction and NSVT on ambulatory monitoring, in both the MUSTT and MADIT I trials of ICD therapy. The relatively high mortality rate in the noninducible patients in the registry of the MUSTT trial was one of the rationales for requiring only a low LVEF for inclusion in MADIT II. Although EPS was not a requirement for the MADIT II trial, such studies were performed in 593 of the 742 ICD-treated patients. The likelihood of inducibility was higher in patients with subsequent VT than in those who did not experience a device discharge (44% versus 34%) but was lower than in patients with subsequent VF.[25] When VT or VF, whichever occurred first, was used as a combined endpoint, inducibility was not useful in identifying which patients would receive appropriate ICD therapy for malignant ventricular arrhythmias. Overall, EPS was believed to be insufficient as a risk stratifier for malignant ventricular arrhythmias in patients who fulfilled the MADIT II criteria.

Rates of inducibility of monomorphic VT at EPS are significantly lower in the setting of dilated cardiomyopathy as compared with coronary artery disease, even though polymorphic ventricular arrhythmias can be induced in up to 86% of these patients.[26] More importantly, inducible ventricular arrhythmias are believed to be less predictive of arrhythmia recurrence and sudden death in the setting of NIDCM than in the setting of patients with IRCM. Because EPS has repeatedly been shown to have limited value, as it does in the risk stratification of patients with NIDCM, it has not been included as an entry criterion in any major ICD trial involving these patients.

Additional Noninvasive Risk Stratification for Sudden Cardiac Death

In addition to the risk factors already mentioned, other markers of malignant arrhythmias have been investigated to predict the risk of sudden cardiac death in patients after MI and in patients with nonischemic cardiomyopathy. The sensitivity and specificity of any single test for predicting major arrhythmic events are limited. This was illustrated in a pooled analysis of 44 studies of over 25,500 patients where the sensitivity and specificity of individual tests ranged from 43% to 62% and 77% to 86%, respectively.[27] Despite the limited predictive accuracy of any single clinical variable or test in better predicting arrhythmic outcomes, the use of a combination of clinical variables and/or tests has been shown to significantly increase the ability to predict the rates of total, as well as arrhythmic, mortality in a given population. For example, although the predictive value of heart rate variability (HRV) for post-infarction risk stratification is independent of other factors such as depressed LVEF, increased ventricular ectopic activity, and the presence of late potentials, decreased HRV by itself is insufficient as a single risk stratifier. HRV has a low overall predictive value for the rate of total or sudden-death mortality, but the value increases to almost 50% when HRV is combined with traditional risk factors such as VPCs, signal-averaged ECG (SAECG), or LVEF. A variety of studies have also evaluated the usefulness of other noninvasive markers (alone or in combination with each other) such as SAECG , baroreflex sensitivity (BRS), T wave alternans (TWA), and QRS prolongation on ECG (Table 21–2).[56-58]

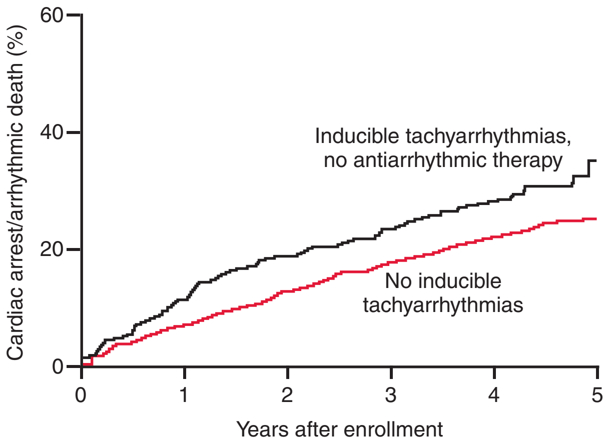

Figure 21–3 Induction of ventricular arrhythmia identifies a high-risk patient. In the MUSTT trial, the outcome of 353 patients with coronary disease, a left ventricular ejection fraction ≤40%, and a sustained ventricular tachyarrhythmia induced during electrophysiologic study—but who did not receive antiarrhythmic therapy—was compared with those of 1397 patients without an inducible ventricular tachyarrhythmia who were entered into a registry. Kaplan-Meier analysis showed that the rate of cardiac arrest or arrhythmic death was lower in patients without inducible arrhythmia at 2 (12% versus 18% for those with inducible arrhythmia) and 5 years (24% versus 32%, adjusted $P <$ 0.001). Overall mortality at 5 years was significantly lower in those without inducible arrhythmia (44% versus 48%). (Data from Buxton, AE, Lee, KL, DiCarlo, L, et al: Electrophysiologic testing to identify patients with coronary artery disease who are at risk for sudden death. Multicenter Unsustained Tachycardia Trial investigators. N Engl J Med 2000;342:1937.)

Trials of Primary Prevention

Risk stratification for fatal arrhythmias after acute MI has become more important because it is used to guide the selection of patients who will benefit from an ICD. The role of the risk stratification variables mentioned earlier in selecting patients for such therapy has been explored in several major randomized trials. These trials include patients with a reduced LVEF after MI (MUSTT, MADIT I, and MADIT II; Table 21–3),[1,15,28,29] patients with a reduced LVEF undergoing a revascularization procedure (Coronary Artery Bypass Graft [CABG]-Patch and Defibrillator in Acute Myocardial Infarction Trial [DINAMIT]; Table 21–4),[30,31] and patients with a reduced LVEF and NIDCM (The Cardiomyopathy Trial [CAT], Amiodarone Versus Implantable Cardioverter-Defibrillator [AMIOVERT], Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation [DEFINITE], and the

Table 21–2 Noninvasive Risk Factors for Sudden Cardiac Death*

Noninvasive Risk Factor	Comment
QRS prolongation on ECG	Intraventricular conduction delay and LBBB have been associated with a 50% increase in arrhythmic and total mortality
Late potentials on Signal-Average ECG (SAECG)	Defined as a filtered QRS duration >114 msec, a terminal (last 40 msec) QRS root mean square voltage <40 μV, and a low amplitude (<40μV) late potential duration >38 msec; late potentials have a negative predictive accuracy of 95-99% for VT in post-MI patients with a single risk factor (e.g., ventricular ectopy or severe LV dysfunction), but a positive-predictive accuracy of only 14-29%.[43,44]
Heart Rate Variability (HRV) and Baroreflex Sensitivity (BRS)[45]	Relative risk of cardiac mortality was increased by low values of either HRV or BRS in the ATRAMI trial, particularly when associated with an LVEF < 35%. As noted in the DINAMIT trial, reduced HRV may identify patients at high risk, not only for arrhythmic death, but also for nonarrhythmic death.
T Wave Alternans (TWA)[46]	High sensitivity and specificity for predicting inducible ventricular arrhythmias on EPS

SCD-HeFT (Bardy et al., N Engl J Med 2005;352:225	Compare ICD with amiodarone in patients with CHF and LVEF $\leqslant$ 35%	2521 with NYHA II-III CHF and LVEF $\leqslant$ 35%	25%; I: 0% II: 70% III: 30%	All-cause mortality; 3.8 (median)	22% vs. 28% (amiodarone) at 5 years; RR = 23%; NNT = 13	(not reported)	4.4% vs. 5.7%	(not reported)

Comparison of ICD and non-ICD use in trials of primary prevention in patients with non-ischemic dilated cardiomyopathy (NIDCM).[32-35] Annualized figures represent the reported endpoint in each group divided by the average follow-up period. The SCD-HeFT trial included patients with infarct-related cardiomyopathy as well as NIDCM. AAD, antiarrhythmic drug; CABG, coronary artery bypass graft; EPS, electrophysiology study; ICD, implanted cardioverter-defibrillator; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NNT, number needed to treat; NS, nonstatistically significant; NSVT, nonsustained ventricular tachycardia; NYHA, New York Heart Association; PCI, percutaneous coronary intervention; PVC, premature ventricular contraction; RR, relative risk reduction; VF, ventricular fibrillation.

Sudden Cardiac Death-Heart Failure Trial [SCD-HeFT; Table 21–5).[32-35]

PRIMARY PREVENTION OF SUDDEN DEATH IN OTHER DISEASES

A number of diseases other than IRCM and NIDCM have been associated with an increased incidence of sudden cardiac death. These include inherited diseases of ion channels, such as long-QT syndrome, Brugada syndrome, and catecholaminergic VT. Other structural heart diseases, such as right ventricular dysplasia, hypertrophic cardiomyopathy, and certain types of congenital heart disease, may also be associated with an increased risk of sudden death. The incidence of these conditions is far less than those of IRCM and NIDCM—making prospective, randomized, control trials difficult to perform. Nonetheless, nonrandomized observational studies suggest that subgroups of high-risk patients may benefit from ICD therapy.

Hypertrophic Cardiomyopathy

Ventricular ectopic beats and episodes of NSVT are common in patients with hypertrophic cardiomyopathy (HCM). In addition, the annual incidence of SCD is increased to 1% to 4% in patients with HCM. Myocardial scarring and fibrosis is believed to contribute significantly to the arrhythmic phenotype in this condition. NSVT appears to confer increased risk for SCD, and certain high-risk patients with NSVT may be candidates for a defibrillator (e.g., those with episodes of NSVT that are prolonged, repetitive, or associated with symptoms of impaired consciousness). Other risk factors for sudden death include survival from cardiac arrest, spontaneous sustained VT, a family history of HCM-related premature SCD, marked hypertrophy with a left ventricular thickness ≥30 mm, and an attenuated or hypotensive blood pressure response to exercise.

Congenital Long QT Syndromes

Mutations in seven genes have been identified in patients with genetic long QT syndrome (LQTS) (see Chapter 25). The vast majority of cases of LQTS are accounted for by three of the seven genotypes: LQT1 (40% to 55%), LQT2 (35% to 45%), and LQT3 (8% to 10%). The incidence of congenital LQTS in the United States is estimated to be 1 in 7000 to 10,000; the condition causes 3000 to 4000 deaths in children annually. The syndrome is associated with an increased risk of polymorphic VT (torsades de pointes) with presenting symptoms that include palpitations, syncope, seizures, and cardiac arrest. Arrhythmia triggers vary with the underlying genotype but typically include exercise for LQT1, acute arousal events (such as exercise, emotion, or noise) for LQT1 and LQT2, and rest or sleep for LQT3. Symptomatic untreated patients with LQTS are at high risk of SCD, with mortality rates of up to 20% at 1 year and 50% to 60% at 10 years. Although β-blockers are the mainstay of therapy for congenital LQTS, ICD implantation is being recommended for survivors of cardiac arrest and for patients with persistent torsades de pointes despite conventional therapy.

Brugada Syndrome

Brugada syndrome is associated with a peculiar pattern on the electrocardiogram (ECG) that consists of a pseudo-right bundle branch block (RBBB) and persistent ST-segment elevation in leads V_1 to V_3 (see Chapter 25). The condition is significant for its propensity for malignant ventricular arrhythmias. SCD may be the first and only clinical event in Brugada syndrome, occurring in as many as one third of patients. Arrhythmic events generally occur between ages 22 and 65 and are more common at night than during the day and during sleep versus while awake. Male sex and a positive family history of SCD are considered risk factors for SCD. Importantly, patients with a previous history of SCD and those with a history of syncope are at significantly increased risk for subsequent arrhythmic events as compared with asymptomatic individuals. Current guidelines advocate ICD implantation for patients with a history of aborted SCD or sustained VT, with the evidence being less well established in patients who have either syncope or a family history of unexplained sudden death. The role of EP testing is uncertain at this time, although a recent study revealed a significant predictive value for EPS in a large series of patients with Brugada type 1 ECG pattern.[36] A randomized trial was performed recently in Thailand in patients with an inherited risk of SCD (sudden unexpected death syndrome, which is believed to represent Brugada syndrome); in this trial (DEBUT)[37] patients were found to have improved survival with an ICD versus β-blocker therapy.

COST EFFECTIVENESS OF THE ICD

The increased ICD use that has resulted from the aforementioned clinical trials has potentially created an enormous financial burden on the health care economy. At this time, there are more than three million patients in North America who are eligible for an ICD based on MADIT II criteria; approximately 400,000 new patients are expected to be added to their ranks each year. A defibrillator costs approximately $30,000 per patient. This translates into an initial cost of $90 billion, with annual costs thereafter being estimated at $12 billion a year—staggering sums by any estimate!

Attempts have also been made to perform cost-effectiveness analysis for ICD use, with analyses, to date, ranging from $20,000 to $70,200 per life-year gained[38,39] (see Chapter 1). Because a treatment is generally considered to be cost effective if its cost is similar to that of hemodialysis—between $35,000 and $60,000 per life-year gained—ICDs compare relatively favorably. Unfortunately, this does not lessen their financial impact on an already strained health care budget.

The hope is that ICDs will become less expensive over time, as research and development costs are gradually recovered by industry; market competition will also likely play a role. There is also pressure on ICD manufacturers to develop inexpensive shock-only devices in order to drive down ICD cost. Other than attempts to curtail the cost of these devices, a "fine-tuning" of ICD use in patients who are most likely to use them will also decrease the cost of ICD therapy. Attempts at better risk stratification for SCD (and resulting ICD use) are ongoing.

COMPLICATIONS, FOLLOW-UP, AND SPECIAL CONSIDERATIONS

Although the implantation of ICDs continues to become easier—both in terms of smaller systems and improved equipment—complications still occur. Device infection can occur in up to 1% to 2% of cases and may require extended antibiotic use or repeat procedures.[40] Lead malfunction may cause delivery of inappropriate shocks and changes in the patient's metabolic condition due to the addition of medication or from electrolyte abnormalities that may increase the defibrillation threshold (see Appendix 2). The psychological stress of frequent ICD shocks, appropriate or inappropriate, may also negatively impact a patient's quality of life (Table 21–6).

After ICD implantation, routine follow-up is mandatory. This usually includes a wound check within the first few days to weeks after implantation, as well as scheduled visits to monitor lead and device functioning and documentation of bradycardia and tachycardia therapies. Unnecessary pacing has been shown to have adverse effects and should be assessed.[41,42] An important aspect in care of the patient with an ICD is to provide recommendations about how to respond to a device discharge (Fig. 21–4).[43] Because the application of a magnet over an ICD will suspend ICD tachycardia therapies (i.e., device discharge) but will not affect bradycardia therapies, special consideration must be made for patients undergoing surgery. In pacemaker-dependent patients with an ICD, reprogramming may be necessary to ensure an adequate heart rate during surgery because electrocautery may inappropriately inhibit function (Fig. 21–5).[44]

CURRENT GUIDELINES FOR ICD THERAPY

The American College of Cardiology (ACC), American Heart Association (AHA), and Heart Rhythm Society (HRS; formerly known as the North American Society of Pacing and Electrophysiology, NASPE) updated guidelines for ICD implantation in 2002, and the European Society of Cardiology (ESC) published its guidelines in 2003.[45-47] Based on these guidelines and incorporating the results of randomized studies published since their publication, the Center for Medicare & Medicaid Services (CMS) expanded the indications for coverage for ICD insertion in January 2005.[48] An algorithm for the indications for ICD implantation is presented in Figure 21–6.

FUTURE DIRECTIONS

Novel factors are being sought to stratify patients at risk of SCD more effectively. The search for better markers of ventricular arrhythmias is being driven by the observation that

Table 21–6 Complications of ICD Therapy

Device-Related	Therapy-Related
• Infection or erosion	• Inappropriate shocks
• Hematoma	• Acceleration of VT
• Pneumothorax	• Psychological trauma (frequent shocks)
• Lead dislodgment	• Unintended hospitalization
• Inadequate defibrillation threshold	
• Lead malfunction	
• Electromagnetic interference	

Complications of implanted cardioverter defibrillator therapy.

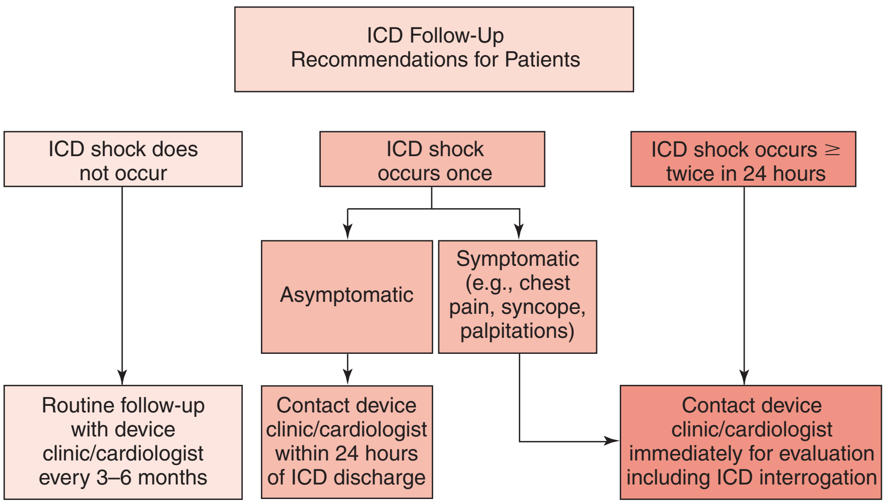

Figure 21–4 ICD follow-up recommendations for patients. If no device discharge occurs, then follow-up should be routine. If a single shock occurs and the patient is asymptomatic, then the device clinic/cardiologist should be contacted within 24 hours. If the patient is symptomatic or has more than one shock within 24 hours, the patient should immediately contact the device clinic/cardiologist; in some cases, the management will be done as an outpatient. ICD, implantable cardioverter-defibrillator. (From Sears SF, Jr., Shea JB, Conti JB: Cardiology patient page: How to respond to an implantable cardioverter-defibrillator shock. Circulation 2005;111:e380-2.)

the majority of SCD occurs in patients who would not be considered "high risk" by any of the currently available risk-stratification methods and by the cost of ICD implantation and use. More sensitive tests are needed to identify patients in what are now considered low-risk populations (e.g., those with coronary artery disease but no prior history of sudden cardiac death and preserved left ventricular systolic function). Furthermore, as indications for ICD use broaden, the sheer expense of ICD therapy threatens to make widespread implantation prohibitive in most countries. Although some have suggested a need to manufacture cheaper devices (i.e., ICDs that can deliver appropriate therapy for ventricular tachyarrhythmias but lack several of the currently available diagnostic features),[49] many others feel that better risk stratification may be the key to keeping costs down. Of the available tests, LVEF is still the most sensitive but suffers from a lack of specificity. Only approximately 23% of MADIT II patients actually receive appropriate therapy from their devices for potentially life-threatening ventricular arrhythmias (at an average follow-up of 21 months). The role of an ICD in all patients meeting MADIT II criteria is, therefore, controversial. Some have suggested that the benefit of ICD therapy in MADIT II patients might be largely limited to patients with inducible VT, which was an entry criterion in MADIT I and MUSTT. However, inducibility at EPS was not found to be sufficient as a risk stratifier in the MADIT II study population.

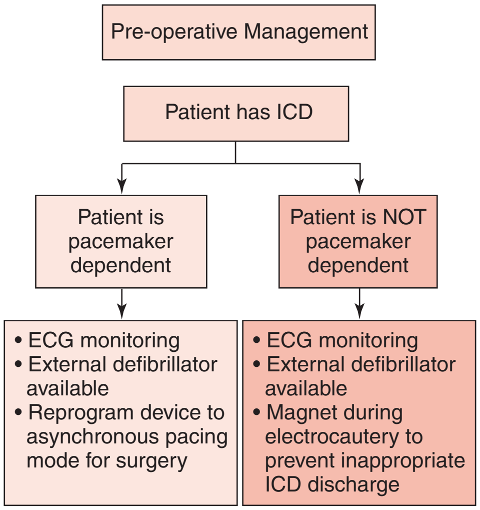

Figure 21–5 Suggested management of patients with ICDs at the time of surgery. Reprogramming may be necessary if the patient is pacemaker dependent because magnet placement will suspend tachycardia therapies but will not change bradycardia parameters and therapies. ECG, electrocardiogram; ICD, implantable cardioverter-defibrillator. (From Blomberg P: Personal communication, 2005.)

Role of Cardiac Imaging in Risk Stratification for SCD

Two imaging modalities are currently being investigated: nuclear imaging to visualize the cardiac nervous system and cardiac MRI to assess for nonviable myocardium (and the resultant risk of malignant arrhythmias). Imaging of the cardiac autonomic nervous system has been performed by several groups with radiopharmaceutical agents such as

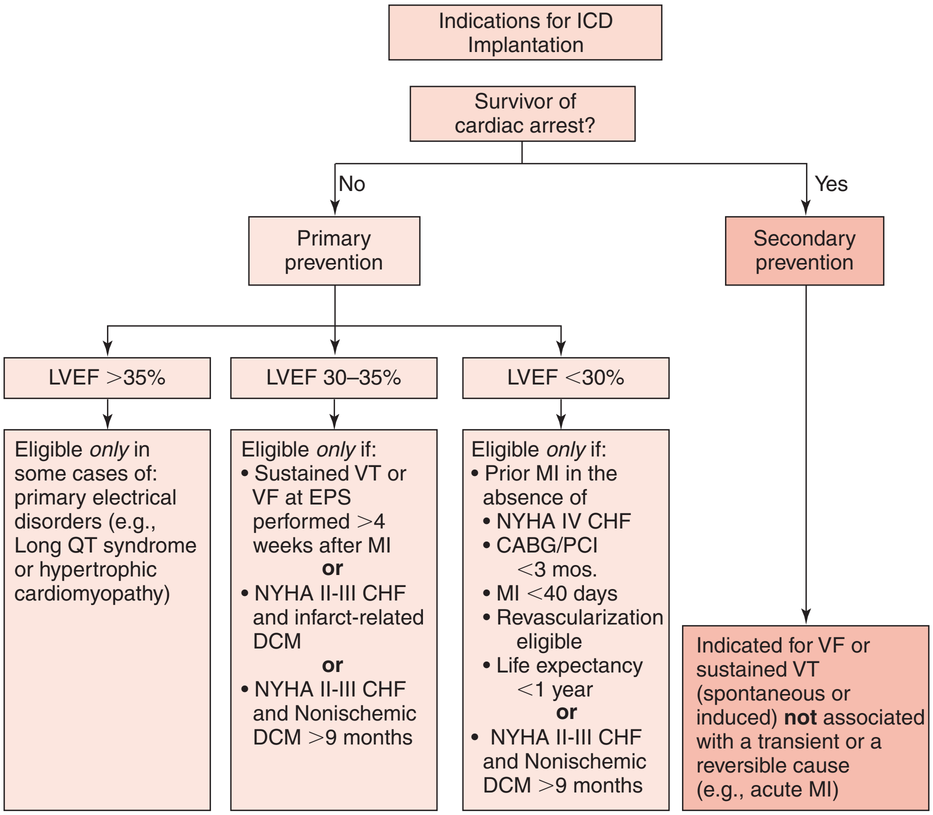

Figure 21–6 Algorithm for indications for ICD implantation. CABG/PCI, coronary artery bypass graft/percutaneous coronary intervention; CHF, congestive heart failure; DCM, dilated cardiomyopathy; ICD, implantable cardioverter-defibrillator; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NYHA, New York Heart Association; VF, ventricular fibrillation; VT, ventricular tachycardia. (From references 45 to 48.)

^{123}I-MIBG (using a gamma camera) or ^{11}C-HED (using PET). The extent and heterogeneity of sympathetic denervation with either agent have been shown to be predictive of ventricular arrhythmias or SCD. A combination of ^{123}I-MIBG and HRV variables has been demonstrated to correlate with ICD shocks in a heterogeneous population of ICD patients.[50] An increase in the use of autonomic imaging of the heart, in conjunction with other markers of SCD, may thus enhance the ability to detect patients who may benefit most from ICD use.

Cardiac MRI also holds promise as a method of risk stratification for SCD. Studies[51,52] have demonstrated the sensitivity of cardiac MRI in detecting nonviable myocardium or scar, even when the global LVEF appears to be well preserved. Bello and colleagues[53] have shown a significant correlation between left ventricular scar as detected on cardiac MRI and inducible ventricular tachyarrhythmias at electrophysiologic study. In this study, infarct surface area and mass—as measured by cardiac MRI—were better identifiers of patients who have a substrate for monomorphic ventricular tachycardia rather than LVEF. As a result, an ICD trial being planned will assess the usefulness of MRI to better risk stratify patients with mild-to-moderate left ventricular dysfunction.

Role of Genetic Testing in Prediction of SCD

Basic, as well as clinical, studies performed over the last few years point toward intricate genetic mechanisms that underlie not just the genetics of ion channel function but also atherogenesis, plaque destabilization, and the thrombotic cascade.[54] Advances in molecular and genetic electrophysiology include an increased understanding of the genes that control ion channel pore structure (e.g., KvLQT-1, HERG, and SCN5A) and those that control their associated modulatory peptides (e.g., minK, MiRP-1). Genes that modulate or modify calcium handling (e.g., RyR2 and CASQ2) are associated with arrhythmias, some of which may occur because of interactions between these calcium handling proteins and the KvLQT-1/minK complex. Interactions between multiple genes, as well as interactions occurring between genetic and environmental factors, may be required for final common pathophysiologic pathways such as atherogenesis, the thrombotic cascade, and the resulting arrhythmic phenotype. Stepwise integration of these characteristics for individuals by means of complex analytic methods offers the hope of a field of genetic epidemiology that would more accurately identify those patients at increased risk of SCD.[55]

Chapter 22

Surgical Options for the Treatment of Arrhythmias

Adam E. Saltman

CHAPTER CONTENTS

Overview of the History of Surgical Therapy for Arrhythmias

The surgical treatment of cardiac arrhythmias has undergone significant change over the last four decades. Although many of these procedures were among the first performed by the nascent field of cardiac surgery, they have undergone one of the most astounding cycles of development and then recession seen anywhere in medicine. The purpose of this chapter is to overview this history briefly and then to concentrate on those procedures in use today by the cardiac surgeon, how they are developing and changing rapidly, and how they will be applied in the near future.

Summary of the Field Today

Unlike all other operations performed by the cardiac surgeon, those designed to treat arrhythmias are, by nature, ablative: They destroy tissue in order to restore normal rhythm and electrical conduction. In the early days of cardiac surgery, when cardiopulmonary bypass was still a very dangerous adjunct, the subspecialty of cardiac electrophysiology did not yet exist. Hoffman and Cranefield[1] provided the basis of principles in the basic laboratory and the pioneering studies of Durrer and colleagues[2] led to the use of surgery to treat arrhythmias.

The job of the surgeon was first to understand the mechanism underlying the arrhythmia, and second, to destroy it. This might mean transecting an accessory bypass tract, locating and ablating a focus of abnormal automaticity, or even creating lines of conduction block in order to stop reentrant wavelets. Through these efforts much was learned about the anatomy of the heart, about epicardial and endocardial mapping, interpretation of electrograms, and about methods of tissue destruction that could safely remove abnormal tissue yet leave the heart a functioning syncytium. The progress over the last two decades has been one more of miniaturization than of discovery.

The task confronting today's surgeon is how to apply his or her skills in the manner that best complements those of colleagues in the electrophysiology laboratory. For some arrhythmias, there is no doubt that an endocardial percutaneous approach is best, yet for others this is not the case. The challenge for surgeons of today and tomorrow is to provide the best approach to the heart for specific arrhythmia treatment yet combine this with the least invasive methods and—most of all—maintain efficacy.

HISTORICAL PROCEDURES

Wolff-Parkinson-White Ablation

The existence of electrical conduction across the atrioventricular (AV) groove was first demonstrated in 1967 during intraoperative mapping.[3] The Duke group was the first to report the successful surgical treatment for Wolff-Parkinson-White (WPW) syndrome in 1968.[4] The procedure involved approaching the heart via a median sternotomy mapping the site of earliest ventricular activation during atrial pacing (ventricular insertion rate) and the earliest site of atrial activation during circus movement tachycardia. The AV ring was then incised to cut the accessory pathway.

As experience increased, cure could be attained in nearly 100% of patients. By the 1980s, hundreds of cases were being performed yearly. By the end of the 1980s, however, transvenous catheter ablation techniques were developed. Currently, catheter ablation techniques (see Chapter 20) have almost completely obviated the open surgical approach.[5] Nevertheless, there are patients in whom catheter-based ablation is occasionally unsuccessful and a surgical approach is still needed.

Atrioventricular Nodal Reentrant Tachycardia

Reentry within the AV node results from communication between the slow and fast pathways of conduction involving the AV node and transitional fibers[6] (see Chapter 23). Ross and colleagues developed a surgical approach to treat AV nodal reentry,[7] but this was replaced by catheter ablation.[8,9] Surgical ablation of the AV node had been performed for many years until Dr. Scheinman introduced transcatheter ablation in 1982, using high-energy shocks within the His bundle region.[10] Currently, ablation of the AV node with RF energy is the preferred method.

Post-infarction Ventricular Tachycardia

Ischemic ventricular tachycardia after myocardial infarction remains a significant problem, especially as survival continues to improve after myocardial infarction. It has generally been thought that these arrhythmias resulted from reentry in heterogeneous tissues surviving after infarction. Endocardial and epicardial catheter mapping of VT was pioneered by Josephson and colleagues.[11,12] This led to map-guided subendocardial resection to treat VT.[12,13]

Endocardial resection and ablation, combined with repair of ventricular aneurysms, has become a highly effective treatment for this disorder.[14,15] Considering the patient population on whom this operation is performed, however, there has been a significant degree of morbidity and mortality. Combined with advances in catheter ablation techniques and the demonstration of the effectiveness of implantable cardioverter-defibrillators, this procedure has also been almost completely eliminated from surgical practice, confined only to those patients who have incessant tachycardias and have been refractory to drug therapy, had complications from catheter therapy, or who also are to be treated for advanced-stage heart failure or complications from their large ventricular aneurysms. This is unfortunate because, unlike ICDs, surgery cures the problem. There may be a resurrection of surgery in the future.

CURRENTLY PERFORMED PROCEDURES

Atrial fibrillation

Atrial fibrillation, far from being a nuisance arrhythmia, has been clearly shown to increase mortality and to inflict considerable morbidity on its victims. Despite four decades of attempts at pharmacologic therapy, little success has been achieved, and many of the drugs in use today carry with them significant, limiting side effects. Over the last 10 years, there has been an explosion in the level of interest in nonpharmacologic treatments for atrial fibrillation (AF) (Figs. 22–1 to 22–3).

The Electrophysiologic Basis of Atrial Fibrillation and the Development of a Procedure

The initial attempts at the surgical treatment for AF focused mainly on "disconnecting" the atria from the ventricles, mainly to control ventricular response. The right atrial isolation operation,[16] the left atrial disconnection operation,[17] and the Corridor operation[18,19] all met with reasonably high success rates. However, those procedures left components of the atria still fibrillating. The patient remained exposed to the risk of stroke and required continuing therapy with anticoagulants and their attendant risks. In effect, they were no better at treatment than the commonly performed percutaneous AV nodal ablation procedure, yet the latter therapy avoided open heart surgery.

The theoretical principles underlying AF were proposed 100 years ago. Experimental evidence in the past four decades suggested that reentry could serve as the mechanism for AF. It was not until Dr. Cox and Boineau's pioneering work in the 1980s that proof was obtained in vivo. They were able to show in human and animal mapping experiments using high-density multipolar electrodes that AF was a self-sustaining arrhythmia, dependent on multiple reentrant waves wandering at random throughout the atrial syncytium.[20,21] Despite making considerable steps toward the development of such a procedure, which included transecting the posterior atrium, isolating the pulmonary veins (PVs), and creating linear lesions toward the mitral annulus and the inter-atrial septum, the operation would not stop AF reliably in humans.[22]

As further experience was gained in the laboratory and the operating room, it became apparent that AF might not be the result of a single underlying mechanism but rather a combination of several possible mechanisms. Unfortunately, it remains technically impossible to complete the construction and analysis of a complete activation map of atrial fibrillation in real time. Thus, an anatomically guided operation was designed to treat as many patients as possible. The resulting iterations of Dr. Cox's Maze procedure, now settling on the Maze-III, have become the standard approach for patients undergoing surgery for AF. This operation has met with a very high degree of success over long-term follow-up (see later) and is today the standard against which other procedures must be compared. It has been the interest of many surgeons since the mid-1990s to adapt the Maze-III to a less invasive and less morbid approach.

Subsequent work has been done in advancing real-time intraoperative mapping and in tailoring surgical therapy either toward the PVs or the entire atrium, depending on the individual patient's arrhythmia. However, there has currently been no validation of mapping during AF as a useful guide to surgical therapy. We will have to wait to see if this approach evolves to be an accurate, reproducible, and meaningful method of guiding surgery.

The Experience with the Maze Operation

In its current incarnation, the Maze-III operation has met with excellent success in a wide variety of settings and institutions. Gratifyingly, the mortality rate of the operation has been low, ranging from 1.4% to 3.6%.[23-25] When performed for lone AF, it has been reported to "cure" as many as 96.3% of patients.[23] When applied during mitral valve surgery, it restores sinus rhythm in 65% to 82% of patients.[24,25] It has been used with reoperations as well as with coronary bypass grafting and aortic valve replacements.[25-27]

One of the most interesting findings in patients who have undergone the Maze-III procedure is that there is a reportedly low incidence of stroke, less than 0.1% per year in Dr. Cox's experience.[28,29] This is surprising because these patients carry a large burden of suture and pledget material in their atria and are not typically placed on anticoagulant therapy. Possibly this is because the left atrial appendage has been removed from each patient, but it may also be a result of restored right and left atrial transport function in the majority of patients, although the extent of that restoration is controversial.[30-32]

The Design of an Effective Ablative Procedure

It has been only over the last 10 years that scientific data have become available concerning the underlying pathophysiologic mechanisms of AF. This is largely because of the appearance

of an animal model of permanent AF,[33] as well as the demonstration in humans that episodes of paroxysmal AF may begin in or around the PVs.[34]

With regard to paroxysmal AF, these findings have led to a tremendous surge in interest toward either ablating PV foci or electrically disconnecting the PVs from the remainder of the left atrium. As a result of its original design, the Maze procedure mandated creating a completely encircling line of scar around all four PVs as a single pedicle. It would have been expected to eliminate—and has been quite successful at eliminating—paroxysmal AF. Attempts to recreate the Maze lesion set with endocardial RF probes met with very long and sometimes multiple EP laboratory sessions, low success rates, and high complication rates.

The developments in catheter ablation have mirrored what has been known to the surgeon for some time: A complete electrical disconnection of the PV *pedicle* or *antrum,* possibly requiring the portion of the left atrial wall posteriorly and between the PVs results in a high "cure" rate for patients with paroxysmal AF (see Fig. 22–1). This remains the cornerstone of treatment for these patients because, even though several investigators have now shown that abnormal impulses can originate outside of this region,[35,36] the majority of patients with PAF can be treated by this encompassing ablative approach.

With regard to permanent fibrillation, however, the situation is far more complex. Some investigators have shown that the mechanism underlying permanent fibrillation is possibly random reentry[37]; others suggest that focal drivers or "mother rotors" may perpetuate the arrhythmia.[38,39] In view of this uncertainty, it is unlikely that isolation of one or even a small number of atrial muscle regions or veins will prove successful at treating these patients. Rather, it will more likely be necessary to create conduction obstacles that prevent reentry by containing excitation to defined regions of the atrium, extinguishing abnormal impulses yet preserving connections among regions and between the SA node and the AV node. The design of the Maze procedure(s) has attempted to achieve this and, as discussed earlier, has met with excellent success and durability.

It is, therefore, rational to employ different ablative strategies for patients presenting with different forms of AF. Rather than mapping the location of each site of impulse origination in each patient with paroxysmal AF, it would be more effective to electrically isolate the PVs and posterior left atrial wall from the rest of the atrium. This would be expected to successfully treat approximately 90% of PAF originating in pulmonary veins. For patients presenting with or progressing to more permanent forms of AF, however, a more complete lesion set would be advised: This set should isolate the PVs but also include extensions to the mitral annulus, the left atrial appendage, and even over the right atrium (see Fig. 22–3) until it has been proved that these Maze lesions are not necessary. This argument is made stronger if lesion creation can be accomplished with little or no additional risk to the patient.

It is with this in mind that future procedures must be designed, implemented, and studied. The random application of poorly defined lesion sets to heterogeneous groups of patients just because "they have AF" should be discouraged. It will almost certainly meet with a higher-than-necessary degree of failure and make it quite difficult to determine where improvements can be made.

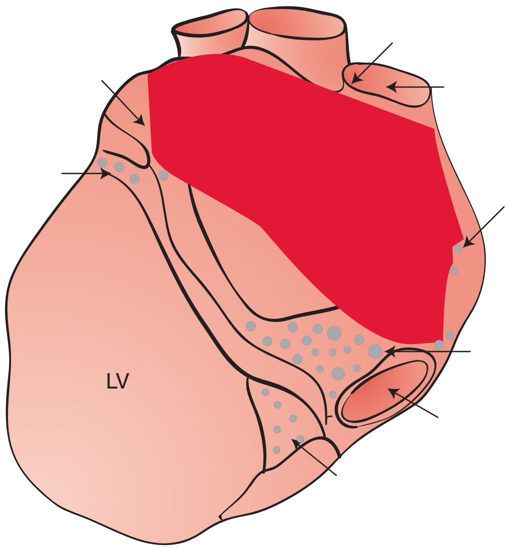

Figure 22–1 Illustration of a "box" lesion placed on the posterior wall of the left atrium (dark red area), completely surrounding the pulmonary veins as a pedicle. The view is posterior, showing the aorta and pulmonary artery superiorly and the left ventricle inferiorly. The superior and inferior vena cavae are to the right and the left atrial appendage is to the left. (LV, left ventricle.)

THE FUTURE OF SURGICAL THERAPY

There has been a marked reduction in the number of cut-and-sew Maze operations, but the number of ablative procedures performed during open heart surgery for the treatment of atrial fibrillation has skyrocketed, entirely because newer technologies have become available (see Fig. 22–2). It is reasonable, therefore, to expect that new ablative devices will become, much more widely used as time goes by and as their safety, effectiveness, and ease of use become widely known. At this point, it is not clear what technology (or technologies) should be used, on which patients, and for what pattern of lesions.

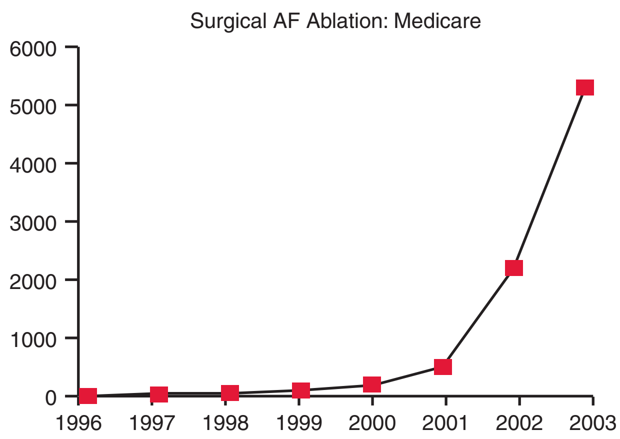

Figure 22–2 Medicare data from 2004 showing the rate of increase of surgical atrial fibrillation cases performed over a 7-year period.

The Case for Concomitant Therapy

The justification for treating AF in patients about to undergo open-heart surgery is an easy one: If an effective and safe procedure can be performed, then it is indicated. As stated earlier, although thousands of ablative procedures have been performed using a number of different technologies to create lesions, there have been no organized, prospective, controlled studies addressing the issues of technology or lesion selection. The literature consists of case reports, small retrospective series, and an occasional prospective registry-type report. Despite this, the results have been generally gratifying and complication rates have been low.[40]

The Data Supporting Treatment

There is an interesting and common misconception in the surgical community that patients with valvular disease and AF will be cured of their AF if the valve issues solely are addressed. This is clearly not the case, and a unique opportunity will have been forfeited if concomitant therapy is withheld. Elahi and coworkers showed in a group of 877 patients undergoing isolated coronary bypass surgery that if they came to the operating room in AF, only 5% regained sinus rhythm at their 1-year anniversary.[41] Raine and colleagues followed 92 patients undergoing isolated mitral valve replacement and found that only 8.5% of those starting in AF returned to SR.[42]

Remaining in AF after cardiac surgery is not benign: The odds for suffering stroke were 3.4 times higher if AF is the predominant rhythm after mitral surgery[43] and 2.2 times higher after aortic surgery.[44] Furthermore, the presence of AF after valve surgery proved to be an independent risk factor for heart failure and death.[45]

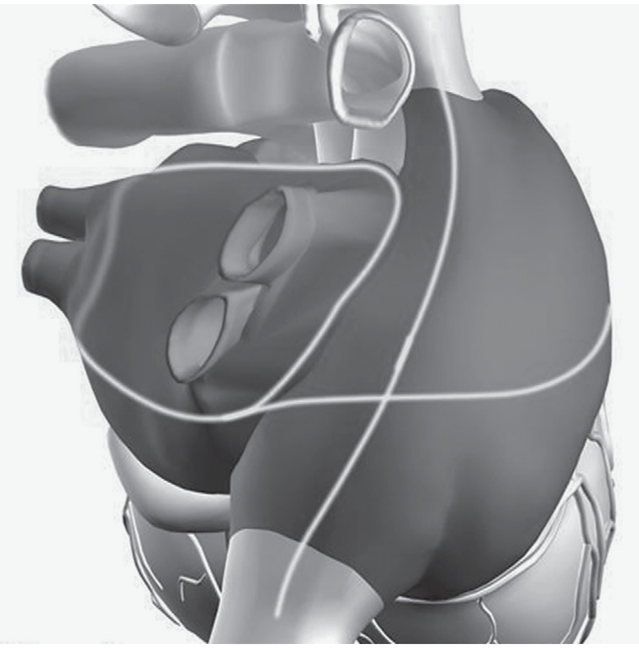

Figure 22–3 Illustration of right atrial lesions placed on the free wall of the right atrium and between the two vena cavae. The box lesion encircling the pulmonary veins can also be seen.

Is return to sinus rhythm beneficial? In Bando's series of 241 patients who underwent either mitral valve or aortic valve surgery with a combined Maze procedure, survival improved over the 5-year follow-up period if sinus rhythm was restored.[46] The incidence of stroke likewise decreased from 19.1% to 6.4% with sinus rhythm. Return to sinus rhythm was also associated with a fall in pulmonary artery pressures[47] and improvements in left atrial size and function.[48] Clearly, because the patients with valvular disease are the most likely to have AF at the time of surgery, they will benefit the most from concomitant treatment and it should be offered to them. Although patients with isolated coronary disease might not benefit as much as those with valvular disease, if they too can undergo ablation with minimal risk it should be offered to them.

A Review of the Available Technologies

The classic lesion creation method is cutting and sewing tissue. This creates a scar composed mostly of collagen and little-to-no cellular material. It is, therefore, not electrically conductive. The goal of "alternative technologies" has been to create a similar scar by thermal injury and coagulation necrosis. To produce such an injury, the tissue must be either heated to 50°C or frozen to –60°C. The quantity of tissue injured is usually directly proportional to the duration of time during which the tissue is held at either temperature. The various energy sources discussed below differ mainly in the method by which they transfer energy to the tissue and how deeply that energy is conducted into the tissue.

A summary review of some characteristics, advantages, and disadvantages of each method is given in Table 22–1. It should be noted that at present (2006) the devices discussed as follows are all FDA-labeled for the ablation of soft tissues (all except the Atricure device are also labeled for cardiac muscle ablation) but *none* is approved for the treatment of AF. Therefore, they are all currently being used "off-label" for the treatment of AF.

Despite clearly different energy forms and application methods, it is interesting to note that when applied with the left atrium open, from the endocardial aspect with full cold cardioplegic arrest, there seems to be very little difference in the safety or efficacy of any one device over the others.[40]

The most extensive experience has been with the dry unipolar RF devices, mainly Boston Scientific's Cobra probe. The probe consists of a malleable 6 cm long × 2 mm diameter active tip that can be shaped as the operator desires. Surveying its reported use in 16 studies including 1187 patients, Khargi and his colleagues found that dry unipolar RF was effective at freeing patients from AF 78% of the time (reported success ranged from 42% to 92%).[40] There have been several complications attributed to the use of the probe; the most worrisome were esophageal injuries, resulting in death 60% of the time.[40a] As more experience has been gained with the device and safer methods of ablation have been developed—such as placing a cold, wet sponge between the posterior wall of the left atrium and the esophagus and/or shielding the probe in nonconducting sheaths—these injuries should become rare.

There are many energy sources available to the surgeon and no overwhelming advantages or disadvantages to any one of them. The choice is mainly up to the person performing the procedure; however, there may be some points to consider in

Table 22–1 Characteristics, Advantages, and Disadvantages of Each Method of Tissue Ablation in Use by Cardiac Surgeons in 2005

Energy Source	Method	Advantages	Disadvantages	Brand name
Dry Unipolar RF	Contact resistive heating	• Well-understood technology • High tissue temperatures achieved • Flexible delivery system	• Poor temperature control • Fat does not heat well or conduct well • No transmurality feedback • Dosimetric energy delivery • Collateral damage from conduction into surrounding structures	Boston Scientific Cobra
Irrigated Unipolar RF	Contact resistive heating	• Higher energy delivery at lower operating temperature • Small tip can make many lesions • Complete operator control over lesion set	• Highly operator-dependent (otherwise same as dry unipolar RF)	Medtronic Cardioblate
Dry Bipolar RF	Contact resistive heating	• Shielded energy source • Very localized lesion • Possible transmurality feedback, used to control energy delivery • Very fast ablation times	• Fixed device shape, limiting lesion types • Large device, making minimal access difficult	Atricure
Irrigated Bipolar RF	Contact resistive heating	• Device more malleable than dry bipolar RF • Irrigation avoids char (otherwise as with dry bipolar RF)	Same as dry bipolar RF (except more flexible delivery system)	Medtronic Cardioblate BP
Microwave	Radiation into tissue	• Shielded energy source • Flexible probe • Penetrates fat well • Does not require direct tissue contact	• Dosimetric energy delivery • No transmurality feedback	Guidant Flex 4 and Flex 10
High-intensity focused ultrasound	Radiation into tissue	Same as microwave	Same as microwave	St. Judes Medical Epicor
Laser	Radiation into tissue	Same as microwave	Same as microwave	Edwards Lifesciences OptiWave
Cryothermy	Direct tissue freezing	• Wide safety margin (otherwise as with microwave)	• Question about energy "sink" problems (otherwise similar to microwave)	Cooper Medical Frigitronics; CryoCath SurgiFrost

RF, radiofrequency.

selection: If the device can only be used from the endocardium, then it likely will not be useful in treating patients with only coronary artery disease or only aortic valve disease in whom the left atrium will not routinely be opened. Conversely, if the device can be used from either the epicardium or endocardium, then more patients could be treated. If the device is rigid, with a fixed shape, then it cannot be used to make lesions of arbitrary shape or size unless access is established to the endocardium and, even then, such lesions may not be possible. A malleable device can be used on any patient and from any approach. If the device emits energy in one direction only ("unipolar"), then there is currently no way to know precisely when an endpoint such as transmurality has been reached. Bipolar clamp devices follow specific algorithms that are designed to stop ablation when transmurality has been achieved.

Ablative Therapy of Lone Atrial Fibrillation

Since its development more than 15 years ago, very few Maze operations have been used for the treatment of lone AF, despite its demonstrated efficacy and safety. This lack of enthusiasm has been largely due to its invasiveness, its risks, and the daunting prospect of a prolonged recovery from open-heart surgery. In an effort to make ablative therapy more palatable to patients and referring physicians, surgeons have been making significant efforts at miniaturizing the Maze procedure, mostly through the use of small access incisions and alternative ablative technologies, such as those discussed earlier. This is a worthwhile goal because it is quite unlikely that the total number of concomitant ablations will ever exceed 40,000 annually (totaling the number of patients with coronary disease and/or valve disease who present in the operating room with AF), whereas there are more than 2 million people suffering with AF in the United States alone.

Currently, fewer than 0.1% of patients with AF receive any form of nonpharmacologic therapy, and it remains unknown exactly how many patients with lone AF might benefit from ablation. However, the case for treating these patients early in their course is easy to defend. Cure rates with pharmacologic therapy have been disappointing and AF is clearly a progressive disease. Between 5.5% and 8.6% of patients who are newly diagnosed with paroxysmal AF progress to more permanent forms over the next 5 years.[48, 49] Because the treatment of AF is much simpler in its paroxysmal stage and because patients are likely to be healthier overall, an ablative treatment offered early would provide them with a safe and lifelong cure.

Less Invasive Procedures

The key to enhancing the adoption of any new procedure is the avoidance of the sternotomy incision. Performing the ablation on the beating heart without the use of cardiopulmonary bypass is desirable although less important. Growing experience and sophistication with minimally invasive surgical techniques have helped with the emergence of two procedures that fit this criterion. One technique uses small thoracotomies and a bipolar RF clamp device, whereas the other employs fully endoscopic methods with a microwave or laser device.

Wolf and associates first described the use of small bilateral thoracotomy incisions and video-assisted methods to electrically isolate the PVs with a bipolar clamp device.[50] Through a 5-cm working incision and two ancillary 10-mm ports, these surgeons were able to surround and electrically isolate the PVs on one side of the heart and then repeat the procedure on the contralateral side for the other PVs. They reported their results in 23 patients followed for more than 3 months with 91% freedom from AF. No complications were reported. The main advantage of this technique is the use of the bipolar clamp device, which has good transmurality feedback guiding lesion creation. It also provides access for managing the left atrial appendage. The main disadvantage is that the procedure can perform only PV isolation. The clamp device cannot connect the PV "loop" lesions to each or perform any other linear lesions without opening the left atrium. The operation also requires repositioning the patient and essentially conducting two separate operations, one on each side of the chest, to obtain full access.

The first procedure employing bilateral simultaneous thoracoscopy was developed and reported by Saltman and colleagues using the Flex 10 microwave device.[51] This completely endoscopic procedure avoids open incisions in the chest, and instead employs port access techniques, varying between 5 mm and 12 mm each. It has been modified by several other surgeons[52] and has now also been used with the OptiWave laser device manufactured by Edwards Lifesciences.

The originally described procedure used six ports, three into the right pleural space and three into the left. The port configuration is shown in Figure 22–4. The most critical part of the procedure is to establish access posterior to the left atrium and to surround the PVs with the ablation device. This is done first through the right pleural space. The right side of the left atrium is accessed through a vertical pericardiotomy, extending from the aorta to the diaphragmatic fat pad, as shown in Figure 22–5. The transverse and oblique sinuses are then entered from the right side using common endoscopic dissecting instruments to remove the fold of pericardium protecting them. Once the sinuses are entered, the Flex 10 ablative element is introduced using guide catheters (Fig. 22–6). The guide catheters are generally not threaded completely around the heart from the right-sided approach because of the possibility of entrapping the left atrial appendage. Rather, they are left in place and retrieved from a left-sided vantage point. If the Flex 10 were to remain medial to the appendage, the proximal circumflex coronary artery would be endangered and the PVs would not be surrounded.

After the guide catheters are positioned, the right lung is inflated and the left lung is deflated. The pleural space is accessed through the ports as indicated in Figure 22–4. The left side of the heart is accessed through a small left pericardiotomy. The guide catheters are retrieved and the final positioning of the device is assured under direct vision by drawing it around the heart under traction. Once the ablation element is in position, it is activated sequentially to create a completely encircling lesion around the PV pedicle and the posterior LA wall. This typically requires 7 to 10 energy applications at 65 W and 90 seconds each. Once the PV pedicle has been isolated, the Flex 10 is withdrawn from the posterior pericardium and placed against the lateral wall of the left atrial appendage such that a lesion is created extending from the transverse sinus out to the tip of the appendage. This requires another 1 or 2 energy applications. The Flex 10 is then either withdrawn from the chest entirely (for treating paroxysmal AF) or access is reestablished from the right side to create right atrial lesions (for treating permanent AF). After the Flex 10 has been withdrawn, the left atrial appendage is removed by stapling with an automatic endoscopic stapler (SurgASSIST, Power Medical Interventions, New Hope, PA). Obliteration of the appendiceal stump is confirmed by transesophageal echocardiography (TEE) guidance. Figure 22–7 shows the intermediate-term success rates for maintaining sinus rhythm.

Ganglionated Plexuses

There has been a great deal of interest in the role of atrial autonomic innervation and its role in the genesis and perpetuation of AF.[53,54] The Oklahoma group has shown that

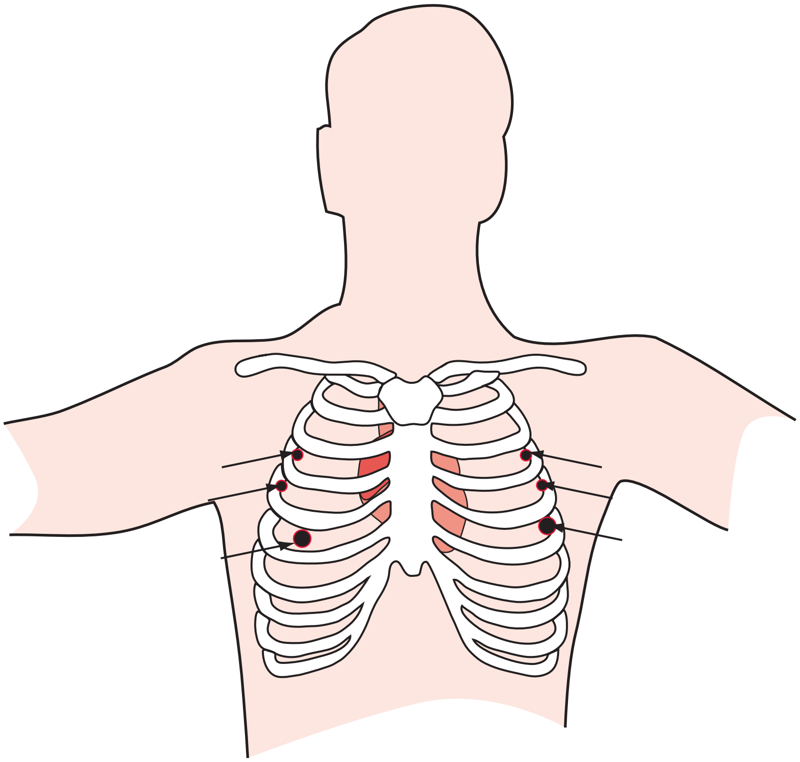

Figure 22–4 Position of thoracoscopic port access points on the chest wall (*arrows*). Typically, six access sites are used: Four 5-mm ports are inserted between the third and fourth intercostal spaces in the anterior axillary line behind the pectoral fold on either side of the chest and two 12-mm ports are inserted between the fifth and sixth intercostal spaces. On the right side of the chest, this lowermost port is located in the anterior axillary line; on the left side it is located in the posterior axillary line to permit optimal positioning of the endoscopic stapler.

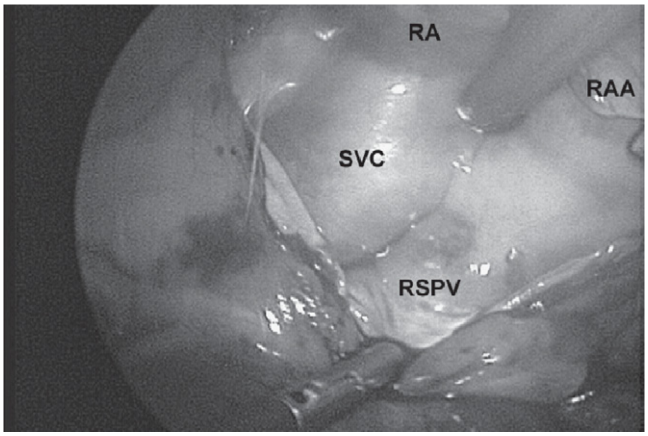

Figure 22–5 Intraoperative photograph taken during thoracoscopic exposure of the right side of the heart. After pericardiotomy, the right-sided structures are exposed, as indicated by labels. For orientation, the patient's head is located to the left of the photograph. (Ao, aorta; RA, right atrial free wall; RSPV, right superior pulmonary vein; SVC, superior vena cava.)

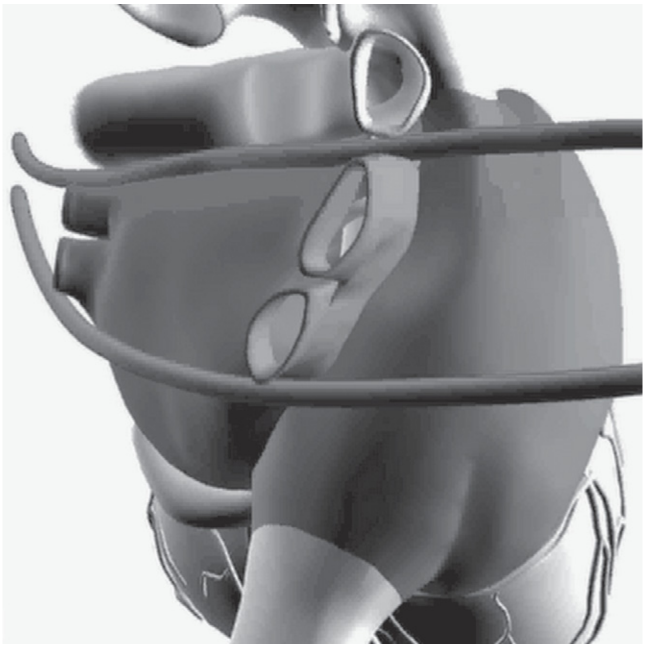

Figure 22–6 Illustration of rubber catheters being placed behind the heart, through the transverse sinus (superiorly) and the oblique sinus (inferiorly) from right to left direction. The catheters are used to guide and position the microwave ablation device completely around the pulmonary vein pedicle.

directed ablation of the ganglionated plexuses located on the epicardial surface of the atrium can increase success at achieving sinus rhythm from 70% to 91%.[55] The exact role of the plexuses, however, is not yet clear and remains the topic of active research; in fact, the concept of controlling AF by ablating them is not new. It is also not yet known how best to ablate them; although it appears that less energy and lower tissue temperatures will be required to destroy the plexuses, thereby being a theoretically safer procedure than full-thickness, transmural muscle ablation.

The ability of minimally invasive epicardial approaches to visualize, test, and ablate the plexuses effectively gives them a significant advantage over endocardial, catheter-based methods. Ablation over the plexuses can be accomplished easily (almost automatically) with a flexible encircling probe;

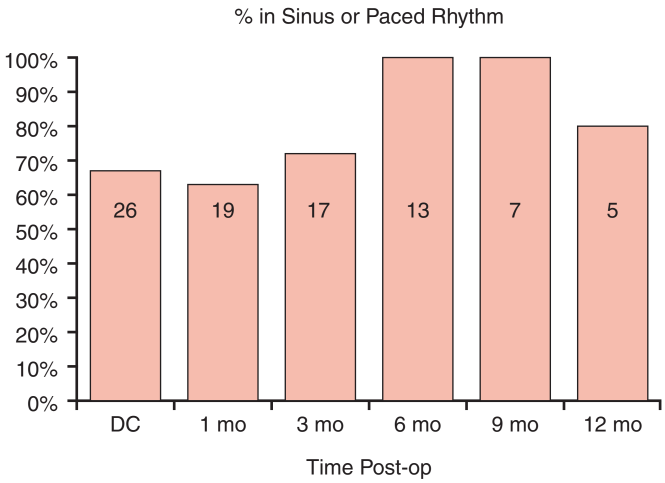

Figure 22–7 Percentage of patients achieving freedom from atrial fibrillation on routine ECG after endoscopic microwave ablation, as measured from time of operation. DC, hospital discharge.

in contrast, plexus destruction with a bipolar clamp is not possible and requires adjunctive measures such as bipolar forceps coagulation.

Hybrid Procedures and the Future

Although the early results of these minimally invasive procedures appear promising, there are clearly some problems that may permanently hinder complete success. Foremost among these is the general inability of any epicardial method to create a lesion from the PVs toward and including the mitral valve annulus. This lesion has long been believed to be critical at preventing atypical left atrial flutter from appearing, but has been shown in a series of concomitant ablation cases to enhance long-term success.[56]

Considering the amount of fatty tissue located epicardially to the mitral annulus, as well as the fact that vascular structures such as the coronary sinus and terminal branches of the left circumflex coronary artery traverse the same region, it is doubtful that ablation from the epicardium will ever be safe or even possible. Ablation from the endocardial surface, however, has been performed often in the electrophysiology laboratory and in the operating room without adverse experiences. Therefore, it is logical to assume that the best approach to the mitral annular lesion would be endocardial, given current technology. Perhaps in the near future the PV isolation and LA appendage management could be carried out from the epicardium and the mitral annular lesion would be created from the endocardium.

Before such a simultaneous, combined approach can be widely adopted, it must balance the risk of failure to prevent AF without the mitral annular lesion against the risk of the left-sided catheter-based approach (transseptal puncture, intracardiac imaging, cardiac chamber perforation, thromboembolism, atrioesophageal fistula, and so on). For example, if 80% to 90% of patients would be cured without the mitral lesion, is it justified to perform many unnecessary catheter ablations? Or should only those patients who show failure after 3 to 6 months of follow-up have a mitral lesion added?

Chapter 23

Acute and Chronic Pharmacologic Management of Supraventricular Tachycardias

J. Michael Mangrum, John D. Ferguson, and John P. DiMarco

CHAPTER CONTENTS

Drug therapy remains an important component in both the short- and long-term management of patients with supraventricular tachycardias. The appropriate use of drugs in these patients requires an understanding of the electrophysiologic mechanisms and pathways responsible for each particular arrhythmia, the pharmacology of the tissue or tissues involved, and the properties of the drugs themselves. Drugs may be used both as immediate therapy to terminate episodes of tachycardia or in chronic prophylactic therapy to maintain sinus rhythm long term. The most common supraventricular tachycardias involve reentry over a single circuit, and a very short duration of drug effect may be all that is necessary to break the tachycardia episode. Prophylaxis of recurrent arrhythmias requires a different strategy than that for termination. In reentrant arrhythmias, complete and permanent conduction block in the circuits involved is achievable only rarely, and if the tissue is required during normal conduction, fixed block may not be desirable. Effective strategies may include facilitation of early termination via rate-related block in the atrioventricular (AV) node, drug-induced changes in conduction times, or production of block only in abnormal, nonvital conduction pathways. Long-term suppression of automatic arrhythmias often requires approaches to eliminate or modify precipitating stimuli or to suppress or eliminate selectively the responsible tissues. This chapter deals primarily with therapy for paroxysmal supraventricular tachycardia (PSVT) and atrial flutter.

PHARMACOLOGY OF SUPRAVENTRICULAR TACHYCARDIAS

Drug therapy of supraventricular arrhythmias is typically based on the concept of a "vulnerable parameter" that can be the primary target of drug action.[1] The sinus node and the AV node have calcium-mediated action potentials and are more sensitive to direct effects of calcium channel blockers and adenosine and indirect (autonomically mediated) effects of adenosine, β-adrenergic blockers, or cardiac glycosides. Atrial muscle will have conduction depressed by sodium channel blockers and refractory periods prolonged by potassium channel blockers. Enhanced or abnormal automaticity in atrial muscle may be due to many mechanisms; therefore adenosine, β-adrenergic antagonists, calcium channel blockers, and sodium channel blockers may all be effective in selected cases. Most accessory pathways have electrophysiologic properties similar to those of atrial or ventricular muscle. Conduction and refractory periods of accessory pathways are most susceptible to sodium and potassium channel blockers, but some pathways sensitive to adenosine have been described. Although there are limitations to the Vaughan Williams classification of antiarrhythmic drugs,[2] it may still be useful as a general guide for the selection of drug therapy (Table 23–1 and Appendix 1, Cardiovascular Drugs: Comprehensive Drug Tables).

EVALUATION OF THERAPY

Several types of studies have been used to establish the effectiveness of drug therapy in patients with supraventricular arrhythmias. The most reliable studies are randomized trials comparing the study drug with either a placebo control or a second active agent. The range of doses studied during the course of drug evaluation should include both minimally and maximally effective doses. When two agents are compared, it is important that each drug be tested at doses expected to produce a maximal or near-maximal response.

For acute termination of an episode of tachycardia, the efficacy of a drug is relatively easy to evaluate. Patients presenting with an appropriate arrhythmia are entered into the trial. Both spontaneous and stimulation-induced episodes of arrhythmia may be included. After an observation period to establish stability of the tachycardia, the patient is administered one or more doses of the drug under study or the active or inactive control. Total response is determined by the proportion of episodes converted within a specified period of time. The maintenance of normal rhythm after conversion for some specified period of time can serve as a secondary endpoint.

The prevention of arrhythmia induction in an electrophysiologic study during drug therapy is rarely used as an endpoint in patients with supraventricular arrhythmias for several reasons. First, radiofrequency ablation has become pri-

Table 23–1 Drug Actions in Supraventricular Arrhythmias

mary therapy for many supraventricular arrhythmias owing to its high success rate and low complications. The administration of a drug that blocks conduction in the target tissue during the study might interfere with the primary goal of the procedure. Second, the role of autonomic nervous system influences on arrhythmia initiation and maintenance may be profound, and in many cases, changes in autonomic tone can override drug effects.[3] Additionally, protocols for the initiation of supraventricular tachycardias and the correlations between changes in response to stimulation and clinical efficacy are not well established.

Most of the common forms of PSVT are now treated with catheter ablation when that modality is available. Therefore, there are only limited contemporary data about chronic drug therapy for common varieties of PSVT. When placebo-controlled studies have been performed, they usually have used endpoints such as the total number of episodes and the time to first recurrence.[4,5]

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA

Paroxysmal supraventricular tachycardia (PSVT) is a common arrhythmia with a prevalence of about 2.5 per 1000 adults.[6-8] PSVT in the absence of structural heart disease can manifest at any age but most commonly first occurs between ages 12 and 30 years. In most patients, PSVT due to atrioventricular nodal reentrant tachycardia (AVNRT) or atrioventricular reentrant tachycardia (AVRT) is not causally associated with structural heart disease although exceptions exist (e.g., Ebstein's anomaly, familial preexcitation with cardiomyopathy). Atrial tachycardias may occur either in structurally normal or abnormal hearts. In normal patients, the physical examination during PSVT is significant mainly for the rapid heart rate. Prominent jugular venous pulsations due to atrial contraction against closed AV valves may be a clue that AVNRT is the mechanism. The patient's history, physical examination, and ECG constitute an appropriate initial evaluation. Further diagnostic studies are indicated only if signs or symptoms that suggest structural heart disease are present.

MECHANISMS OF PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA

Figure 23–1 schematically illustrates the common forms of PSVT.[7] The AV node sits in the triangle of Koch in the floor of the right atrium. Separate pathways, characterized by their conduction velocities as fast or slow, provide input into the AV node. If these pathways have different refractory periods, reentry using one pathway for anterograde conduction and one for retrograde conduction may occur. The P wave position during AVNRT depends on the types of pathways used. In the most common form, slow pathway—anterograde, fast pathway—retrograde, the P wave is either not seen or is visible

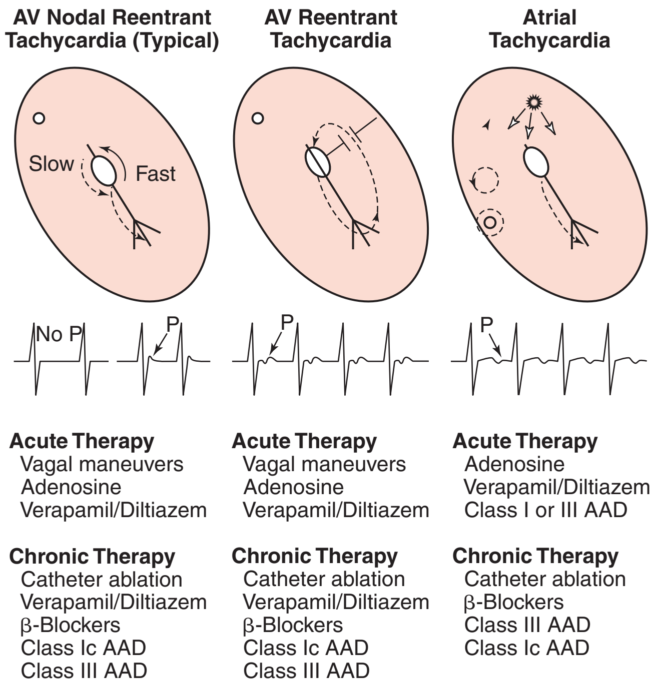

Figure 23–1 Schematic illustration of the common forms of PSVT. AV, atrioventricular, AAD, antiarrhythmic drug. (Adapted from Ferguson JD, DiMarco JP: Contemporary management of supraventricular tachycardia. Circulation 2003;107:1096-9.)

in the terminal portion QRS. If two slow pathways or if a fast anterograde and slow retrograde pathways are used, the RP' interval will either be short or long, respectively. Although uncommon, AV block is possible during tachycardia if the block occurs distal to the turnaround point where the pathways join.

In AVRT, an extranodal accessory pathway connects the atrium and ventricle. Accessory pathways may exhibit both anterograde and retrograde conduction, or either only antegrade (uncommon) or retrograde conduction. In the latter situation, the pathway is called a "concealed" pathway. When the pathway manifests anterograde conduction, a delta wave will be present on the surface ECG, and a diagnosis of Wolff-Parkinson-White syndrome is made if the patient has PSVT. Accessory pathways usually manifest rapid AV conduction with no change in conduction velocity over a range of cycle lengths, but a minority of pathways may manifest slower conduction with a decreased velocity at faster rates. The most common form of AV reentry, orthodromic AVRT, uses the accessory pathway as the retrograde limb and the AV node-His as the anterograde limb, resulting in a narrow QRS. Functional or fixed bundle branch block, a reversal of the circuit (antidromic AVRT), or the presence of two accessory pathways can lead to a wide QRS complex during PSVT owing to AV reentry. Accessory pathways can also conduct as passive bystanders during AVNRT or atrial tachycardias, but these patterns are uncommon. In AVRT the ventricle is an obligate part of the circuit, and thus AV block cannot occur.

Atrial tachycardia is the least common form of PSVT in normal individuals but may predominate in patients who have significant atrial scarring, especially those who have undergone earlier atrial surgery. Atrial tachycardias may be due either to enhanced or triggered automaticity or to reentry. Because the AV node and ventricle are not required participants in the arrhythmia, AV block commonly occurs if there is a short atrial cycle length. The PR or apparent RP' intervals depends on the response of the AV conduction system to the atrial rate. P wave morphology depends on the site of origin in the atrium. If the site of origin is within or involves the sinus node region, the terms sinus node reentrant or inappropriate sinus tachycardia are often applied.

Management of Acute Episodes of Paroxysmal Supraventricular Tachycardia

PSVT rarely is so poorly tolerated that it requires immediate termination with electrical cardioversion. Most episodes can be managed with physiologic maneuvers or drugs. The most common types of PSVT require intact 1:1 AV nodal conduction for continuation and are classified as AV nodal-dependent tachycardias. Because the refractory period of the AV node may be modified by vagal maneuvers and by many pharmacologic agents, and because prolongation of AV nodal refractoriness can lead to transient block, AV nodal conduction is the "weak link" targeted by most acute therapies.

Many patients learn to terminate acute episodes of PSVT by employing vagal maneuvers early during the episode. Valsalva is the most effective technique for adults, but carotid massage may be effective.[6] Facial immersion is the most reliable method for infants. Vagal maneuvers are less effective once a sympathetic response to PSVT has become established; therefore patients should try them soon after onset.

Oral antiarrhythmic drug tablets are not reliably absorbed during rapid PSVT,[9] but some patients may respond to self-administration of crushed medications. In one small study,[10] a combination of diltiazem (120 mg) plus propranolol (80 mg) was shown to be superior to placebo and flecainide (about 3 mg/kg). Hypotension and bradycardia after termination are rare complications of this approach in otherwise healthy individuals, and the need for parenteral therapy may be eliminated.

Adenosine and the non-dihydropyridine calcium antagonists, verapamil and diltiazem, are the intravenous drugs of choice for termination of PSVT.[6,7] Adenosine is an endogenous purine nucleoside that slows AV nodal conduction and results in transient AV nodal block when administered during an episode of PSVT (Fig. 23–2).[11] Conduction in rapidly conducting accessory pathways is not affected by adenosine, but pathways with long refractory periods or slow conduction may exhibit block. Exogenous adenosine is cleared extremely rapidly from the circulation by cellular uptake and metabolism with an estimated half-life of <5 seconds. Adenosine effect is typically seen 15 to 30 seconds after rapid peripheral infusion as a first-pass effect. Administration via a central line requires dose reduction. The effective dose range in adults is 2.5 to 25 mg. If no upper dosage limit is imposed, at least transient termination of AV node-dependent PSVT can be produced in all patients. The recommended adult dosage is 6 mg followed, if needed, by a 12-mg dose. In pediatric patients, the

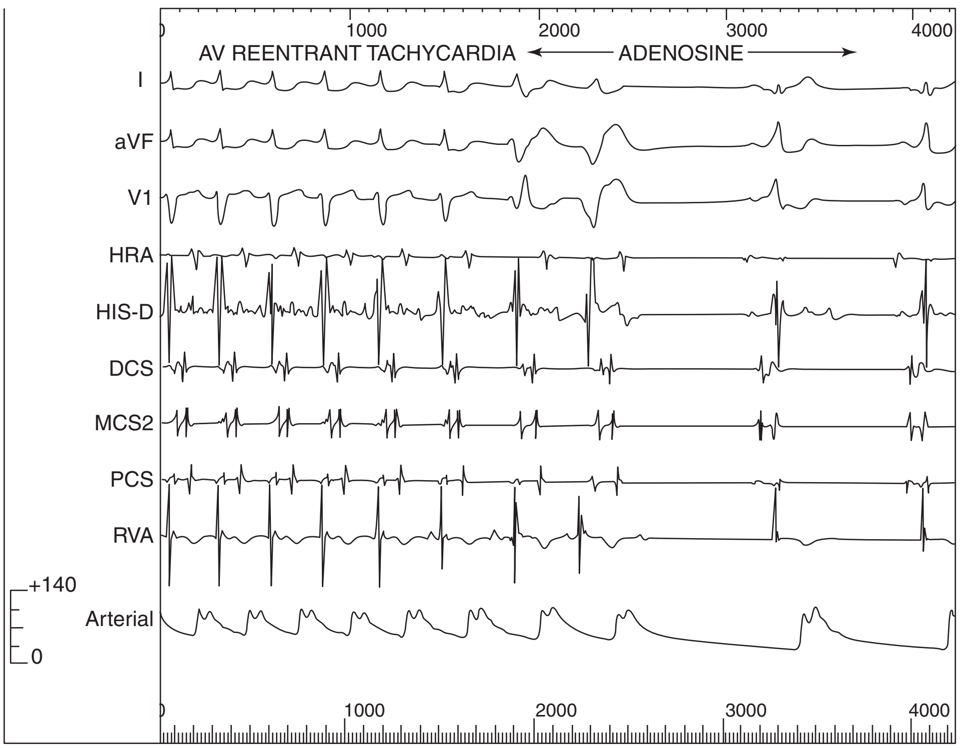

Figure 23–2 Termination of AV reentrant tachycardia with adenosine. The tracings (*from top to bottom*) represent ECG leads 1, aVF and V_1, intracardiac recordings from the high right atrium (HRA), the distal bundle of His (HIS-D), the distal, mid, and proximal coronary sinus (DCS, MCS2, and PCS) and the right ventricular apex (RVA), a femoral arterial pressure and time lines. Adenosine, 6 mg, was infused several seconds before this recording. Note that the tachycardia breaks as AV conduction blocks without a decrease in blood pressure. The first beats after termination show preexcitation over a left-sided accessory pathway.

dose range is 50 to 250 mcg/kg using an upward dose titration. Because of the ultrashort duration of action, cumulative effects of sequential doses are not seen.

Minor side effects that include transient dyspnea or chest pain are common with adenosine. Sinus arrest or bradycardia may occur but resolves quickly if appropriate upward dose titration is used. Atrial and ventricular premature beats are frequently seen with PSVT termination. A few patients with adenosine-induced polymorphic ventricular tachycardia and ventricular fibrillation have been reported.[11,12] The majority of these patients had long baseline QT intervals during tachycardia and had long pauses during adenosine-induced AV block that led to bradycardia-dependent polymorphic VT. Adenosine shortens the atrial refractory period, and atrial ectopy may induce atrial fibrillation. (Fig. 23–3) This may be a dangerous situation if the patient has an accessory pathway capable of rapid anterograde conduction. Because adenosine is cleared so rapidly, re-initiation of PSVT after initial termination may occur. Repeat administration of the same dose of adenosine or substitution of a calcium channel blocker (see later) is likely to be effective.

Adenosine mediates its effects via a specific receptor cell surface receptor, the A_1 receptor. Theophylline and other methylxanthines block the A_1 receptor. Caffeine levels seen after beverage ingestion do not usually interfere with the effect of adenosine. Dipyridamole blocks adenosine elimination, thereby potentiating and prolonging its effects. Cardiac transplant recipients are also unusually sensitive to adenosine. If adenosine is chosen in the latter situations, much lower starting doses (i.e., 1 mg) should be selected.

The AV-node action potential is calcium channel-dependent, and the non-dihydropyridine calcium channel blockers, verapamil and diltiazem, are very effective for terminating AV node-dependent PSVT.[7,11,12] The recommended initial dosage of verapamil is 5 mg intravenously over 2 minutes, followed in 5 to 10 minutes by a second 5 to 7.5 mg dose. The recommended initial dosage of diltiazem is 20 mg followed, if necessary, by a second dose of 25 to 35 mg. PSVT termination should occur within 5 minutes of the end of the infusion, and more than 90% of patients with AV node-dependent PSVT respond to the dosages just listed.

As with adenosine, transient arrhythmias that include atrial and ventricular ectopy, atrial fibrillation and bradycardia may be seen after PSVT termination with calcium channel blockers. Persistent hypotension may occur with calcium channel blockers, particularly if the PSVT does not terminate. Calcium channel blockers are not recommended in infants and neonates with PSVT owing to reports of cardiovascular collapse.[13] Extreme bradycardia after PSVT termination can be seen if calcium channel blockers are given to a patient who has just been loaded with an intravenous β-adrenergic blocker. Adenosine and verapamil have been shown to have equivalent efficacy in several randomized clinical trials.[14-16] Most PSVT patients can be acutely managed with either agent (Table 23–2). To minimize the potential for adverse effects, adenosine should be selected for patients with severe hypotension or heart failure, for infants and neonates, and for those at risk for severe bradycardia. Verapamil and diltiazem should be chosen for patients with poor venous access, for patients with bronchospasm, and for those on agents that interfere with adenosine action or metabolism. Patients with more than a single recurrent episode may do better on a calcium channel blocker compared with multiple bolus injections of adenosine.

AV node-dependent PSVT can manifest with a wide QRS complex in patients with fixed or functional aberration or when an accessory pathway is used for antegrade conduction. However, most wide complex tachycardias are due to mechanisms that may worsen after IV administration of adenosine and calcium channel blockers. Unless there is strong evidence

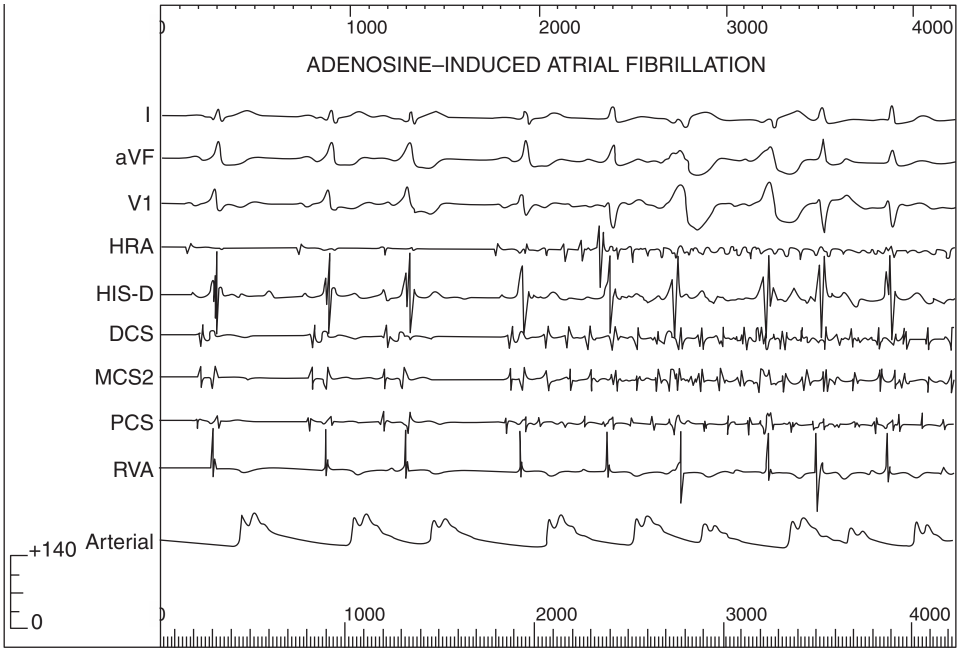

Figure 23–3 Adenosine-induced atrial fibrillation. The tracings are also from the patient shown in Figure 23–2 and were recorded about 15 seconds later. Atrial fibrillation occurs and conduction over both the accessory pathway and the normal conduction system during atrial fibrillation is seen.

Table 23–2 Acute Therapy for PSVT

Adenosine Preferred	Neutral	Calcium Blocker Preferred
Neonates	Routine PSVT	Poor IV access
Hypotension	Central line*	Dipyridamole*
Uncertain diagnosis		Transplant*
Prior IV β-blocker		Theophylline

*Dose reduction for adenosine required.
IV, intravenous; PSVT, paroxysmal supraventricular tachycardia.

that a wide QRS tachycardia is AV node-dependent, test doses of adenosine, verapamil, or diltiazem should not be used.

There are only limited data on the acute pharmacologic therapy of atrial tachycardias.[17] Automatic or triggered atrial tachycardias and those due to sinus node reentry are likely to terminate with adenosine, verapamil, diltiazem, or β-adrenergic blockers. Tachycardias caused by scar-related atrial reentry are more likely to manifest AV block with an unchanged atrial cycle length after administration of these agents.

A selective adenosine A_1 receptor agonist, tecadenoson (CVT-510), is currently undergoing clinical studies.[18,19] This agent can terminate acute episodes of AV nodal-dependent PSVT and may be associated with fewer side effects because it avoids the vasodilatation and bronchoconstriction that can be seen with adenosine itself.

Chronic Therapy of PSVT

Patients with well-tolerated episodes of PSVT, that always either terminate spontaneously or can be broken quickly and reliably by the patient, do not require chronic prophylactic therapy. Selected patients may be treated only for acute episodes as mentioned earlier. For other PSVT patients, either catheter ablation or chronic drug therapy may be appropriate. Current guidelines consider catheter ablation to be the treatment of choice for patients with more than minimal symptoms.[6] Previously asymptomatic patients with preexcitation may also benefit from ablation if they have inducible PSVT at electrophysiologic study.[20] A treatment algorithm we follow is shown in Figure 23–4.

Pharmacologic Therapy

For AV node-dependent PSVT, calcium channel blockers and β-adrenergic blockers will improve, but rarely totally eliminate, symptoms in 60% to 80% of patients.[8,9] Flecainide (50 to 100 mg twice daily) and propafenone (150 to 300 mg twice daily) have effects on both the AV node and the accessory pathways and will also reduce episode frequency.[21,22] These agents can be used safely if patients with ischemic heart disease and/or congestive heart failure are excluded from therapy.[23] Sotalol (80 to 320 mg daily in divided doses), dofetilide (125 to 500 mcg twice daily), and amiodarone (100 to 200 mg daily) should be considered second-line agents.[6] Because sympathetic stimulation can antagonize the effects of many antiarrhythmic agents, concomitant therapy with a β-adrenergic blocker may improve clinical efficacy.

Pharmacologic treatment strategies for atrial tachycardias have not been well evaluated in controlled clinical trials. Depending on the mechanism responsible for the arrhythmia, β-adrenergic blockers, calcium channel blockers, and class I or class III antiarrhythmic drugs may reduce or eliminate symptoms. Scar-related atrial tachycardias, particularly those associated with earlier surgery for congenital heart disease, may be particularly difficult to control. In selected patients, it may be necessary to use AV nodal blocking agents to control ventricular rates during ongoing tachycardia.

Atrial Flutter

Clinical investigations during the last 15 years in patients with atrial flutter have greatly expanded our understanding of this relatively common arrhythmia.[6] In atrial flutter, the ECG will

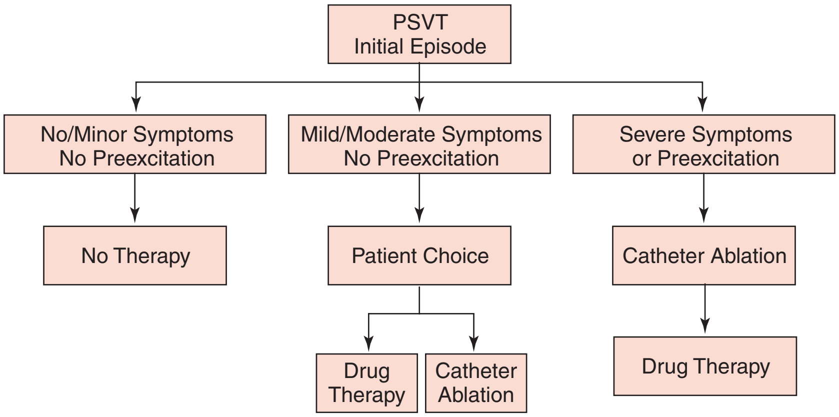

Figure 23–4 Algorithm for the management of paroxysmal supraventricular tachycardia (PSVT).

show an organized atrial rhythm at a rate of 300±50 beats per minute. Patients with atrial flutter share many characteristics with patients with atrial fibrillation, and many patients will manifest both arrhythmias. In most cases, atrial flutter is due to reentry over a large, well-defined circuit within the atria. In classic atrial flutter, a counterclockwise circuit is present in the right atrium, of which the cavotricuspid isthmus forms a crucial portion. In classic or typical atrial flutter, this circuit produces an ECG pattern with negative flutter waves in the inferior leads and a positive atrial deflection in lead V_1. The same isthmus-dependent circuit can also be used in a clockwise fashion with reversal of these ECG findings. Because the atrial cycle length in atrial flutter is less than the refractory period of the AV node, 2:1 or greater block is most commonly seen but 1:1 conduction may be seen if adrenergic tone is high or if the flutter cycle length is relatively slow. Other ECG patterns in atrial flutter may also be observed. Some atrial flutters, although still isthmus dependent, will involve circulation around the inferior vena cava owing to conduction across the *crista terminalis*, a pattern described as "lower-loop reentry."[6,24,25] If the reentry circuit does not involve the cavotricuspid isthmus, the patient is said to have atypical flutter, and a variety of ECG patterns may occur, some of which can mimic the patterns seen in typical atrial flutter.

Atrial flutter can manifest with a wide range of symptoms that are largely dependent on ventricular rate. Some patients may be asymptomatic, despite a ventricular rate of 150 beats per minute and 2:1 AV block. Patients with advanced forms of heart disease may not tolerate atrial flutter even when ventricular rates can be controlled.

Acute Management of Atrial Flutter

Management of the patient who presents with atrial flutter may involve termination of the arrhythmia, ventricular rate control, and steps taken for prevention of thromboembolism. Although data specifically relating to patients with atrial flutter are limited, guidelines for the prevention of embolic events in patients with atrial flutter are the same as those for patients with atrial fibrillation.

As with other arrhythmias, the immediate management strategy for patients with atrial flutter will depend on the clinical situation, the patient's symptoms, and the patient's hemodynamic status. Cardioversion with a direct current shock is highly effective in atrial flutter but is rarely required as an urgent intervention and does not protect against recurrence. Rapid atrial pacing is also quite effective. Stable rate control in atrial flutter is often difficult to achieve because concealed conduction in the AV node is not prominent at the cycle lengths seen in atrial flutter. Intravenous diltiazem and verapamil may slow the ventricular rate, but their effects may be transient and hypotension may complicate therapy.[26-28] Intravenous β-adrenergic blockers and amiodarone may also be used for rate control in critically ill patients. Selected patients with conduction system disease may achieve stable ventricular rates during drug therapy for atrial flutter, but most patients will require termination of the arrhythmia.

Although several antiarrhythmic drugs have been reported to be effective for terminating atrial flutter, the response rates in clinical practice are often disappointing. Class III drugs have been the most successful, presumably because they slow conduction velocity and prevent wavelength shortening.[29] Intravenous ibutilide (1 to 2 mg) is the agent that has been studied most thoroughly. In placebo-controlled trials, ibutilide has shown efficacy rates of 38% to 76%.[30,31] Ibutilide has been shown to be superior to both procainamide and sotalol.[6,30,31] The major problem with ibutilide is a risk of proarrhythmia. About 1% to 2% of patients in clinical trials of ibutilide developed QT prolongation and sustained polymorphic ventricular tachycardia. Nonsustained ventricular tachycardia episodes after ibutilide occur with an incidence of 1.8% to 6.7%. Assessment of serum potassium levels and the QT interval are important steps to take before ibutilide administration. Pretreatment with intravenous magnesium before ibutilide infusion would be a reasonable precaution but has not been systematically studied. Intravenous dofetilide is also quite effective for conversion of atrial flutter but is available now only in an oral formulation.[32] The class Ic agents, propafenone and flecainide, have limited efficacy in atrial flutter,[29] and, should they slow the atrial cycle length, may allow 1:1 AV conduction with a paradoxical increase in ventricular rate.

Long-Term Management of Atrial Flutter

Atrial flutter is less commonly recurrent or persistent than atrial fibrillation. Few data are available that specifically focus on the long-term efficacy of drug therapy for atrial flutter. Long-term rate control may be an option in selected patients who have intrinsic conduction system disease. In most others, concealed conduction in the AV node is not prominent owing to the regularity of the atrial cycle length and, as a result, effec-

tive long-term rate control is usually difficult to maintain.[6] The approach to prophylactic drug therapy in atrial flutter is similar to that used in patients with atrial fibrillation (see Chapter 21). If class Ia, class Ic, or class III drugs are used, AV nodal-blocking agents are usually also prescribed to protect against 1:1 conduction, should atrial flutter recur with a cycle length prolonged by the drug. Dofetilide has been shown to be somewhat more effective in patients with atrial flutter as compared with patients with atrial fibrillation.[32]

As discussed in Chapter 20, catheter ablation of isthmus-dependent atrial flutter is often the therapy of choice for many patients. This procedure, in which a linear ablation line is drawn from the tricuspid valve isthmus to the inferior vena cava and/or eustachian valve, is highly (more than 90%) successful in the short term. Although early recurrence rates were found to be high when this technique was first employed, this was probably due to incomplete lesions that failed to produce complete bidirectional isthmus block. Current techniques have reduced the incidence of recurrence of typical atrial flutter after the initial ablation procedure. However, many patients, particularly those who have associated structural heart disease, will remain at risk for developing atrial fibrillation despite a previously successful ablation for atrial flutter.[33,34]

Multifocal Atrial Tachycardia

Multifocal atrial tachycardia is characterized by three or more distinct P wave morphologies at an irregular rate that ranges from 110 to 180 beats per minute. It is usually associated with a severe underlying illness—often respiratory insufficiency or methylxanthine toxicity. Rate control is difficult because there is little concealed conduction in the AV node, and the patient's background sympathetic tone is often high. β-Adrenergic blockers may slow the rate but are often contraindicated by bronchospasm. Intravenous calcium channel blockers often produce hypotension. High-dose intravenous magnesium has been reported to facilitate conversion, but hypotension and nausea may complicate the effect.[35] Therapy is, therefore, best directed at the underlying disease process. AV junctional ablation and pacemaker insertion may be required for selected patients.

Inappropriate Sinus Tachycardia

Inappropriate sinus tachycardia may be diagnosed when a persistent, nonparoxysmal tachycardia with a P wave morphology identical to that seen in sinus rhythm is present during the waking hours.[36] Secondary systemic causes should be excluded. Typical symptoms include palpitations, dizziness, fatigue, dyspnea, and chest pain. β-Blockers are the usual agents selected initially for therapy, but some patients will respond to verapamil or diltiazem. Total relief of symptoms with drug therapy alone is unusual.

JUNCTIONAL ECTOPIC TACHYCARDIA

This rhythm occurs primarily in infants and children. A congenital form and the more common postoperative form have been described.[37,38] The congenital form usually manifests with congestive heart failure in infancy. The postoperative form is seen after surgery to repair tetralogy of Fallot, transposition of the great vessels, and other forms of complex congenital heart disease. The mechanism for both arrhythmias is believed to be enhanced automaticity in the AV junction proximal to the region that gives rise to the His potential. Because of the incessant nature of the tachycardia and its resistance to cardioversion and most forms of drug therapy, mortality rates are high when the arrhythmia is seen in critically ill postoperative patients. Limited experience with sotalol, propafenone, flecainide, and amiodarone suggests that trials with these drugs are warranted. In addition, total body cooling may be helpful in postoperative patients. However, catheter ablation with permanent pacing, if needed, may be required for patients who fail to respond to drugs.

Chapter 24

Atrial Fibrillation

Peter Zimetbaum and Rodney H. Falk

CHAPTER CONTENTS

Atrial fibrillation (AF) is the most common arrhythmia in clinical practice and, in many ways, the most complex to manage. Our understanding of this disorder has increased immensely in the last decade, and new therapeutic options are developing at a rapid pace. AF is increasingly recognized to be a heterogeneous disease that cannot be managed with a "one-size-fits-all" solution. Instead, the approach to the optimal treatment of a patient with AF requires the clinician to address the underlying heart disease and its interactions with potential therapies, the individual's estimated risk of thromboembolism associated with the arrhythmia, and the presence and severity of arrhythmia-related symptoms. The general physician and the cardiologist treating AF should know when to refer the patient for an electrophysiologic intervention, and the cardiac electrophysiologist should know when to offer one of several invasive approaches.

CLASSIFICATION

AF may be classified by the underlying disease,[1] by the frequency and duration of its occurrence,[2] or by a combination of both. *Paroxysmal* AF is defined as a self-terminating arrhythmia, usually lasting less than 48 hours and rarely more than 7 days. *Persistent* AF is an arrhythmia that fails to convert spontaneously but will do so with intervention (usually cardioversion or drug therapy), and *permanent* AF is an arrhythmia that is resistant to conversion to sinus rhythm. "Permanent AF" is the loosest term of the trio because its definition is, in many cases, dependent on the vigor with which the physician pursues sinus rhythm restoration. To these three terms is added the term "*new-onset* AF" that represents the initial documented event, because the outcome of a first episode of arrhythmia is not known. The "three Ps" are not static categories and may merge with one another over time such as when new-onset and paroxysmal AF become sustained in a significant percentage of patients. The presence or absence of symptoms, their severity, and an assessment of whether they are related to inadequate ventricular rate control or to loss of normal AV synchrony are helpful adjuncts to the classification of AF, but it should be recognized that thromboembolic risk is unrelated to the presence or absence of arrhythmia-related symptoms.

The Decision for Rhythm or Rate Control

A series of randomized controlled trials of rhythm control compared with rate control as treatment strategies have been published.[3-6] These studies were generally conducted in older patients with AF and clinical risk factors for thromboembolism but who were minimally symptomatic. The methods varied and, in most instances, anticoagulation in the rhythm control group was not mandated (although it was commonly used). In the largest of these trials, the AFFIRM study,[6] the primary endpoint was mortality, and the uniform finding of all these studies was that neither strategy was superior to the other in terms of any of the primary endpoints. When a post-hoc analysis was done as to outcomes *by rhythm* (regardless of assigned strategy), the presence of sinus rhythm in the AFFIRM trial favored survival, whereas the presence of coronary disease, diabetes, and/or smoking were adverse factors in terms of mortality rate.[7] To maintain sinus rhythm, however, antiarrhythmic agents generally had to be used, and these were associated with a decreased likelihood of survival, which offset any potential benefit of sinus rhythm. Although this observation might be used to argue that an optimal strategy is sinus rhythm maintenance by nonpharmacologic means, the complexity of this retrospective analysis is such that it should be thought of only as an hypothesis-generating observation and not as a well-supported conclusion. Indeed, a subsequent analysis of the RACE trial data failed to demonstrate any benefit of sinus rhythm over AF.[8] Functional status was slightly better in the AFFIRM trial among patients in sinus rhythm, regardless of assigned group.[9]

The trials of rate versus rhythm control treatment strategy are not the last word in this controversy because large groups of patients including the young and very old, those with congestive heart failure, and those with highly symptomatic AF were underrepresented. As a consequence, there is ongoing debate regarding the relative merits of these two approaches.[10,11]

Regardless of the questions left unanswered by these trials, an important and consistent finding was that stroke risk was not reduced by the strategy of rhythm control when compared with the strategy of rate control and anticoagulation. Although most of the patients in both groups received warfarin, it was stopped more often in the group in which sinus

rhythm had apparently been restored; recurrent sustained or paroxysmal AF in this group was most likely responsible for thromboembolic events. Thus, decisions regarding rhythm versus rate control must not be based on the desire to withdraw or withhold warfarin, because recurrence is common and may be both asymptomatic and paroxysmal, rendering its detection on routine examination difficult. Although the decision to attempt to maintain sinus rhythm or to choose rate control should be an individualized decision based on a careful assessment of clinical and echocardiographic features in each patient, patients with severe symptoms and young age are generally preferred candidates for attempted rhythm control, whereas older patients with minimal symptoms may be equally, if not better, served by a rate control strategy.

Rate Control

In patients with new-onset AF, the average ventricular response is 100 to 150 beats per minute.[12] The irregular R-R intervals are associated with a marked variation in stroke volume,[13,14] and this possibly contributes to the uncomfortable sensation of AF with a poorly controlled heart rate. With stimuli that result either in vagal tone withdrawal or an increase in sympathetic tone such as exertion, fever, hyperthyroidism, or blood loss, the ventricular rate in AF may increase markedly. Thus, a good rule of thumb for the clinician is to ask "If this patient were in sinus rhythm, would he or she have sinus tachycardia?" If the answer is "yes," then the rapid ventricular response may reflect the presence of a condition that will need to be corrected before rate control can be achieved.

For some patients, particularly those with paroxysmal AF, a rapid ventricular response is associated with uncomfortable symptoms, most commonly palpitations or dyspnea.[15] In persistent AF, a disproportionate rise in heart rate with exertion may lead to dyspnea or fatigue.

Pharmacologic Rate Control in Atrial Fibrillation—What Is the Optimal Ventricular Rate?

Control of the ventricular rate in AF has a twofold aim: elimination of symptoms and improvement of cardiac efficiency. As heart rate increases in AF, stroke volume tends to decrease, but cardiac output is generally maintained over a relatively wide range, probably decreasing when mean heart rate exceeds 110 to 120 beats per minute.[16] However, a higher resting heart rate probably is inefficient because it is associated with a higher myocardial oxygen demand. Thus, it is appropriate to attempt to reduce heart rate during AF.

The AFFIRM investigators defined adequate rate control as an average heart rate < 80 beats per minute at rest and either a maximum heart rate <110 beats per minute during a 6-minute walk ***or*** an average heart rate during 24 hours of ambulatory monitoring <100 beats per minute, with no heart rate greater than 110% maximum predicted age-adjusted exercise heart rate.[17] Using this definition, β-blocking agents were the most effective initial drug for rate control, with a 70% success rate if used either alone or with digoxin compared with 54% for calcium channel antagonists and 54% with digoxin alone.[17] These results document in an older population with cardiac disease the apparent superiority of β-blockers. They also show that digoxin alone, although not effective in everyone, still has a role to play in heart rate control in patients with AF. Furthermore, digoxin is synergistic with both calcium channel blockers and β-blockers and may decrease the required dosages of these agents and decrease their associated side effects.[18]

It is also important to recognize that tighter heart rate control based on the number of beats per minute does not necessarily translate into improved symptoms. Although calcium channel antagonists are less effective than β-blockade for heart rate control, trials of β-blockers in patients with sustained AF have failed to show an improved exercise tolerance. Moreover, if peak heart rate is excessively blunted, exercise tolerance may decrease.[19]

Traditionally, when considering agents for ventricular rate control in AF, the discussion is usually separated into β-blocking agents, calcium channel antagonists, and digoxin, as if each of these classes of agents were mutually exclusive (Table 24–1). Although monotherapy may be effective in a significant number of patients, the addition of digoxin and an intermediate dose of a β-blocker or a calcium channel blocker may produce excellent heart rate control, even though a high-dose single agent has failed. Evaluation of information from the AFFIRM trial shows that physicians frequently use a combination of agents for heart rate control and that combination therapy seems to have a greater likelihood of tight rate control compared with monotherapy with any agent.[17] In a small but well-designed crossover trial, it was shown that the addition of digoxin to either diltiazem or to a β-blocker resulted in superior rate control than when any of these agents was used as monotherapy.[18] Caution should, however, be exercised in using such combinations because the negative chronotropic effects of the combination may produce significant sinus bradycardia should sinus rhythm return. If verapamil is chosen, the verapamil-digoxin interaction is likely to necessitate a lower dose of digoxin than would be required if used alone or with diltiazem.[20]

Nonpharmacologic Approach to Rate Control

Interruption of AV nodal function with catheter ablation and concomitant pacemaker implantation is a highly effective strategy for rate control. It is a relatively simple procedure that is associated with a significant and sustained improvement in quality of life.[21] Data suggest, however, that, at least in the setting of impaired ventricular function, right ventricular pacing may be harmful.[22,23] Such a realization has tempered enthusiasm for this procedure except in cases where pharmacologic management proves impossible.

Rhythm Control

The strategy of rhythm control involves the restoration and maintenance of sinus rhythm. AF may spontaneously revert to sinus rhythm or may persist indefinitely unless cardioversion is performed. Spontaneous cardioversion occurs most often within 48 hours of arrhythmia onset.[24] If spontaneous cardioversion does not occur, sinus rhythm can be restored through the use of antiarrhythmic drugs or DC electrical cardioversion. Before cardioversion, appropriate precautions need to be taken to prevent thromboembolic events.

Table 24–1 Pharmacologic Heart Rate Control in Atrial Fibrillation

Drug	Control of Acute Episode	Control of Sustained AF	Comments
Calcium Channel Blockers			
Diltiazem	20 mg bolus followed, if necessary, by 25 mg given 15 min later. Maintenance infusion of 5-15mg/hr	Oral controlled-release diltiazem 180-360 mg daily	Long-term rate control may be better with the addition of digoxin.
Verapamil	5-10 mg IV over 2-3 min repeated once, 30 min later. Maintenance infusion rate is not reliably documented	Slow release verapamil 120-240 mg release once or twice daily	Causes elevation in digoxin level. May have more negative inotropic effect than diltiazem.
β-Blockers*			
Esmolol	0.5 mg/kg IV, repeated if necessary. Follow with infusion at 0.05 mg/kg/min, increasing as needed to 0.2 mg/kg/min	*Not available in oral form*	Hypotension may be troublesome, but responds to drug discontinuation.
Metoprolol	5 mg IV bolus repeated twice every 2 minutes. No data on maintenance infusion	50-400 mg daily in divided doses	Useful if concomitant coronary disease present.
Propranolol	1-5 mg IV (given over 10 minutes)	30-360 mg in divided doses or as long-acting form once daily	Noncardioselective: caution with history of bronchospasm
Digoxin	1.0-1.5 mg IV or PO over 24 hours in increments of 0.25 to 0.5 mg	0.125-0.25 mg daily	Renally excreted. Slow onset of action intravenously, with less effective control than other agents, although may be synergistic with them. Least effective agent, but may be acceptable monotherapy in sedentary patients.

*Several other oral β-blockers have similar efficacy for rate control.
AF, atrial fibrillation; IV, intravenous/intravenously.

Pharmacologic Cardioversion

Intravenous and oral drugs are available for pharmacologic cardioversion (Table 24–2). Pharmacologic cardioversion is most successful when used within 24 to 48 hours of onset of AF.[25] The use of pharmacologic agents for conversion should be followed by electrical therapy if this approach fails. The currently available intravenous agents in the United States are procainamide and ibutilide. The success rate of these agents for the conversion of AF is poorer with procainamide than with ibutilide, and ibutilide is superior for the conversion of atrial flutter than for AF.[26]

Caution must be used when administering these drugs owing to the risk of torsades de pointes (TDP) with either agent (as high as 3% to 5% with ibutilide),[27] and hypotension with procainamide.[26] Patients must be monitored for proarrhythmia for at least 2 hours following the termination of the infusion.

An alternative approach to intravenous therapy is the use of high-dose oral antiarrhythmic drugs for the conversion of AF to sinus rhythm. Quinidine, in an initial dose of 200 mg, repeated in a dose of 200 mg every 2 hours for 3 separate doses, has a high success rate for conversion,[28] but it has fallen into disfavor because of a high incidence of side effects, including TDP.[29] High-dose oral therapy has been widely studied, using high doses of type IC medications (450 to 600 mg of propafenone[30] or 300 to 400 mg of flecainide).[31,32] These drugs should be avoided in patients with bundle branch block, structural heart disease, or ventricular preexcitation. There is a risk of proarrhythmia including atrial flutter with 1:1 AV nodal conduction and hemodynamic collapse, as well as ventricular tachycardia.

The initial administration of these drugs should be in a monitored setting with the capability for defibrillation. If found to be successful without adverse effects, oral therapy can subsequently be used as a self-administered approach by selected patients with a structurally normal heart (the so-called "pill-in-the-pocket" approach).[33] Oral amiodarone has been extensively studied for the conversion of AF. It has been shown to be safe to load during AF in the outpatient setting and is associated with a rate of successful cardioversion of up to 80% after 24 hours in AF of 48 hours duration or less[34] (although the success rate is much lower for arrhythmia of longer duration).[35]

Electrical Cardioversion

Electrical cardioversion for AF can restore sinus rhythm in >90% of instances.[36] Successful cardioversion is defined as the restoration of sinus rhythm if even for only one beat, and it is inversely related to the duration of AF and the size of the left atrium. Biphasic defibrillator waveforms are more successful than monophasic waveforms,[37] and anteroposterior electrode

Table 24–2 Recommended Doses of Drugs Proven Effective for Pharmacologic Cardioversion of Atrial Fibrillation

Drug*	Route of Administration	Dosage†	Potential Adverse Effects
Amiodarone	Oral Intravenous/oral	Inpatient: 1.2 to 1.8 g per day in divided dose until 10 g total, then 200 to 400 mg per day maintenance or 30 mg/kg as single dose Outpatient: 600 to 800 mg per day divided dose until 10 g total, then 200 to 400 mg per day maintenance 5 to 7 mg/kg over 30 to 60 min, then 1.2 to 1.8 g per day continuous IV or in divided oral doses until 10 g total, then 200 to 400 mg per day maintenance	Hypotension, bradycardia, QT prolongation, torsades de pointes (rare), GI upset, constipation, phlebitis (IV)
Dofetilide	Oral	Creatinine Clearance (mL/min) — Dose (mcg BID) More than 60 — 500 40 to 60 — 250 20 to 40 — 125 Less than 20 — Contraindicated	QT prolongation, torsades de pointes; adjust dose for renal function, body size, and age
Flecainide	Oral Intravenous	200 to 300 mg‡ 1.5 to 3.0 mg/kg over 10 to 20 min‡	Hypotension, atrial flutter with high ventricular rate
Ibutilide	Intravenous	1 mg over 10 min; repeat 1 mg when necessary	QT prolongation, torsades de pointes
Propafenone	Oral Intravenous	600 mg 1.5 to 2.0 mg/kg over 10 to 20 min‡	Hypotension, atrial flutter with high ventricular rate
Quinidine§	Oral	0.75 to 1.5 g in divided doses over 6 to 12 h, usually with a rate-slowing drug	QT prolongation, torsades de pointes, GI upset, hypotension

*Drugs are listed alphabetically.
†Dosages given in the table may differ from those recommended by the manufacturers.
‡Insufficient data are available on which to base specific recommendations for the use of one loading regimen over another for patients with ischemic heart disease or impaired left ventricular function, and these drugs should be used cautiously or not all in such patients.
§The use of quinidine loading to achieve pharmacologic conversion of atrial fibrillation is controversial, and safer methods are available with the alternative agents listed in the table.
AF indicates atrial fibrillation; BID, twice a day; GI, gastrointestinal; and IV, intravenous.
Adapted from ACC/AHA/ESC: Guidelines for the management of patients with atrial fibrillation. Circulation 2006;114:e257-e354.

positioning is somewhat more successful than anterolateral placement, although this is not a consistent finding.[38,39] The immediate reversion to AF after either a single beat of sinus rhythm or seconds to minutes of sinus rhythm occurs in about 12% of patients[40] and is termed the early recurrence of AF (ERAF[41]). It may be prevented by antiarrhythmic drugs such as ibutilide.[42,43]

If cardioversion fails at the maximum energy output of the device, a second shock at the same energy level a minute or so later may succeed because the level of transthoracic impedance falls with each shock. Alternatively, a change to another orientation will occasionally be successful. Application of pressure to the anterior electrode will also diminish the transthoracic impedance and improve success rates.[44] Finally, pretreatment with an intravenous or oral antiarrhythmic drug can facilitate cardioversion by lowering defibrillation thresholds and reducing early recurrence of AF.[42,43]

MAINTENANCE OF SINUS RHYTHM

Pharmacologic Approaches

Antiarrhythmic drugs are widely prescribed for the maintenance of sinus rhythm. In general, these agents have a similar efficacy, with about a 50% rate of recurrence of symptomatic AF at 1 year compared with about 20% to 25% maintenance of sinus rhythm in the absence of antiarrhythmic drugs. Amiodarone has consistently been shown to be more efficacious than other available antiarrhythmic drugs with a 75% rate of AF suppression at 1 year.[45] If one agent fails to maintain sinus rhythm, a second agent may be successful, particularly one from another group of drugs.[46] It is unrealistic to expect complete suppression of AF with any of these agents. Instead, the goal should be a significant reduction in the frequency of AF compared with pretreatment patterns.

Table 24–3 Antiarrhythmic Drugs, Dosages, and Toxicities

Drug	Dose (24hr)	Cardiac Toxicity	Noncardiac Toxicity	Recommended Monitoring and Drug Interactions
Amiodarone	200-400 mg (initial load 600-1200 mg for 1-2 weeks). Choose lower dosing for smaller and older patients	Bradycardia, TDP (rare)	Pulmonary toxicity,* photosensitivity, hepatic toxicity,* GI upset and neurologic toxicity (dose related), thyroid dysfunction,* Rise in INR with warfarin	LFTs q 6 months PFTs at baseline and only with symptoms of potential toxicity CXR yearly TFTs: baseline, 3 mos, then q 6 mos. Potentiates warfarin, digoxin, dilantin, tricyclics
Dofetilide	500-1000 mcg	TDP	NS	In-hospital initiation for 72 hrs, creatinine clearance q 3 months QT interval. Levels increased by multiple drugs (e.g., verapamil)
Sotalol	160-320 mg	TDP, CHF, sinus bradycardia	Bronchospasm	QT interval
Flecainide	200-300 mg	Ventricular tachycardia, atrial flutter with 1:1 conduction	Dizziness	NS
Propafenone	450-900 mg	Ventricular tachycardia, atrial flutter with 1:1 conduction	Metallic taste	NS
Quinidine	600-1500 mg	TDP, enhanced AV nodal conduction	Thrombocytopenia, fever, nausea, diarrhea	QT interval Platelet count Will increase digoxin levels Can potentiate warfarin
Procainamide	1-4 g	TDP	Agranulocytosis, lupus-like syndrome	QT interval NAPA increased by ethanol
Disopyramide	400-750 mg	TDP, CHF	Urinary retention, dry mouth, contraindicated if existing glaucoma	QT interval

AV, atrioventricular; CHF, congestive heart failure; CXR, chest x-ray; GI, gastrointestinal; INR, International Normalized Ratio; LFTs, liver function tests; NAPA, *N*-acetyl procainamide; NS, not significant/not stated; PFTs, pulmonary function tests; TDP, torsades de pointes; TFT, thyroid function tests.

The major toxicities of antiarrhythmic drugs include both proarrhythmia and noncardiovascular adverse effects. The noncardiovascular toxicities differ by drug and range from benign changes in taste to life-threatening pulmonary or liver toxicity (Table 24–3). Antiarrhythmic drugs alter cardiac sodium and/or potassium channel function either to slow conduction (sodium channel blockers) or to prolong the refractory period (potassium channel blockers).[47] Prolongation of the refractory period (prolongation of repolarization) results in QT prolongation, which may be excessive if dosing is too high; if excretion is reduced, if there is a genetic predisposition to a prolonged QT or if the patient has genetically prolonged drug metabolism.[48] Prolongation in conduction such as that produced by the IC agents causes QRS prolongation, which is more marked at faster heart rates.[49] QT prolongation may result in TDP,[49,50] and antiarrhythmic drugs that block the delayed rectifier potassium channel (IK_r and/or IK_s) may cause TDP in up to 5% of patients.[49] Drug-related TDP is more likely to occur in association with slow heart rates, electrolyte abnormalities (hypokalemia or hypomagnesemia), female gender, unrecognized congenital long QT syndrome, and pauses associated with the conversion of AF to sinus rhythm.[51] The concomitant use of drugs that interfere with the hepatic metabolism of antiarrhythmic drugs may also result in QT prolongation.[52] Reduced urinary clearance of renally excreted medications may also result in toxicity.[53] In some instances, such as with sotalol or dofetilide, the risk of TDP is proportional to blood levels and related to renal excretion;[54] with quinidine, it is idiosyncratic and not dose related. A metabolite of procainamide, *N*-acetyl procainamide, prolongs the QT interval,

	Lone AF	Depressed LV function/ Congestive heart failure	Coronary artery disease, Normal LV function	Hypertrophic cardiomyopathy

Figure 24–1 Algorithm for the choice of antiarrhythmic drug based on the patient's clinical characteristics.

whereas the parent compound has little effect on repolarization. Slow acetylators produce less *N*-acetyl procainamide and have a lower risk of TDP. Rapid acetylators develop more *N*-acetyl procainamide and are more prone to TDP.[55]

Ventricular tachycardia may occur in patients taking antiarrhythmic drugs. This complication is well described in patients who take type IC medications (flecainide and propafenone) and who have had a prior myocardial infarction and impaired ventricular function.[56] Atrial flutter with a slow atrial rate and 1:1 AV nodal conduction that produce a widened QRS duration with hemodynamic collapse may also occur, particularly with class IC drugs.[57] This latter complication can generally be avoided with the addition of atrioventricular nodal blocking medications.

Bradyarrhythmias develop most often as a result of sinus node suppression or slowing of conduction through the atrioventricular node. Both of these complications are more frequently seen in elderly patients with underlying sick sinus syndrome.[58] Ambulatory monitoring (see later) and appropriate dose reduction or drug discontinuation can prevent serious consequences.[59]

Choice of Drug

The toxicity of antiarrhythmic drugs can be reduced by the careful selection of agent with regard to the patient's clinical history. Briefly, the risk factors for adverse effects include left ventricular hypertrophy, myocardial scarring (most commonly due to earlier myocardial infarction), and left ventricular systolic dysfunction. The presence of any of these clinical features should be evaluated before choosing an antiarrhythmic drug (Fig. 24–1). For patients without structural heart disease, the choice of drugs is wider, but it is still important to evaluate noncardiac comorbidity.

Initiation and Monitoring of Antiarrhythmic Drugs

The toxicity of antiarrhythmic drugs can be reduced with the appropriate choice of dose and method of monitoring during the loading phase. For example, unexpected bradycardia can often be avoided by reducing the usual loading dose of amiodarone or starting with a low dose of sotalol and increasing to therapeutic dose as tolerated. This strategy is particularly important in patients with suspected sinus node dysfunction.

Some controversy exists regarding the need for in-hospital initiation of antiarrhythmic drugs for the treatment of AF. The major concern is the precipitation of TDP. This proarrhythmic effect occurs in drugs that prolong repolarization and is almost never seen with flecainide and propafenone. In-hospital monitoring for 72 hours is incorporated into the drug labeling of dofetilide and is, therefore, mandatory for this drug, regardless of the presence or absence of structural heart disease.[60] Quinidine is rarely used owing to its significant and idiosyncratic propensity for provoking TDP,[61] but it is an effective atrial antiarrhythmic agent. Experimental data suggest that the risk of TDP can be reduced by the concomitant use of verapamil. Two large trials of quinidine for either paroxysmal AF or the maintenance of sinus rhythm after an episode of persistent AF demonstrated that, when it was combined with verapamil, it was as effective as sotalol with less risk for TDP.[62,63] As noted earlier, a pause associated with the conversion of AF to sinus rhythm may promote the development of TDP. Consequently, in patients with paroxysmal AF, it is advisable to initiate antiarrhythmic drugs with the potential for TDP while the patient is in sinus rhythm.

In contrast to QT-prolonging agents, in-hospital initiation of type IC agents (which should only be used in patients with a structurally normal heart) and amiodarone (which may be used in any form of heart disease) is generally not required. There is considerable experience with the initiation of amiodarone in the outpatient setting during AF, without significant toxicity.[35,59,64] QT prolongation is common with amiodarone, but it is not generally associated with a large risk of TDP (<1%) unless the corrected QT interval is significantly prolonged (>500 milliseconds).[65]

The concern with type IC agents is the conversion of AF to atrial flutter with 1:1 conduction to the ventricles and hemodynamic instability. It is, therefore, strongly recommended that atrioventricular nodal blocking agents be used in conjunction with a type IC agent.[66] Particular caution should be exercised for patients who are athletic because the development of atrial flutter during exercise may be associated with 1:1 conduction even in the presence of digoxin or calcium channel blockers. Theoretically, the antisympathetic aspects of β-blockade should be more effective in such patients.

Amiodarone may be initiated in the outpatient setting during AF, given the widespread safety data with this practice. If there is no congestive heart failure and if the patient is

in sinus rhythm, it may be possible to initiate other antiarrhythmic drugs, with the exception of dofetilide, in the ambulatory setting. To increase the safety of this approach, patients can be monitored with a continuous event recorder. The transmission of a single 30-second tracing daily permits monitoring for bradycardia, QT prolongation, and tachyarrhythmias. This protocol is continued for 10 days and has been shown to be quite effective.[59]

Despite safe initiation of an antiarrhythmic drug, the long-term possibility of proarrhythmic effects still exists. It is, therefore, important that physicians and patients are aware of circumstances that may render previously tolerated medications to be dangerous. Examples of these situations include the initiation of diuretics or certain antibiotics in patients taking QT-prolonging drugs, and the development of renal dysfunction in patients receiving renally excreted antiarrhythmic drugs such as sotalol or dofetilide.

Adjunctive Therapy for the Maintenance of Sinus Rhythm

Advances in the understanding of the electrical and mechanical remodeling of the atrium that occurs during AF have led to the evaluation of drugs that are not primarily antiarrhythmic in nature as an adjunct to maintaining sinus rhythm. The calcium channel blocking agents may blunt electrical remodeling of the atrium, and several trials have evaluated the efficacy in the pericardioversion state. As single agents, diltiazem and verapamil do not appear to prevent recurrence of AF in humans.[67] However, when given for a few weeks before cardioversion and continued for a few weeks after cardioversion of AF in the setting of an antiarrhythmic agent, there appears to be a modest, synergistic benefit.[68] In large clinical trials of losartan versus atenolol for hypertension, AF was reduced in the group treated with these drugs.[69] Several small trials seem to demonstrate a benefit of pericardioversion use of these agents,[70] although the results are more consistent with angiotensin receptor blockers than with calcium channel antagonists.[71] Currently, no specific recommendations regarding the use of calcium channel antagonists, ACE inhibitors, or angiotensin blockers as an adjunctive therapy can be made. However, if a patient with AF for whom cardioversion is considered needs antihypertensive therapy, the use of either an ACE inhibitor or angiotensin receptor blocker seems prudent.

Nonpharmacologic Approaches for the Maintenance of Sinus Rhythm

The invasive approach to the management of AF is rapidly evolving. As noted previously, certain antiarrhythmic agents may transform AF into atrial flutter. Advantage has been taken of this transformation because atrial flutter may be cured by the application of a line of ablation from the tricuspid valve to the inferior vena cava. This so-called "hybrid therapy," defined as the conversion of AF to atrial flutter by an antiarrhythmic drug (most commonly flecainide or propafenone) with subsequent ablation of atrial flutter,[72] is most commonly unplanned and is suitable for only a small number of patients with AF in whom flutter fortuitously occurs.

Percutaneous left atrial ablation is now widely employed for the attempted prevention of AF recurrence. There are multiple permutations of this procedure, but all involve the electrical isolation of the pulmonary veins to prevent atrial premature beats from entering the left atrium and triggering the onset of AF.[73-75] Some clinicians choose to create additional linear lesions in the left atrium to impair the perpetuation of AF, should it become triggered by a nonpulmonary vein source or by an incomplete pulmonary vein isolation (PVI). The optimal ablation procedure and the best choice of patient population for this procedure continue to evolve. Although relatively uncommon, the risks include pulmonary vein stenosis, pericardial tamponade, stroke, and atrial-esophageal fistula formation.[76] This procedure is associated with a 60% to 70% rate of suppression of AF during a 12- to 24-month follow-up period.[77-80] Recurrent AF, which may be reduced in frequency and/or symptoms, is seen in the majority of the remaining patients. Left atrial tachycardia has been noted in 5% to 30% of patients and appears more frequently when additional linear lesions are created.

Studies of arrhythmia surveillance post-PVI have demonstrated significant rates of asymptomatic AF.[81] It is, therefore, necessary to continue anticoagulation in patients with clinical risk factors for stroke, irrespective of the perceived success of the PVI procedure.

The surgical correlate of the percutaneous PVI procedure is the maze procedure. The modern maze procedure is a series of ablations performed on the endocardial surface, most often in conjunction with a coronary artery bypass or valve operation.[82] The left atrial appendage is generally oversewn as part of this procedure. Data on patients with preoperative AF undergoing the maze procedure along with mitral valve surgery showed a 78% to 81% actuarial rate of sinus rhythm at 5 years compared with <10% in a group with mitral surgery but no maze procedure.[83] The efficacy of this procedure has been reported to be substantially higher in patients with paroxysmal AF, and the overall efficacy will vary from center to center depending on the experience of the surgeon and the selection of patients. The obliteration of the left atrial appendage as part of the maze procedure carries the potential additional advantage of reducing stroke risk. Nevertheless, caution must be taken in discontinuing warfarin after this procedure because no data confirm that the combined maze and left atrial ablation obliteration completely abolish thromboembolic risk.

A minimally invasive variant of the maze procedure involves the creation of lesions around the pulmonary veins via a thoracoscopic or mini-thoracotomy approach. The left atrial appendage can be obliterated from the epicardial surface as well. This procedure is under investigation and the long-term efficacy is awaited.

The early recurrence of AF after the surgical maze procedure approaches 30%. These early recurrences do not necessarily predict long-term failure of the primary procedure. To reduce short-term postoperative AF after the maze procedure, amiodarone is often prescribed for 1 to 3 months postsurgery. If AF redevelops after discontinuation of the amiodarone, the procedure is recognized as unsuccessful.

Pacing for the Maintenance of Sinus Rhythm

Current guidelines favor the use of dual- compared with single-chamber pacing to reduce the frequency of AF in

Table 24–4 The $CHADS_2$ Scoring System for Assessing Annualized Stroke Risk

$CHADS_2$ Score	No Aspirin-Adjusted Risk (CI)*	On Aspirin†
0	1.9 (1.2-3.0)	0.8 (0.4-1.7)
1	2.8 (2.0-3.0)	2.2 (1.6-3.1)
2	4.0 (3.1-5.1)	4.5 (3.5-5.9)
3	5.9 (4.6-7.3)	8.6 (6.8-11.0)
4	8.5 (6.3-11.1)	10.9 (7.8-15.2)
5	12.5 (8.2-17.5)	12.3 (6.6-22.9)
6	18.2 (10.5-27.4)	13.7 (2-97)

Risk of stroke per 100 patient-years among patients not receiving warfarin. The score is calculated by assigning 1 point each for **C**ongestive heart failure, **H**ypertension, **A**ge ≥75 years, **D**iabetes, and 2 points for prior **S**troke or transient ischemic attack. The two columns of data are derived from different cohorts, and the wide confidence intervals with 6 points represent a relatively small number of patients with this score in this cohort. A simplified scheme classifies patients into low stroke risk (score 0), moderate risk (score 1-2) and high risk (score 3-6).

patients with a history of AF.[84] Efforts to reduce the frequency of AF through alternative site pacing techniques have demonstrated marginal to no benefit. The one exception may be the use of postoperative pacing to prevent cardiac surgery-associated AF.[85,86]

THROMBOEMBOLIC PROPHYLAXIS

Stroke represents the most devastating complication of AF, and the percentage of strokes attributable to this arrhythmia increases with the increasing age of the population.[87] Thus, it is estimated that >35% of strokes in patients >80 years of age are directly attributable to AF.[87] Strokes in patients with AF tend to be more severe than those that result from other causes, such as carotid artery stenosis, and they carry a higher mortality rate.[88,89] Several large trials performed in the late 1980s and early 1990s clearly demonstrated a very significant benefit of warfarin therapy for the prevention of stroke among patients with nonrheumatic AF.[90-97] Paroxysmal AF was shown to have the same annual stroke incidence as persistent AF, and the development of stroke was shown to be an ongoing risk. These trials also defined several subsets of patients with AF who were at a greater risk of stroke than patients in whom the arrhythmia existed in isolation (lone AF). The risk of stroke is greatest in patients with prior stroke or TIA (11% per year), and other risk factors include congestive heart failure, systolic ventricular dysfunction, hypertension (whether current or treated), older age, and diabetes.[98-101] The finding on a transesophageal echocardiogram of dense left atrial spontaneous contrast, diminished left atrial appendage velocities, or complex aortic plaque was associated with a risk of stroke in excess of 13% per year[101-103]; many of these features were associated with the clinical findings noted earlier and transesophageal imaging is not mandatory for risk stratification. Using a simple point system referred to by an acronym such as the $CHADS_2$, an annual stroke estimate can be assessed[100,104] (Table 24–4). For patients deemed to be at moderate-to-high risk of stroke, warfarin is indicated, prescribed to maintain an INR of 2.0 to 3.0. The role of aspirin therapy in AF is less clear. Low-dose aspirin (81 mg) is not effective, and the efficacy of higher dose aspirin (325 mg daily) is controversial.[105,106]

The risk of major bleeding in association with warfarin is low, even in the elderly, if the INR is maintained below 3.0.[107-109] Tight control of the INR can be facilitated by attention to medications and foods that interact with warfarin (Table 24–5). Unfortunately, despite overwhelmingly convincing evidence of the efficacy of warfarin for preventing stroke in AF, a significant number of patients, particularly the elderly, are not prescribed appropriate thromboembolic prophylaxis with warfarin.[110-112] This is due more to a misconception of the risk-benefit ratio of anticoagulation in the elderly, in whom thromboembolic strokes are frequent, often devastating, and sometimes fatal.

Pericardioversion Anticoagulation

The pericardioversion period represents a special situation in terms of thromboembolic risk. After restoration of sinus rhythm, atrial mechanical function may be diminished, and left atrial appendage-emptying velocities may be even lower than they were during AF.[113,114] This occurs more frequently if the duration of AF is long. The return of atrial function generally occurs in 7 to 14 days after restoration of sinus rhythm, and this is a period of high thromboembolic risk. Thus, anticoagulation is mandated during this time, even if a transesophageal echocardiogram showed no thrombus imme-

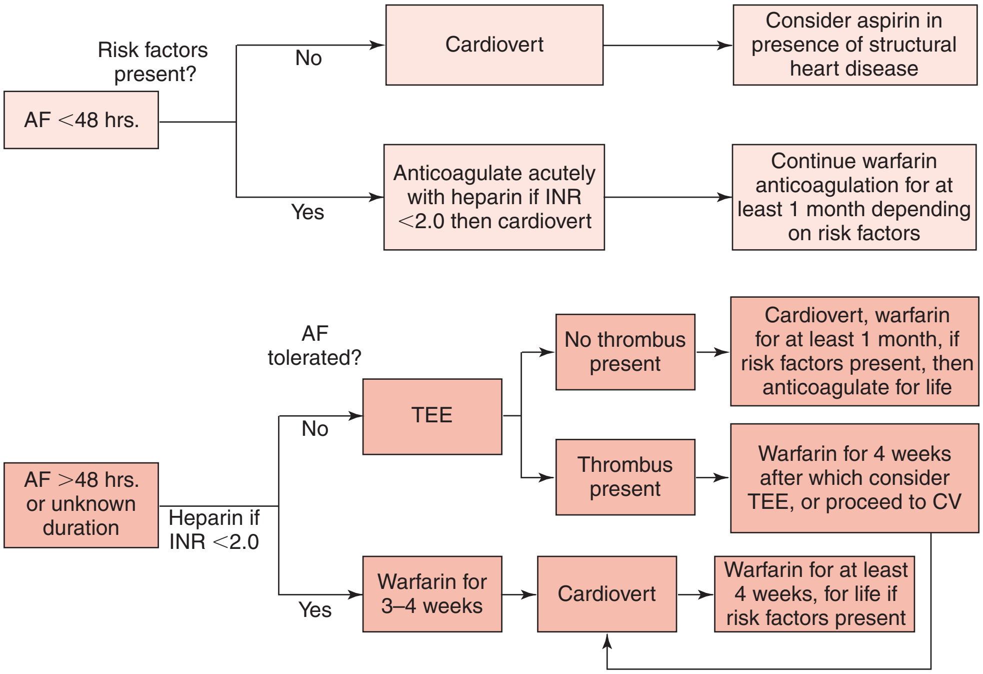

Figure 24–2 Algorithm for anticoagulation pericardioversion.

diately before cardioversion, and even in patients who are deemed not to need long-term warfarin while in AF (i.e., those with lone AF) (Fig. 24–2).[115,116] Current data suggest no clinical benefit to early, transesophageal-guided cardioversion followed by warfarin over a strategy of 3 to 4 weeks of warfarin before cardioversion and continued after cardioversion, although there may be some modest cost savings.[117-119]

ATRIAL FIBRILLATION POSTCARDIAC SURGERY

AF in the postcardiac surgery setting represents a unique situation. AF develops in 30% to 60% of cases and is more likely to occur with valvular surgery than isolated bypass surgery. As with other types of AF, older age is a major risk factor. It most often develops within the first 72 hours after surgery and may be asymptomatic or associated with rapid rates and significant symptoms. Unlike most other types of AF, postoperative AF tends to be self-limited and rarely recurs more than 4 weeks after surgery.

There is a fourfold approach to postoperative AF: (1) perioperative pharmacologic prophylaxis; (2) anticoagulation, if perioperative pharmacologic prophylaxis fails; (3) electrical or pharmacologic termination; (4) ventricular rate control. In addition, several intraoperative measures have been investigated for their effect on prophylaxis of postoperative arrhythmia.

Prevention of postoperative AF, if possible, is the preferred approach . β-Blocking agents have consistently been shown to reduce postoperative AF and should be started preoperatively and continued postoperatively.[120] Amiodarone, ideally in conjunction with β-blockers, seems to be superior to β-blockers alone, but the long half-life of the drug is such that it is best started several days before cardiac surgery.[121,122] As many patients go to cardiac surgery urgently, the optimal use of prophylactic amiodarone is limited to elective patients, and the drug also has significant side effects including postoperative bradycardia and, occasionally, postoperative pulmonary damage. Neither digoxin nor calcium channel antagonists have been shown to prevent postoperative AF, and they should not be used for this indication.[120]

Should a patient develop postoperative AF, the risks of anticoagulation with recent surgery need to be carefully weighed against potential benefits of thromboembolism prophylaxis. No prospective trials have evaluated postoperative anticoagulation as part of the treatment of postoperative AF. Consensus guidelines suggest that heparin should be limited to those patients with postoperative AF who are deemed to be at higher risk of thromboembolism, particularly those who have had a prior stroke or transient ischemic attack. For patients with arrhythmia that has persisted for at least 48 hours, warfarin anticoagulation is recommended (without heparin overlap) with an aim of continuing the drug for approximately 4 weeks after restoration of sinus rhythm.[123] Naturally, extreme care needs to be taken in adjusting anticoagulation in this patient population, and there may be a significant proportion of patients who are deemed to be at a higher-than-average risk of bleeding and for whom anticoagulation is considered inadvisable.

The postcardiac surgery patient may be hemodynamically unstable and, consequently, ventricular rate control in AF is important. On the other hand, many patients already have a relatively well-controlled ventricular response because they are on β-blocking agents, and the concern for ischemia is relatively low, as those with coronary artery disease will have had coronary revascularization.

Intravenous β-blockers and calcium channel blockers (diltiazem and verapamil) have been shown to be effective in controlling ventricular rate in postoperative patients.[124] Digoxin is generally not so effective as the calcium channel blockers or β-blockers as it performs poorly in the setting of high sympathetic tone. However, it may be a useful adjunctive drug for rate control and should certainly be considered in a patient with AF and impaired systolic ventricular function.

There are no trials that compare a strategy of restoration of sinus rhythm in patients with postoperative arrhythmia with that of anticoagulation and rate control to allow for spontaneous resolution of the AF. Should a patient deteriorate with the onset of AF and fail to improve with rate control, electrical cardioversion should be attempted. However, the short-term recurrent nature of postoperative AF often requires an antiarrhythmic agent to maintain sinus rhythm and prevent recurrence. Special considerations about antiarrhythmic agents in the postoperative patient include rapid shifts in electrolytes that might potentially pose an increased risk of TDP, and depressed ventricular function that may increase other proarrhythmic effects. If left ventricular dysfunction is present, amiodarone is considered the drug of choice should conversion to, and maintenance of, sinus rhythm be needed. In patients with normal ventricular function, ibutilide may be used to restore sinus rhythm, but it cannot be used for sinus rhythm maintenance. Sotalol may be a reasonable choice given its β-blocking properties, although excessive bradycardia may occur with sotalol in the postoperative patient.

CONCLUSIONS

The management of AF has undergone considerable change in the last decade and will doubtless continue to evolve. Advances are being made in the field of anticoagulation with the development of direct thrombin inhibitors that do not need constant monitoring[125]; constant refinements are being made in ablation procedures; and new antiarrhythmic drugs are under development. It is likely that the adjunctive therapy of AF will be applied as prophylaxis in high-risk populations and, with all these measures, the goal should be to reverse the increasing incidence and prevalence of this common arrhythmia and to make it easier to treat effectively those patients in whom it still occurs.[126]

Genetics of Inherited Arrhythmias

Silvia G. Priori and Carlo Napolitano

CHAPTER CONTENTS

Inherited arrhythmogenic disorders are genetically transmitted diseases associated with increased susceptibility to cardiac arrhythmias in patients with structurally intact hearts. They typically manifest with peculiar electrocardiographic patterns, syncope, and sudden death in young, otherwise healthy, individuals. In these conditions, there is a common denominator represented by a genetic abnormality in one of the several proteins that control the excitability of myocardial cells (Fig. 25–1).

In this chapter, we will review the current understanding of molecular pathways and the genetic determinants that predispose to cardiac arrhythmias. We will also summarize the main clinical features of inherited arrhythmogenic diseases and the role of genetic testing in management and risk stratification.

FUNCTIONAL PATHWAYS INVOLVED IN INHERITED ARRHYTHMIAS

Potassium Currents

Potassium currents participate in the control of repolarization of the human heart and determine the resting membrane potential. Over the past 10 years, genes encoding a wide range of pore-forming K^+-channel α-subunits and accessory β-subunits have been cloned, and their electrophysiologic properties have been characterized by in vitro expression in heterologous systems.[1] Subsequently, mutations in some of them have been linked to the pathogenesis of inherited cardiac arrhythmias (see Fig. 25–1). Interestingly, each disease is caused by mutations in different genes, and different mutations within the same gene have been associated with distinct phenotypes, as in the case of "long QT" and "short QT" syndromes. This complex scenario is reviewed in the following sections in which each current implicated in the repolarization of the heart will be discussed, together with the diseases caused in the presence of genetic defects that alter its physiologicl behavior.

Slow Delayed Rectifier (IK_s) Current and Associated Phenotypes

KCNQ1 and *KCNE1* genes encode the α(KvLQT1) and the β(MinK) subunit of the potassium channel that conducts the IK_s current, the slow component of the delayed rectifier current (IK). KvLQT1 is a protein formed by six transmembrane segments that tetramerizes in the membrane to constitute a functional pore-forming unit called the α-subunit of the IK_s channel This α-subunit coassembles with two or more minK subunits, also called β-subunits,[2] to recapitulate the functional channel that conducts the IKs current.[3]

Mutations in the *KCNQ1* and *KCNE1* genes have been identified in patients who are affected by the long QT syndrome (LQTS) (Table 25–1) (http://www.fsm.it/cardmoc). In vitro expression of mutant proteins suggested that they share a common functional result[4] represented by a loss of function. This reduced activity of the channel is either a consequence of haplo-insufficiency or of a dominant negative effect. In genetic diseases that are transmitted as dominant conditions, a "dominant negative effect" is present whenever a mutant protein inhibits the function of the wild-type protein encoded by the wild-type allele.[5] The functional abnormalities observed in patients with mutations in the *KCNQ1* gene adequately explain the clinical phenotype: the reduced potassium extrusion capabilities of the mutant IKs channels impair the repolarization process, leading to a prolongation of cellular action potential and of QT interval that produces an electrically unstable substrate predisposing to the development of ventricular tachycardia and fibrillation.

Interestingly, mutations of the *KCNQ1* and *KCNE1* genes that lead to a "gain of function" represented by an increased IKs repolarizing current have been identified in patients affected by a disease called the "short QT syndrome" (SQTS) and in patients affected by familial atrial fibrillation (FAF). In the presence of gain of function mutation and of an excess of potassium repolarizing current, the cardiac action potential and refractory period shortens in the atria and in the ventricles, facilitating reentrant arrhythmias[6] (see Table 25–1).

Fast Delayed Rectifier (IK_r) Current and Associated Phenotypes

KCNH2 and *KCNE2* genes encode the α-(HERG) and the β-(MiRP) subunits of the potassium channel conducting the IK_r current, the rapid component of the cardiac delayed rectifier. The *KCNH2*-encoded protein, HERG, is a six-transmembrane segment protein that forms homotetramers in the plasmalemma to make up functional channels. The

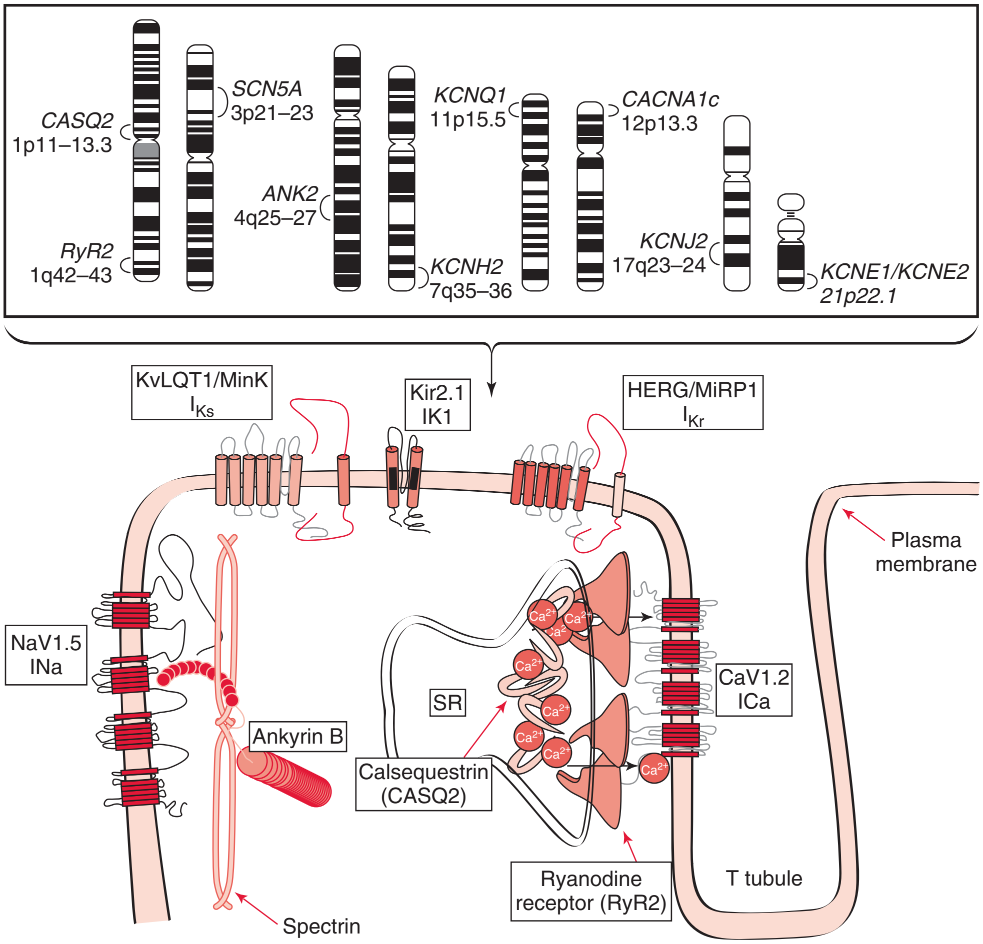

Figure 25–1 Genes and proteins involved in inherited arrhythmias. The *upper panel* shows symbols and chromosomal localization of the genes involved in inherited arrhythmogenic disorders. The proteins encoded by these genes (plasmalemmal and sarcoplasmic reticulum [SR] channels, and intracellular proteins) are schematically illustrated in the *lower panel.*

physiologic role of MIRP protein to recapitulate the current has been postulated,[7] although coassembly of MIRP with other voltage-gated potassium channels such as KvLQT1 has been also reported.[8]

Loss of function mutations in *KCNH2* and *KCNE2* cause the LQT2 and LQT6 variants of the long QT syndrome (see Table 25–1). Although LQT2 is the second most common variant of LQTS and accounts for 35% to 40% of mutations (http://www.fsm.it/cardmoc), mutations in the *KCNE2* gene[7] are uncommon (<1%) and are associated with mild clinical manifestations. *KCNH2* mutations found in LQTS patients cause a reduction of IK_r current (loss of function).[4] Gain of function *KCNH2* mutations causing an increased IK_r have been reported in patients with SQTS,[9] whereas the *KCNE2* mutation that causes an arginine-to-cysteine mutation at position 27 (R27C) has been reported in familial atrial fibrillation (FAF).[8] This latter mutation was found in 2/28 probands of families with FAF in whom a systematic screening of cardiac ion channel encoding genes was carried out. Functional study revealed that the mutation had a gain-of-function effect on the *KCNQ1-KCNE2* channel; unlike long QT syndrome-associated *KCNE2* mutations, it did not alter *KCNH2–KCNE2* current.

Inward Rectifier (IK1) Current and Associated Phenotypes

The inwardly rectifying potassium channels (Kir2.x) primarily mediate cardiac IK1. The Kir family includes two transmembrane segment channels that coassemble in the membrane by forming homo- or heterotetramers.[10] IK1 current plays an important role in late-phase repolarization and in maintaining the resting membrane potential. Among known Kir-encoding genes, only the *KCNJ2* encoding for the Kir2.1 has been associated with genetically determined cardiac arrhythmias[11,12](http://www.fsm.it/cardmoc).

KCNJ2 mutations were initially identified in patients with Andersen-Tawil syndrome,[11] a multisystem disease characterized by potassium-sensitive periodic paralysis, ventricular ectopy, and dysmorphic features. Patients with Andersen syndrome present with a variable degree of QT interval prolongation and, therefore, this disorder is also referred to as LQT7. Additional *KCNJ2* mutations have been identified in families with SQTS and FAF.[12,13] Analogous to what has been previously described for mutations in IKr and IKs proteins, *KCNJ2* mutations also lead to different phenotypes because they may cause either a gain of function or a loss of function. As expected from the electrocardiographic phenotype, mutations identified in patients with LQT7 cause a loss of function, whereas those identified in patients with SQTS and FAF mutations produce a gain of function (see Table 25–1).

Overall, experimental data demonstrate that three major repolarizing currents are involved in the pathogenesis of inherited arrhythmogenic syndromes (IKs, IKr, and IK1). At the cellular level, all of them may harbor both loss and gain of function mutations, and the associated clinical phenotypes vary accordingly. These findings highlight the remarkable genetic and phenotypic diversity of inherited arrhythmias.

Table 25–1 Potassium Channels Involved in Inherited Arrhythmias

Gene	Protein	Phenotypes	Mechanism	Inheritance
KCNQ1	I_{Ks} potassium channel α-subunit (KvLQT1)	Long QT syndrome (LQT1, JLN1) Short QT syndrome (SQTS2) Familial atrial fibrillation	Loss of function Gain of function Gain of function	AD/AR AD
KCNH2	I_{Kr} potassium channel α-subunit (HERG)	Long QT syndrome (LQT2) Short QT syndrome (SQTS1)	Loss of function Gain of function	AD
KCNE1	I_{Ks} potassium channel β-subunit (MinK)	Long QT syndrome (LQT5, JLN2)	Loss of function	AD/AR
KCNE2	I_K potassium channel β-subunit (MiRP)	Long QT syndrome (LQT6)	Loss of function	AD
KCNJ2	I_{K1} potassium channel (Kir2.1)	Long QT, potassium-sensitive paralysis, dysmorphic features (LQT7—Andersen syndrome) Short QT syndrome (SQTS3)	Loss of function Gain of function	AD AD

AD,autosomal dominant; AR; autosomal recessive; JLN, Jervell and Lange-Nielsen syndrome.

Sodium Current (INa)

The cardiac sodium channel (Nav1.5), encoded by the *SCN5A* gene, is a transmembrane protein composed of four homologous domains (DI-DIV), each containing six transmembrane spanning segments (S1 to S6). Thus, unlike potassium channels, there is no need for coassembly of subunits to obtain a pore-forming protein.

Four arrhythmogenic disorders have been linked to *SCN5A* mutations. Three of them have an autosomal dominant pattern of inheritance (the LQT3 variant of long QT syndrome,[14] the Brugada syndrome [BrS],[15] the progressive cardiac conduction defect [CCD],[16] and the fourth is inherited as autosomal recessive sick sinus syndrome [SSS]) (Table 25–2).

SCN5A-related phenotypes are due to either gain (LQT3) or loss (BrS, CCD, SSS) of function mutations. It is still unclear why some loss of function mutations of the *SCN5A* gene cause CCD, whereas others cause BrS: it is, therefore, possible that the phenotype is the result of variable expressivity of a single disease that may manifest either with ST-segment elevation in the right precordial leads or with conduction abnormalities. The understanding of what mediates the prevailing phenotypic manifestation is still unclear.

Calcium Current (ICa) and Intracellular Calcium Handling

Calcium entry through plasmalemmal voltage-gated channels (ICa current) is the major determinant of the duration of the plateau of the cardiac action potential. The presence of a normal Ca^{2+} inward current is critical to ensure the rapid mobilization of Ca^{2+} from the sarcoplasmic reticulum stores, which trigger the contractile protein activation—the so-called "calcium-induced-calcium release" (CICR) (see Fig. 25–1).

Since 2001, molecular genetic studies have linked mutations in key proteins responsible for the regulation of intracellular calcium with two forms of inherited arrhythmias, namely the Timothy syndrome and the catecholaminergic polymorphic ventricular tachycardia (Table 25–3).

Timothy syndrome (TS), also called LQT8, is a severe variant of long QT syndrome presenting with QT interval prolongation and cutaneous syndactyly of the hands and feet. In a study by Splawski and colleagues,[17] a missense mutation in the *CACNA1c* gene, encoding for the L-type calcium channel (Cav1.2), has been identified with 13 TS probands. Interestingly, all patients presented with the same single amino acid substitution (G403R), and all but one (a case of parental mosaicism), were sporadic cases. Heterologously expressed Cav1.2-G403R mutant channels resulted in an almost complete loss of voltage dependency of channel inactivation with a consequent increase of calcium inward current. Therefore, the net effect of the Timothy syndrome defect is that of a gain of function of the calcium channel causing, at cardiac level, an increased action potential duration.[17] Until now, there was no disease associated with loss of function mutations of the *CACNA1c* gene.

Another key element in the CICR process is the control of Ca^{2+} release from sarcoplasmic reticulum in response to calcium entry from the extracellular space during the plateau phase of action potential. Several proteins are involved in this process and two of them have been associated with the autosomal dominant and autosomal recessive variant of catecholaminergic polymorphic ventricular tachycardia (CPVT).[18] In late 2000, we demonstrated that the cardiac ryanodine receptor gene (*RyR2*), encoding for the sarcoplasmic reticulum (SR) Ca^{2+} releasing channel,[19] causes the autosomal dominant CPVT. The role of this gene was subsequently confirmed by others.[20,21] A few months later, Lahat and coworkers[22] provided the evidence linking *CASQ2*, the cardiac calsequestrin gene, to the autosomal recessive variant of CPVT. *CASQ2* serves as a major Ca^{2+} binding protein localized in the terminal cisternae of the SR and cooperates with the control of the calcium release process from the SR. In vitro expression studies of mutant RyR2 are in agreement by indicating that

Table 25–2 Sodium Channel–Associated Phenotypes

Gene	Protein	Phenotypes	Mechanism	Inheritance
SCN5A	I_{Na} Cardiac sodium channel α-subunit (Nav 1.5)	Long QT syndrome (LQT3)	Gain of function	AD
		Brugada syndrome (BrS1)	Loss of function	AD
		Progressive cardiac conduction defect (CCD1)	Loss of function	AD
		Sick sinus syndrome (SSS)	Loss of function	AR

AD,autosomal dominant; AR = autosomal recessive.

Table 25–3 Calcium Handling Abnormalities in Cardiac Arrhythmias

CACNA1C	I_{Ca} Voltage-gated calcium channel, CaV1.2	Timothy syndrome (LQT8), long QT with syndactyly, septal defect, patent foramen ovale, mental retardation	Gain of function	Sporadic/parental mosaicism
RyR2	Cardiac ryanodine receptor	Catecholaminergic polymorphic ventricular tachycardia (CPVT1)	Gain of function	AD
CASQ2	Calsequestrin	Catecholaminergic polymorphic ventricular tachycardia (CPVT2)	Loss of function	AR

AD,autosomal dominant; AR, autosomal recessive.

the RyR2 mutations cause a Ca^{2+} “leakage” from the SR in condition of sympathetic (catecholamines) activation.[23-25] The authors have developed a knock-in RyR2 mutant mouse that presents the typical CPVT arrhythmias,[26] thus supporting the role of triggered activity as the cellular mechanism of arrhythmias.

One experimental study showed that a defective calsequestrin impairs the SR Ca^{2+} storing and release functions via a reduced Ca^{2+} buffering capability and suggested that, similar to *RyR2*-related CPVT, triggered activity is the cellular arrhythmogenic mechanism.[27]

Inherited arrhythmogenic diseases were initially believed to involve only the plasmalemmal ion channels. The identification of RyR2 and CASQ2 mutations in CPVT provided the evidences that even intracellular proteins may cause abnormal cardiac excitability in a structurally normal heart. Another example is represented by the LQT4 variant of LQTS recently linked to the *ANK2* gene.[28] *ANK2* encodes for an intracellular protein (Ankyrin) that regulates the proper intracellular localization of plasmalemmal ion channels (calcium channel, sodium channel, sodium/calcium exchanger), sarcoplasmic reticulum channels (ryanodine receptor, inositol triphosphate receptor), and other adhesion molecules.[28] From a clinical standpoint, LQT4 is an uncommon condition characterized by QT interval prolongation, sinus bradycardia, paroxysmal atrial fibrillation with polyphasic T waves—but the few cases reported so far do not allow a detailed description of the ANK2-related phenotype.

Taken as a whole, the available data depict the complexity of the pathways underlying inherited arrhythmogenic diseases (Fig. 25–2). Although the common denominator of these diseases is vulnerability to malignant ventricular arrhythmias and sudden death in young subjects with a structurally intact heart, they differ profoundly in terms of pathogenesis and clinical phenotype. The evidence that all the plasmalemmal channels so far associated with inherited arrhythmias may harbor both gain and loss of function mutations further substantiates this concept.

PHENOTYPES, CLINICAL PRESENTATION, AND MANAGEMENT

Although molecular genetics has unveiled the pathogenesis of several inherited arrhythmia syndromes, with the exception of LQTS, there is still a knowledge gap preventing the full applicability of genetics to clinical management. This gap is mainly due to the lack of large cohorts of patients with known mutations that allow genotype-based risk stratification and therapy. In the following paragraphs, we will summarize the main phenotypic features of the most important inherited arrhythmogenic diseases, and we will outline the relevance of genetic to clinical management.

Long QT Syndrome

Clinical Presentation and Its Modulation by Genotype

The long QT syndrome (LQTS) is characterized by a variable degree of QT interval prolongation and an increased susceptibility to life-threatening ventricular arrhythmias in the absence of structural abnormalities of the heart. The mean age at onset of symptoms (syncope or sudden death) is 12 years, and an earlier onset of clinical manifestations is an indicator of adverse prognosis.[29] The diagnosis of LQTS is ECG-based: the measurement of the QT interval corrected for heart rate and the morphology of the ST-T wave must be taken into consideration. Because QT interval is modulated by gender, differential limits must be considered after puberty: QTc should not exceed 440 msec in males and 460 msec in females.[30]

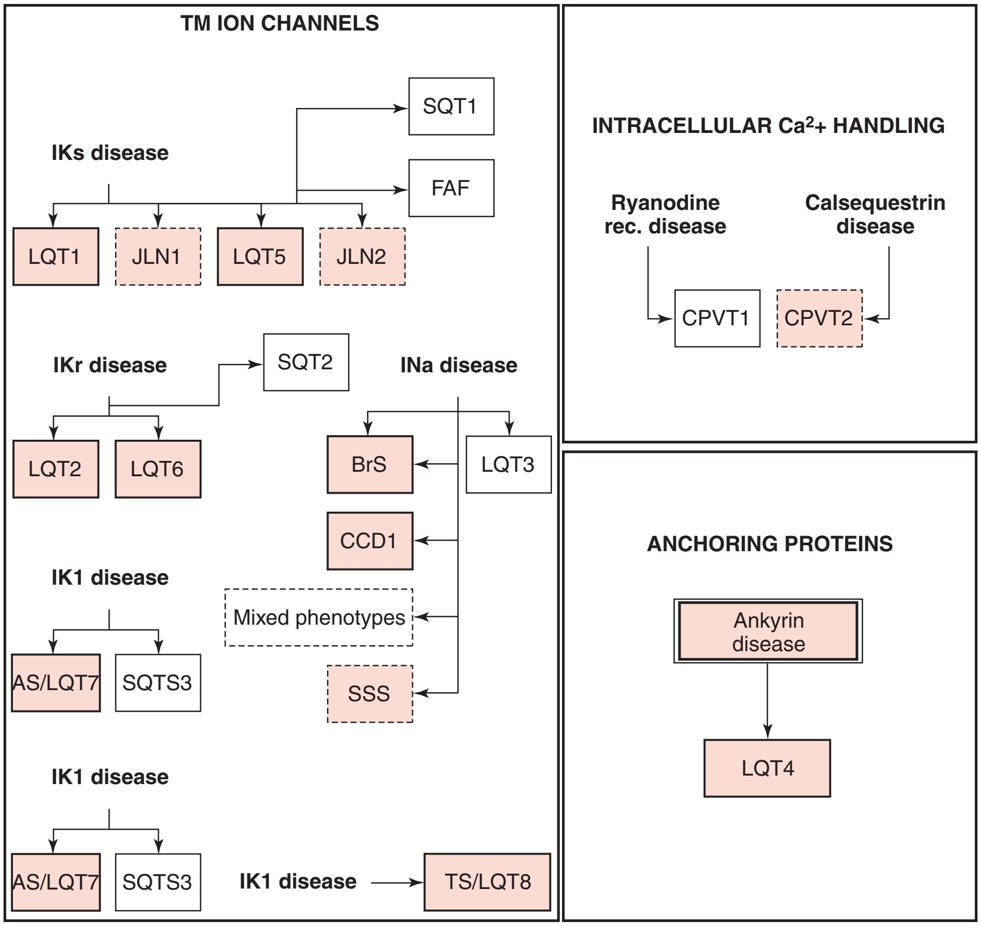

Figure 25–2 Classification of inherited arrhythmogenic diseases according to functional pathways. Three major classes of proteins are identified: transmembrane (TM) ion channels, intracellular calcium handling proteins, and anchoring proteins. *Light pink rectangles* represent diseases caused by loss of function mutations, whereas *white rectangles* represent gain of function mutations. *Continuous lines* and *dotted lines* depict autosomal dominant and autosomal recessive disorders, respectively. "Mixed phenotypes" (e.g., BrS + LQT) are caused by complex biophysical abnormalities of sodium current (INa) (http://www.fsm.it/cardmoc). For abbreviations, see text and tables. (Modified by Priori SG: Inherited arrhythmogenic diseases: The complexity beyond monogenic disorders. Circ Res 2004;94:140-5.)

QTc assessment is the most important step for the diagnosis of LQTS; however, morphologic ST-T wave abnormalities are often evident in LQTS and may support the clinical diagnosis. Further insights into the morphology of ST-T pattern in LQTS may be obtained when the ECG presentation is considered in light of the genetic background. Indeed, the distinguishing of genotype-specific repolarization patterns has been reported.[31,32] Albeit not a surrogate for genetic testing, the morphologic ECG evaluation may be important in defining the genotyping strategy with an advantage to the turnaround time of the analysis (Fig. 25–3).

The onset of rapid polymorphic VT (torsades de pointes) underlies syncope in LQTS.[33] According to the genetic substrate, the triggering factors for cardiac events may vary: LQT1 patients have 90% of lethal events during physical or emotional stress; LQT2 patients are at higher risk for lethal events during arousal or emotional stimulation (49%); LQT3 patients present most of their events (64%) at rest or while asleep and only 4% during exercise.[34] Furthermore, swimming-related events are frequent among LQT1, whereas an acoustic stimulus is a specific trigger for LQT2.[35,36]

Natural History and Risk Stratification

Developments in molecular genetics have allowed the integration of traditional clinical variables (electrocardiographic evaluation, personal, and family history of cardiac events) with the genotype information to reach clinically applicable risk stratification schemes based on natural history. Molecular epidemiology studies[37-39] show that LQT1, LQT2, and LQT3 variants account for approximately 95% of genotyped patients, whereas the other variants are infrequent (<5%). Thus, genotype-phenotype correlations have been carried out mainly on these three subtypes.

Evaluation of the natural history of LQTS on a very large group of patients with known genotype was carried out in 2003 by Priori and colleagues in a cohort of 647 LQTS patients from 193 families.[40] By combining QTc distribution and genotype, it was shown that among LQT1 and LQT2 patients, those with a QTc in the upper quartile (>500 msec) had a 5.3- and 8.4-fold risk increase, respectively, compared with those in the first quartile. However, LQT1 showed a lower cumulative event-free survival versus LQT2 and LQT3.[40] Gender had a different effect across genotypes. It had no influence among LQT1 patients, whereas a higher risk was present for LQT2 females and LQT3 males. It was also observed that the percentage of genetically affected patients with a normal QT interval ("silent mutation carriers") differed strikingly among genotypes, being much more frequent ($P < 0.001$) among LQT1 (36%) than LQT2 (19%) and LQT3 (10%).

In smaller patient groups, it has been suggested that risk stratification may be further refined when the location of a mutation is also taken into consideration. In 2002, Moss and colleagues[41] studied 201 LQT2 patients and showed that individuals with mutations in the pore region were at greater risk

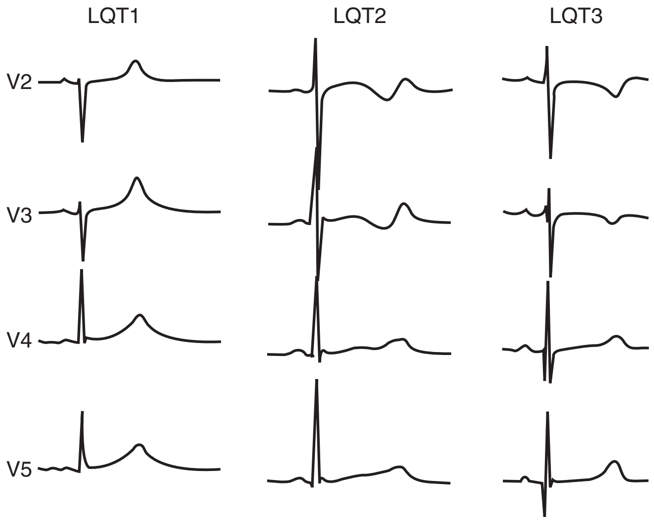

Figure 25–3 Genotype-specific T wave morphology in long QT syndrome (LQTS). Examples of typical precordial lead (V_2-V_5) repolarization morphologies in LQTS patients. From *left to right*: LQT1 smooth broad-based T wave, LQT2 biphasic and notched T wave with low amplitude, LQT3 straight ST-segment with smooth but narrow T wave.

for cardiac events than patients with non-pore mutations—even though the difference was not significant for lethal events (aborted cardiac arrest and sudden death). Some authors suggested that mutations located in the carboxy terminus of the *KCNQ1* gene were associated with a mild clinical phenotype, but these data were not confirmed thereafter.[42,43] Overall, data concerning localization-specific risk stratification require further investigation before reaching a full clinical applicability.

Therapy

The mainstay of LQTS therapy is administration of a β-blocker,[44] which is indicated for all patients with clinically overt LQTS—with or without a history of syncope. An implantable cardioverter-defibrillator (ICD) plus β-blockade is indicated for secondary prevention in patients with an aborted cardiac arrest and for those experiencing a recurrent cardiac event on therapy.[45]

In a study carried out in LQTS patients with known genotype, we demonstrated that genotype has a significant influence on the effectiveness of therapy.[29] Indeed β-blockers are significantly more effective among LQT1 as compared with LQT2 patients (HR versus LQT1 2.81; 95% CI: 1.50 to 5.27) and LQT3 patients (HR versus LQT1 4.00; 95% CI: 2.45 to 8.03). Besides genotype, additional independent predictors of recurrence of cardiac events on therapy were the presence of a first cardiac event before therapy in early childhood (≤7 years) and a QTc interval >500 msec. These data suggest that LQT2 and LQT3 patients with a QTc interval >500 msec are at high risk of events despite active β-blocker therapy. For these individuals, ICD implantation could be considered for primary prevention.

A further clinically relevant issue that progressively emerged after the discovery of LQTS genes is that of silent mutation carriers. These individuals, who represent approximately 30% of all genotyped LQTS patients, despite a normal QT interval, still present a 10% risk for cardiac events before age 40.[40] Thus, the use of prophylactic therapy with β-blockers should be considered for these individuals.

Role of Genetic Testing

The screening of the five LQTS genes (*KCNQ1, KCNE1, KCNE2, KCNH2, SCN5A)* allows identification of the genetic defect in 60% to 70%[37,39,46] of clinically affected individuals. However, because not all the genes for LQTS have been discovered, the lack of identification of a genetic defect cannot rule out the presence of the disease. Screening of family members of a genotyped proband allows presymptomatic diagnosis and it allows definition of the clinical status (affected versus nonaffected) in borderline cases.

Of major relevance, and somewhat unique to LQTS, is the fact that the identification of the genetic defect contributes to risk stratification, therapy selection, and prevention of factors that precipitate arrhythmias (Table 25–4). Indeed, the most recent genotype-phenotype correlation data[29] show that β-blockers provide satisfactory protection against cardiac events among LQT1 patients (*KCNQ1* mutations), whereas LQT2 and LQT3 (*KCNH2* and *SCN5A* mutations, respectively) retain a significant risk of cardiac events (23% among LQT2 and 32% among LQT3). This study also demonstrated that genotype is an independent predictor of events on therapy together with the QT interval duration and the occurrence of a first event in early childhood (≤7 years).[29] Thus, prophylactic ICD implantation was suggested for LQT2 and LQT3 patients with QTc > 500 msec and a history of early events. These data clearly underscore the relevance of genotyping in LQTS. The development of novel strategies to make genetic testing widely available is, therefore, strongly advisable.[46]

Short QT Syndrome

Clinical Presentation and Natural History

The short QT syndrome is a new clinical entity that is associated with sudden cardiac death, syncope, and/or atrial fibrillation. The first report of a clinical condition characterized by abnormally short repolarization was made by Gussak and associates in 2000.[47] They described two siblings and their mother who displayed persistently short QT interval (260 to 275 msec) and a peculiar hyperkalemic-like T wave pattern on the resting ECG. A few additional unrelated cases (<20) were reported thereafter.[6]

As with the majority of inherited arrhythmogenic diseases, SQTS is also characterized by the absence of structural heart disease and by family history of sudden cardiac death in approximately 40% of cases.[6] The available data suggest an overall high mortality rate in the absence of a specific trigger for cardiac events. It should be noted, however, that the very first families affected by a newly described disease tend to have the more malignant form of the condition and this may lead to an overestimation of the severity of the disease. Therefore, it may still be too early to draw conclusions on the incidence of sudden cardiac death in patients with the diagnosis of SQTS. The low number of patients so far reported also prevents the definition of prevalence and genotype-phenotype correlation.

Table 25–4 Indication for Genetic Testing in Inherited Arrhythmogenic Diseases

	LQTS	LQTS-TS*	LQTS-AS*	BrS	SQTS	FAF	CCD	SSS	CPVT

Reproductive counseling	X	X	X	X	X	X	X	X	X

*The two LQTS variants with extracardiac involvement have been listed separately because applicability of genetic testing is different.
† percentage of successfully genotyped probands with clinically overt phenotype.
**No silent carriers have been reported with the exception of one case of parental mosaicism.
BrS, Brugada syndrome; CCD, cardiac conduction defect; CPVT, catecholaminergic polymorphic ventricular tachycardia; LQTS, long QT syndrome; LQTS-TS, long QT syndrome 8 (LQT8) Timothy syndrome; LQTS-AS, long QT syndrome 7 (LQT7) Andersen syndrome; SQTS, short QT syndrome; SSS, sick sinus syndrome.

An important, still-debated issue in SQTS is the QT cut-off limit to establish the diagnosis. The initial patients reported by Gussak[47] had a QT interval of 260 to 275 msec. In 2003, Gaita and associates,[48] reported two families with SQTS and showed that all affected patients had a QTc < 300 msec with a QT interval <280 msec. However, we reported a novel form of short QT syndrome in patients with a QTc up to 320 msec long.[12] The observation obtained in the long QT syndrome showed a sizeable overlap of QTc values between normal individuals and genetically affected patients with normal QTc (approximately 30% of all LQTS), and also put forward the idea that the same overlap could happen at the lower QTc boundary zone between normal and SQTS patients. We extrapolate from these data that SQTS cannot be excluded in patients with a QTc or a QT between 300 to 320 msec.

Therapy

No effective treatment has been identified so far, and the lack of robust markers of risk may suggest the use of ICD for both secondary and primary prevention of sudden cardiac death. However, careful device programming is needed because inappropriate ICD discharges due to T wave oversensing have been reported.[6,49]

Based on the evidence that SQTS is caused by an excess of outward repolarizing current, the use of potassium channel blockers has been considered. Specifically, attempts have been made to counteract the effect of *KCNH2* mutations using sotalol, ibutilide, and quinidine.[50] Only this latter compound was effective in prolonging the QT-interval in the small group of SQTS patients who received this therapy. Indeed, Brugada and colleagues[9] demonstrated that the SQTS-*KCNH2* defect reduces the affinity of a more specific IKr blocker such as sotalol for the mutant channel.

Role of Genetic Testing

Three genes associated with SQTS have been brought to light in only a 5-year time span, but the clinical applicability of genetic testing is still limited. Only a handful of families has been genotyped; therefore, the relative prevalence of the three variants and the genotype-phenotype correlation is still unknown. Thus, the usefulness of genetic testing is still limited, although it is advisable for early diagnosis of asymptomatic individuals owing to the malignancy of the disease (see Table 25–4).

Brugada Syndrome

Clinical Presentation

Brugada syndrome (BrS) is clinically characterized by peculiar ECG alterations (ST-segment elevation in leads V_1–V_3 and complete or incomplete right bundle branch block) and risk of sudden cardiac death due to the onset of fast polymorphic VT and ventricular fibrillation.[51,52] Although a high prevalence of sporadic cases may be seen in clinical practice, BrS is inherited as an autosomal dominant trait.

Diagnosis of BrS may be complicated by the transitory nature of the ECG abnormalities.[53-56] Provocative testing with intravenous administration of sodium channel blockers (flecainide 2 mg/kg or ajmaline 1 mg/kg) (Fig. 25–4), may help to unmask the ECG abnormalities in suspected cases,[57,58] but its sensitivity is yet undefined.[59] The morphology of ST elevation in BrS has also been a matter of debate in the last few years, and criteria have been modified over time. In the earlier reports, BrS diagnosis was considered in the presence of both a "coved-type" and a "saddle-back" ECG pattern.[60] Subsequently,[52] only coved-type ECG (either spontaneous or pharmacologically induced) has been reported as diagnostic for the disease (see Fig. 25–4). In 2005, more restrictive criteria were introduced in a consensus document[61] in which the presence of a coved-type ECG was not considered sufficient for diagnosis in the absence of additional criteria—such as programmed electrical stimulation (PES) inducibility and ventricular arrhythmias (syncope or cardiac arrest). However, this definition is called into question by the results of genetic analysis that shows that carriers of loss-of-function mutation may have a saddle-back ECG and may remain asymptomatic or may not be inducible at PES.[59]

Natural History Risk Stratification and Therapy

Clinical manifestations of BrS include syncope and cardiac arrest—typically occurring in the third and fourth decades of

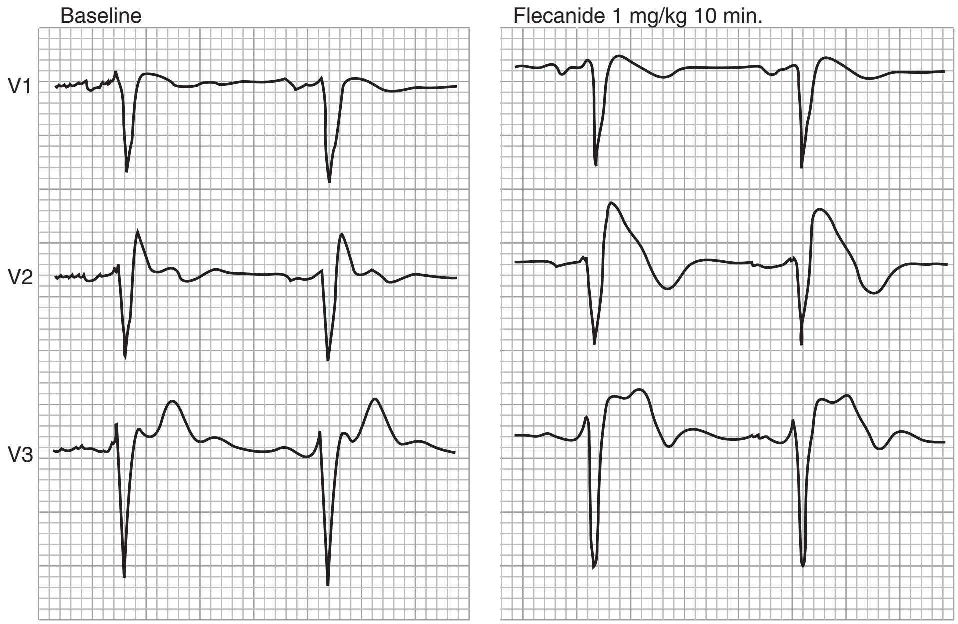

Figure 25–4 ECG in Brugada syndrome (BrS). Right precordial leads V_1-V_3 in a patient with Brugada syndrome recorded at baseline and after pharmacologic challenge with intravenous flecainide. At baseline, (*right panel*) incomplete right bundle branch block and ST elevation (more clearly visible in V_3) with a "saddle-back" morphology are evident. After drug administration, ST elevation is increased >2 mm with conversion to a "coved-type" morphology.

life, and usually at rest or during sleep. Despite the initial reports suggesting a very high incidence of lethal events,[62] it is now evident that most BrS patients are likely to remain asymptomatic.[63-66] The overall picture suggests that approximately 20% of BrS patients have at least one cardiac event in a lifetime. Because an effective pharmacologic therapy has not yet been identified and because the only effective strategy to prevent sudden death is ICD implantation, the risk stratification becomes a primary issue for clinical management.

Although the use of an ICD for secondary prevention of an aborted cardiac arrest is clearly indicated, the correct strategy for identification of patients in whom an ICD is indicated for primary prevention is still debated. The decision should be based on a reliable quantification of risk. In 2002, we showed that the presence of a spontaneous ST-segment elevation in leads V_1, V_2, and/or V_3, especially when associated with a history of syncope, was one of the most robust indicators of risk of cardiac events.[64] This concept was subsequently confirmed by other investigators.[65] On the other hand, the ICD indications for asymptomatic patients remain controversial. This group of patients has a relatively low risk of cardiac events. We reported that 14% of patients experienced a life-threatening event from birth to age 40,[64] and this picture has been more recently confirmed by other authors who reported an 11% aborted sudden death rate in 212 patients with a mean age at diagnosis of 44 years.[67] Therefore, the induction of ventricular fibrillation at PES has been proposed as a risk stratification tool.[65] Unfortunately, short- and long-term reproducibility of PES is unsatisfactory[68,69]; the number needed to treat (NNT = 20) for the use of ICD is high[59]; and the data from an Italian[64] study and from a German[67] study did not confirm the conclusion of Brugada and associates[65] on the good predictive value of PES. Overall, these data do not support the use of PES for risk stratification of asymptomatic Brugada patients, leaving open the issue of identifying a more robust risk stratification marker for this subgroup of patients.

Oral quinidine has been proposed as a gene-specific therapy for BrS patients on the hypothesis that it could reduce the transmural dispersion of ventricular repolarization.[70] Available clinical data show that quinidine prevents arrhythmia inducibility at PES in up to 76% of BrS patients[71-73] and suggest a positive long-term effect in preventing the occurrence of spontaneous arrhythmias.[72] Unfortunately, a high incidence of GI side effects may reduce patient compliance (see Chapter 21).[71] These data are clearly insufficient to propose quinidine as a routine BrS treatment. Nonetheless, this drug should be considered to reduce the number of ICD discharges in highly symptomatic patients with frequent recurrences.

Role of Genetic Testing

Only the *SCN5A* gene has been so far associated with the BrS and only 15% to 20% of patients harbor mutations in this gene.[63] Because the disease manifests in adulthood and it is characterized by incomplete penetrance (i.e., presence of mutation carriers without clinical phenotype),[63,64] the value of genetic analysis for reproductive counseling is less obvious than in other genetic arrhythmias. Genetic analysis is useful in nonpenetrant mutation carriers and in family members of genotyped probands to monitor them to detect early signs of manifestation of the disease but, at present, it is not useful for risk stratification (see Table 25–4).[59]

Progressive Conduction Defects and "Overlapping Syndromes"

Clinical Presentation and Natural History

Cardiac conduction defect (CCD) represents the major cause for pacemaker implantation in the world and one of the more common disorders of the heart. The disease is usually progressive and it is characterized by a slowing of electrical conduction through the His-Purkinje system, which may manifest at the surface ECG with a prolongation of the PR interval and a QRS widening. Complete atrioventricular block may occur with the possible consequence of syncope and sudden death. In some instances, progressive CCD is associated

with other cardiac (e.g., dilated cardiomyopathy) and extracardiac (e.g., muscular dystrophy) manifestations.

Familial cases of isolated progressive CCD with an autosomal dominant pattern of transmission have been reported, and linkage studies have outlined a disease locus on chromosome 19 (19q13.2-q13.3). No gene has been identified so far at this locus,[74] but in 1999 Schott and coworkers[16] reported mutations in the *SCN5A* gene that segregate with CCD in an autosomal dominant fashion in two families. This finding demonstrated that a loss of function mutation in a transmembrane ion channel may be responsible for a defect of impulse conduction in the heart. Additional mutations have been reported thereafter by other groups (http://www.fsm.it/cardmoc). Interestingly, some CCD-*SCN5A* mutations may also cause more complex phenotypes that overlap with the Brugada syndrome and LQT3.[4] Despite the fact that such findings are relevant to understanding the pathophysiology of some CCD cases, the natural history, response to therapy, and risk stratification schemes are still poorly characterized owing to the low number of patients genotyped so far.

Role of Genetic Testing

The yield of *SCN5A* screening in CCD patients is still unknown; therefore, genetic testing is useful for presymptomatic diagnosis and reproductive risk assessment but not for risk stratification and therapy (see Table 25–4).

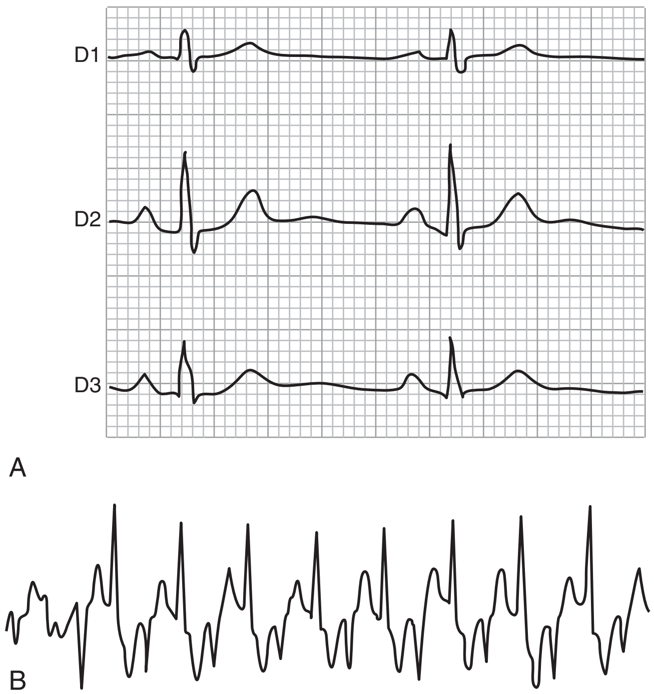

Figure 25–5 ECG in catecholaminergic polymorphic ventricular tachycardia (CPVT). **A,** shows limb leads (D1-D3) of a CPVT patient. No major abnormalities may be observed. The same patient during exercise stress test (**B**) developed the typical pattern of bidirectional ventricular tachycardia with positive and negative QRS complexes alternating on a beat-to-beat basis.

Catecholaminergic Polymorphic Ventricular Tachycardia

Clinical Presentation

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is an arrhythmic disorder that is clinically characterized by ventricular tachycardia, syncope, and sudden death—occurring in familial as well as in sporadic cases.[75] Three distinguishing features are also present[75] (1) direct relationship between adrenergic activation (physical or emotional stress) and cardiac events; (2) typical pattern of bidirectional ventricular tachycardia (VT), with an unremarkable resting electrocardiogram (Fig. 25–5); and (3) a structurally normal heart.

Physical activity or acute emotions are the specific triggers for arrhythmias among CPVT patients. The onset of ventricular arrhythmias is typically reproducible in term of onset heart rate (120 to 130 beats per min) and morphology (alternating 180-degree QRS axis on a beat-to-beat basis—the so-called “bidirectional ventricular tachycardia”). In some instances, however, polymorphic VT without a “stable” QRS vector alternans may be observed.[21,76]

Natural History and Risk Stratification

CPVT usually manifests with syncope triggered by exercise or acute emotion, although sudden cardiac death may be the first manifestation in some families.[21] Symptoms often manifest during childhood with a mean age at first event of 8 years, and approximately 30% of families present with a history of one or multiple premature sudden deaths that usually occur during childhood even if later events also occur (after age 20).[21,77] CPVT is a severe clinical condition, as outlined by data from our registry, including the largest cohort of CPVT patient available: in the absence of appropriate therapy >70% of patient experience syncope or aborted cardiac arrest before the age of 40 years.[78]

The amount of clinical and genetic data so far available does not allow drawing robust genotype-phenotype correlations and risk stratification algorithms. CPVT patients are usually not inducible at PES, making it inadequate for management and risk stratification.[21,77] Preliminary evidence shows that patients with RyR2 mutation have events at a younger age than do patients with nongenotyped CPVT and that male sex is a risk factor for syncope in *RyR2*-CPVT (relative risk = 4.2).[21] The clinical presentation of *CASQ2*- and *RyR2*-related CPVT is similar, although it has been suggested that *CASQ2*-CPVT most often manifests with polymorphic instead of bidirectional ventricular tachycardia.[22,79]

Therapy

Antiadrenergic treatment with β-blockers (in our clinic patients are most often given nadolol 1.5 to 2.5 mg/kg/day) is the cornerstone of therapy for CPVT patients.[21,77,80] The reproducible pattern of arrhythmia during exercise stress test among CPVT patients allows dose titration and monitoring. Chronic treatment can prevent recurrences of syncope in many patients,[21,77] although for approximately 40% of them, the arrhythmia control is unsatisfactory. In such instances, the use of an ICD is indicated because the available evidence

shows appropriate interventions of the device in one half of the implanted patients—despite the antiadrenergic therapy.[21]

Role of Genetic Testing

The screening of the two genes (*RyR2* and *CASQ2*) associated with the autosomal dominant and autosomal recessive forms of CPVT allows the identification of mutations in 70% of patients.[18,78] Even if only two genes are responsible for most of the CPVT cases, genetic analysis of this disease is complicated by the fact that *RyR2* is one of the largest genes in the human genome. Turnaround time and test availability are still, therefore, far from ideal. However, because the clinical diagnosis of CPVT is fairly elusive and because the ECG is unremarkable, genetic analysis may become extremely helpful for establishing the diagnosis. This is especially important because CPVT is a highly malignant disease if left untreated. On the contrary, once it is diagnosed and the appropriate treatment is implemented, the patient's prognosis improves substantially. Presymptomatic diagnosis, diagnosis in silent carriers, and reproductive counseling are additional important benefits of successful genetic analysis (see Table 25–4).

CONCLUSIONS

Transmembrane and intracellular ion channels and transporters have been implicated in cardiac arrhythmias and sudden death. Molecular genetics has revealed a high level of genetic and functional heterogeneity, and the same protein may generate a variety of apparently unrelated (sometimes opposite) clinical phenotypes depending on the specific functional consequences of the single mutations (see Fig. 25–2). Despite such complexity, our understanding of cardiac physiology and pathophysiology has improved substantially in the last decade. Translation into clinical benefits is, again, a complex process that has only recently achieved partial success with progressively more informative management algorithms derived from genotype-phenotype correlations. In the years to come, this process will lead to the development of individualized approaches for prevention and therapy of cardiac arrhythmias and sudden death.

Dyslipoproteinemias/ Atherosclerosis

Chapter 26

Pharmacologic Therapy for Hypertriglyceridemia and Low HDL: Rationale for Combination Therapy

Michael H. Davidson

CHAPTER CONTENTS

Statin outcome trials have proven conclusively that lowering low-density lipoprotein cholesterol (LDL-C) results in significant improvement in the rate of cardiovascular morbidity or mortality. Additionally, primary and secondary prevention studies using statins have established the safety and efficacy of this class of pharmacologic agents. The relationship between LDL-C and coronary heart disease (CHD) events appears to be linear with considerable evidence supporting the "lower is better" hypothesis. However, even with low LDL levels, the residual risk for subsets of high-risk patients continues to be elevated. In the Treating to New Targets (TNT) trial, patients on atorvastatin 80 mg (with a mean LDL-C of 77 mg/dL) had a total of 28% cardiovascular events compared with a 33% event rate for patients on 10 mg atorvastatin with mean LDL-C of 101 mg/dL (a 22% relative risk reduction).[1] Therefore, approximately 70% of the events were not avoided despite significant LDL-C reduction. The 80-mg atorvastatin therapy was also associated with a slightly elevated rate of increased transaminases (0.2% versus 1.2%).[1] Therefore, an important clinical challenge remains to reduce further the residual CHD risk on optimal statin therapy without adversely affecting patient safety.

HIGH-RISK SUBSETS OF PATIENTS FOR CHD EVENTS ON STATIN THERAPY

Posthoc and prespecified analyses of statin outcome trials demonstrate higher CHD event rates for patients with additional risk factors. Of the modifiable risk factors, the presence of diabetes, cigarette smoking, metabolic syndrome, and elevated hs-CRP predicts a high residual risk. The National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) Guidelines update regarding the implication of recent clinical trials recommends an optional LDL-C goal of <70 mg/dL and a non-HDL goal of <100 mg/dL for patients at very high risk.[2] The definition of very high risk included patients with cardiovascular disease with diabetes, cigarette smoking, or factors associated with the metabolic syndrome (Table 26–1). A contemporary survey documented that 75% of patients with cardiovascular disease (CVD) would meet this definition of "very high risk."[3] Therefore pragmatically, most patients with CVD should be considered appropriate for the optional LDL goal of <70 mg/dL. In the Heart Protection Study (HPS) statin therapy (simvastatin 40 mg daily) resulted in highly significant reductions in coronary mortality rate

(18%), incidence rate of first nonfatal myocardial infarction (38%), stroke incidence (25%), and incidence of coronary revascularization (30%),[4] but the diabetic patients with CHD on statin therapy had an event rate of 31% compared with a placebo event rate of 25% in nondiabetic patients with CHD (Table 26–2). In the Reversal of Atherosclerosis with Aggressive Lipid Lowering (REVERSAL) trial, intensive (atorvastatin 80 mg/dL) compared with moderate (pravastatin 40 mg/dL) lipid lowering resulted in greater reductions in LDL-C to mean levels of 78.9 mg/dL compared with 110.4 mg/dL, respectively ($P < 0.001$). In addition, the intensive lipid-lowering intervention resulted in a significantly lower progression rate in the percentage change in atheroma volume ($P = 0.02$).[5] However, the diabetic subset on aggressive lipid-lowering therapy of atorvastatin 80 mg continued to have marked progression of atheroma volume. In the ARBITER 2 trials, the diabetic subset also continued to have progression of IMT despite statin therapy.[6]

A review of diabetic patients or patients with low HDL in statin event trials demonstrates a markedly elevated rate of residual events even on statin treatment (see Table 26–2). In fact, the on-statin event rate in patients with diabetes or low HDL is higher than the placebo event rate for patients without diabetes or low HDL. Therefore, even with an LDL-C <70 mg/dL, a CVD patient with diabetes is likely to have a high recurrent event rate. In the HPS trial the subgroup of patients with low HDL had a significant benefit from simvastatin therapy. CHD events decreased from 29.9% to 22.6%, but the patients on statin therapy still had a higher event rate than the placebo patients in the subgroup with a higher HDL.[4] A similar relationship exists for patients in the HPS trial with elevated triglyceride (TG) levels. Because hs-CRP correlates with the metabolic syndrome, an elevated hs-CRP (>2 mg/L) may represent an important marker of enhanced residual risk. This chapter reviews the use of nonstatin therapies to modify the CHD risk associated with dyslipidemia and the use of combination therapy to reduce the residual risk for patients on statin monotherapy.

Table 26–1 Updated NCEP/ATP III Guidelines

Risk Category	LDL-C Goal
Very high risk defined as: Cardiovascular disease and one or more of: 1) Diabetes mellitus 2) Multiple major risk factors 3 Poorly controlled risk factors 4) Metabolic syndrome 5) Patients with acute coronary syndrome	<100 optional <70
High risk: CHD or CHD risk equivalent	<100
Moderately high risk: • 2 or more risk factors • Framingham score 10-20%	<130 Optional <100
Moderate risk: • 2 or more risk factors • Framingham score <10%	<130
Low risk 0-1 risk factors	<160

CHD, coronary heart disease.

NIACIN

Niacin or nicotinic acid is a soluble B vitamin that has favorable effects on all major lipid subfractions (Table 26–3)[7] but has not been widely used due to the side effect profile. Despite the significant lipid-altering effects, pharmaceutical data in the United States have consistently documented that niacin prescriptions are less than 3% of the very large cholesterol drug market. In Europe the use of niacin is even lower than in the United States. However, clinical trial data suggest a potential important role for niacin therapy, and the FDA has approved a modified release form of niacin (Niaspan) that reduces the side effect profile.

Table 26–2 Event Rates in Statin Trials

	Without Diabetes		With Diabetes	
	On Statin	On Placebo	On Statin	On Placebo
HPS* (CHD patients)	19.8%	25.7%	33.4%	37.8%
CARE*	19.6%	24.6%	28.7%	36.8%
LIPID†	11.7%	15.2%	19.7%	22.8%
PROSPER†	13.1%	16%	23.1%	18.4%
ASCOT†	4.9%	8.7%	9.6%	11.4%
	High HDL on Statin	High HDL on Placebo	Low HDL on Statin	Low HDL on Placebo
HPS*	17%	20.9%	22.0%	29.9%
CARE/LIPID*	18.5%	22.4%	25%	30.8%
PROSPER†	12.8%	11.6%	13%	19.3%

*Coronary heart disease (CHD) death, non-fatal myocardial infarction (MI), coronary artery bypass graft (CABG), percutaneous transluminal coronary angioplasty (PTCA), unstable angina.

ASCOT, Anglo-Scandinavian Cardiac Outcomes Trial; CARE, Cholesterol and Recurrent Events; HDL, high-density lipoprotein; HPS, Heart Protection Study; LIPID, Long-Term Prevention with Pravastatin in Ischaemic Disease; PROSPER, Prospective Study of Pravastatin in the Elderly at Risk.

The pharmacokinetics of niacin and its mechanism of action are not well understood, but niacin appears to reduce apolipoprotein (apo) B secretion, thereby lowering both very low-density lipoprotein (VLDL) and LDL and increasing apo AI and lowering Lp(a).[8] Niacin reduces the mobilization of free fatty acids from the periphery probably by inhibiting hormone sensitive lipase. Therefore, there is less TG substrate for VLDL synthesis and a reduced secretion of VLDL, which is the precursor of LDL (Fig. 26–1). Niacin may also inhibit diacylglycerol-2-acyltransferase (DGAT), a key enzyme in TG synthesis. On average, niacin lowers LDL by 10% to 20%, TGs by 20% to 40%, and Lp(a) by 10% to 30%, and it raises HDL by 15% to 30%.[9] These effects are dose related and shown in Figure 26–2. Niacin is the only known approved lipid-altering drug (with the exception of estrogen) that lowers Lp(a) and is the most potent drug used to raise HDL. Niacin appears to increase HDL by decreasing the hepatic uptake of Apo AI, thereby delaying catabolism.[10] HDL can be taken up by hepatocytes by at least two cellular receptors. SRB1 binds HDL, and cholesteryl ester is effluxed into the hepatocytes. This receptor is not affected by niacin but rather another mechanism of hepatocyte uptake of HDL that most likely involves holouptake of the entire HDL particle. Holouptake of HDL would remove the lipoprotein from circulation; after SRB1 uptake, the delipidated HDL is released to resume reverse cholesterol transport. By inhibiting the holouptake rather than SRB1, niacin promotes cholesteryl ester removal from HDL that results in a longer circulating time for HDL and theoretically improves reverse cholesterol transport.[11]

Niacin can cause significant hepatotoxicity and should be discontinued if liver enzymes (SGOT and SGPT) exceed 3 times the upper limit of normal. Patients who use over-the-counter (nonprescription) niacin should be worried about the hazard of liver toxicity.[12] Many over-the-counter niacin supplements may not be labeled as sustained release, but if niacin is combined with a fiber, such as oat or rice bran, this combination can cause a sustained release and adversely affect the liver enzymes. Patients should generally be advised not to use over-the-counter niacin. Niacin can also increase uric acid levels, thus aggravating gout. Other side effects of niacin include a rash, gastrointestinal problems including worsening of esophageal reflux or peptic ulcers and headache. Rarely, skin lesions, usually in the axillary areas or elbows, called *acanthosis nigricans* can develop.

Niacin is often added to a statin in patients with combined hyperlipidemia, especially if the HDL is low or Lp(a) is high. A number of studies have evaluated the combination of a statin with niacin.[13] The incidence of liver function abnormalities with the combination of a statin plus niacin is generally similar to niacin therapy alone, at least when the combination of both drugs are at the starting doses (e.g., simvastatin 20 mg, pravastatin 40 mg, fluvastatin 40 mg plus niacin 1500 to 2000 mg/d). Myopathy has been reported with statins plus niacin, but the incidence appears to be less than expected with gemfibrozil.[14] Myopathy has developed with the combination, after niacin-induced hepatotoxicity reduces the catabolism of the statin, resulting in markedly elevated statin levels. Therefore, unregulated sustained release niacins that have a higher incidence of hepatotoxicity should be avoided in combination therapy. The vast majority of combination trials have used either immediate-release niacin or sustained release niacin. In one study a single tablet containing both modified-release niacin and lovastatin was dose titrated from niacin 500 mg plus lovastatin 10 mg to niacin 2000 mg plus lovastatin 40 mg to target levels based on NCEP guidelines over a 16-week period.[15] Once on a stable dose, the patients were followed further for 36 weeks. More than 600 patients were enrolled with LDL levels exceeding the NCEP ATP II levels for

Table 26–3 Effects of Niacin

Niacin Decreases	Niacin Increases
Total cholesterol	HDL cholesterol
Total triglycerides	HDL_2 cholesterol
VLDL-C	HDL_3 cholesterol (<HDL_2)
LDL-C	Apolipoproteins A-I, A-II
Small dense LDL	LP A-I
Lp(a)	LP A-I + A-II (<LP A-I)
Apo B	LDL particle size
Total cholesterol/HDL-C	
LDL-C/HDL-C	
Apo B/A-I	

HDL, high-density lipoprotein; LDL, low-density lipoprotein; VLDL, very low-density lipoprotein.

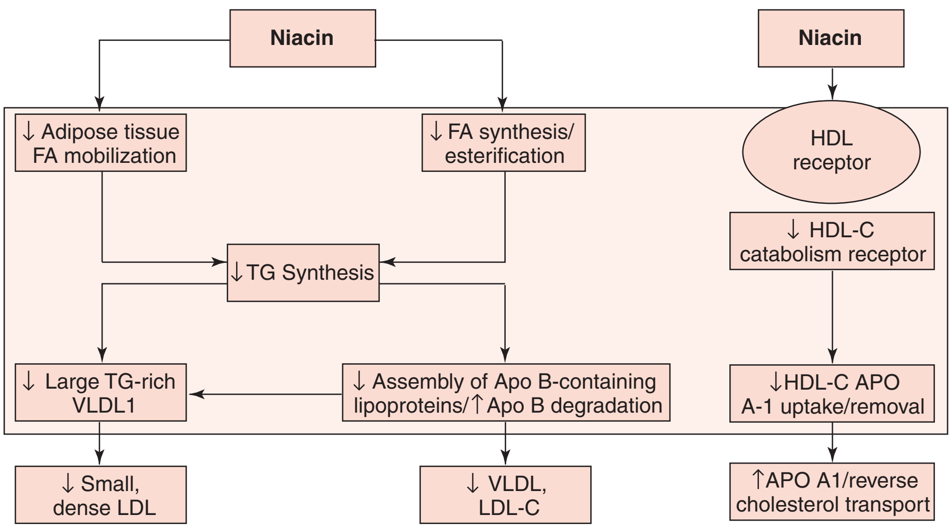

Figure 26–1 Actions of niacin in treating dyslipoproteinemias.

initiating drug therapy. At the 2000/40 mg dose LDL was lowered by 47% and TGs by 42%, and HDL increased by 30%. About 7% of patients withdrew as a result of flushing. There were no cases of drug-induced myopathy, and less than 1% had elevated liver enzymes greater than 3 times the upper limit of normal.

Due to the safety data of Niaspan in combination with a statin, there has been a resurgence of interest in the use of combination therapy to maximize risk reduction in patients with dyslipidemia.[16] Over the past several years, statins have established a large clinical trial base documenting both safety and outcome benefits. Niacin also has demonstrated CHD outcome benefits either as monotherapy or in combination with other lipid-lowering agents (Table 26–4).[17-22] The marked reduction in clinical events in the FATS and HATS trials, although relatively small trials, has provided intriguing data regarding the importance of combining niacin with other lipid-lowering agents. Statins, in general, have demonstrated approximately a 30% reduction in CHD events, but in these small trials when a statin was combined with niacin, the reduction in CHD events was approximately 75%. This 75% reduction in clinical events by combining a statin with niacin is far more expected than with LDL reduction alone. This marked reduction in CHD events suggests that the other effects of niacin, such as raising HDL and lowering TGs and Lp(a), contribute significantly to the benefits. Although the clinical benefit of changing the LDL particle size from small (pattern B) to large (pattern A) is not yet conclusively demonstrated, niacin is one of the most effective agents in modifying LDL particle size, whereas statins are more effective in lowering the total LDL particle numbers.[23,24]

†Greater than recommended daily doses

Figure 26–2 Dose-response of once-daily extended-release niacin (Niacin-ER). (Redrawn from Goldberg AC: Clinical trial experience with extended-release niacin [Niaspan]: Dose-escalation study. Am J Cardiol 82(12A):35U-38U, 1998.)

A subanalysis of the HATS trial showed that statin-niacin therapy significantly increased the large Apo A-1 containing α-1 HDL particles.[25] This increase in the larger HDL particles was associated with less progression of coronary stenosis even after adjusting for traditional risk factors.[25] Although statins may also increase larger HDL levels, niacin appears to have the most significant effect on the levels of the large LpA-1 particles. These data suggest that niacin was a significant contributor to the benefits of the simvastatin-niacin combination treatment in the regression of atherosclerotic development and CHD event reduction.

By recommending non-HDL, as well as LDL, targets if the TGs exceed 200 mg/dL, the ATP III guidelines have also enhanced the need for niacin therapy.[26] On the basis of an evaluation of the safety and pharmacokinetics of statins in combination with fibrates or niacin, an algorithm was developed to use appropriate combination treatment if non-HDL goals have not been achieved (Fig. 26–3).[14]

The use of niacin in diabetics has in the past been considered problematic due to niacin's modest glucose-raising effects. A trial and a reevaluation of the Coronary Drug Project (CDP)[27,28] have provided helpful information on the use of niacin in patients with glucose elevations. A reevaluation of the CDP in the diabetic subpopulation had a similar

Table 26–4 Niacin Coronary Heart Disease Endpoint Trials

Study	Population	Results
Coronary Drug Project	8341 post-MI men Baseline TC 250 mg/dL—9.9% on trial Baseline TG 177 mg/dL—26.1% on trial	27% reduction in definite non-fatal MI—24% reduction in CVA. Total mortality decrease 10.6% at 15 yrs.
Stockholm Ischemia Heart Study	555 consecutive MI survivors <70 yrs old; open label clofibrate/niacin or placebo; baseline TC 245 mg/dL—13% on trial Baseline TG 208 mg/dL—19% on trial	36% reduction in CHD deaths.
Familial Atherosclerosis Treatment Study	146 men with APO B ≥125 mg/dL with CHD. Conventional therapy versus niacin/colestipol or lovastatin/colestipol.	73% reduction in CHD events in patients who received intensive lipid-lowering therapy.
HDL Atherosclerosis Treatment Study (HATS)	160 CHD patients with HDL <35 mg/dL, LDL <145 mg/dL. Treated 3 yrs with niacin/simvastatin or placebo with or without antioxidants.	Reduction of CHD events by 60% (on antioxidants) to 90% (off antioxidants).

reduction in clinical CHD events than did the nondiabetic CHD population. This new information provides support for the use of niacin to treat diabetic dyslipidemia, and although there may be a modest increase in serum glucose levels, the overall benefit is a marked reduction in cardiovascular events. In the Assessment of Diabetes Control and Evaluation of the Efficacy of Niaspan Trial (ADVENT),[29] 148 patients with type 2 diabetes and dyslipidemia were randomized to 1000 mg/d, 1500 mg/d of sustained release niacin or placebo; 47% of the patients were also taking statins.

In the ADVENT trials, extended-release niacin produced a significant effect on both TGs and HDL-C levels. The increase in HDL-C was dose dependent and was significantly greater at all time points for the niacin-treated groups than for the placebo group. In the 1000 mg niacin group, HDL-C increased up to 19% at 16 weeks. In the 1500 mg group, it increased up to 24%. The absolute increases in HDL-C at 16 weeks were 7.6 mg/dL in the 1000 mg group and 11 mg/dL in the 155 mg group, compared with 1.6 mg/dL among placebo-treated patients.

TG reductions were also dose related. Reductions in the patients who received lower-dose niacin were not significantly greater than for those who received placebos. TG levels were reduced by 28% in the 1500 mg niacin group at 16 weeks, a significant difference compared with placebo.

Changes in Hb A_{1c} levels were small in all treatment groups. Hb A_{1c} values in the 100 mg/d treatment group were not significantly different from the placebo group. Changes in Hb A_{1c} levels in the 1500 mg/d group reached marginal significance ($P = 0.048$) at 16 weeks. Increases in fasting blood glucose occurred between weeks 4 and 8 in the niacin-treated groups; levels returned to baseline by week 16.

The ADVENT study demonstrated that extended-release niacin, at the doses tested, is effective and well tolerated in patients who have type 2 diabetes and atherogenic dyslipidemia, whether given alone or with a statin. Low doses of extended-release niacin are therefore an option for the treatment of dyslipidemia in patients who have glucose-controlled type 2 diabetes.

Because of demographic trends toward more obesity and diabetes, the ATP III requirement to treat non-HDL goals, as well as LDL goals, in hypertriglyceridemic patients will become more difficult. Niacin provides a unique range of benefits to the lipid profile that is difficult to achieve with statin therapy alone in many patients. In clinical trials in which both statins and niacin were used together, there have

been impressive reductions in CHD events, although these trials have been relatively small. New information regarding the use of niacin in diabetics has moved this therapy from a relative contraindication to the use of niacin with the appropriate monitoring of glucose levels.

FIBRATES

Five fibrates are currently used in human therapy: clofibrate, gemfibrozil, fenofibrate, bezafibrate, and ciprofibrate. Only gemfibrozil and fenofibrate are available in the United States. Fibrates are peroxisome proliferator-activated receptor (PPAR-alpha) ligands. PPAR-alpha activated by fibrates forms heterodimers with the 9-*cis* retinoic acid receptor (RXR). The PPAR/RXR heterodimers bind to peroxisome proliferator response elements, upregulating the expression of these genes. PPAR-alpha activation by fibrates leads to increasing lipoprotein lipase expression and decreasing apo CIII expression, which results in enhanced catabolism of TG-rich particles. Fibrates also increase the expression of apo AI and apo AII.[30] The net result of fibrate therapy is decreased hypertriglyceridemia and an increase in HDL cholesterol. LDL levels may also decrease, most likely due to a reduction of dense LDL, which is more atherogenic than buoyant LDL and has poor affinity for the LDL receptor. However, LDL may also increase in patients with hypertriglyceridemia with fibrate therapy, but these are usually the less atherogenic buoyant LDL particles. Consequently, fibrates are used almost exclusively for patients with hypertriglyceridemia and low HDL.

Several outcome trials have used fibrates. In patients with hypertriglyceridemia or low HDL, or both, these drugs reduce CHD events or the angiographic progression of atherosclerosis (Table 26–5). In patients with CHD and low HDL, the Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) study[31] shows that gemfibrozil compares favorably with statin therapy, using a number needed to treat (NNT) to prevent one event analysis. The BIP trial failed to demonstrate a significant overall benefit, but for patients with TGs greater than 200 mg per dL, there was a 40% CHD risk reduction ($P = 0.03$).[32] The mean LDL in the VA-HIT study was 111 mg per dL compared with 148 mg per dL in the BIP trial. The lack of benefit for bezafibrate in the BIP trial compared with the significant benefit for gemfibrozil in the VA-HIT study suggests that fibrates need to be targeted for patients with either high TGs or low HDL with a relatively low LDL.

The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) trial[33] did not reduce nonfatal and fatal myocardial interactions significantly (11% reduction, $P = 0.16$), but a secondary endpoint that included fatal CVD events (nonfatal, fatal myocardial interactions, coronary revascularization, and stroke) was reduced significantly by 11% ($P = 0.035$). This study was compromised by a higher statin drop-in rate in the control group during the treatment period, which resulted in only minimal changes in the lipid profile between the two groups. The FIELD patients with preexisting CHD (≈20% of the study patients) had the highest statin drop-in rate during the study, and if the diabetics without CHD (≈80% of the study patients) are evaluated posthoc, there is a 25% CHD reduction, which is comparable with statin trials with diabetic patients.

FIBRATE SIDE EFFECTS AND SAFETY ISSUES

The fibrates are generally well tolerated. The most common side effects are upper gastrointestinal disturbance, headache, myalgia, and loss of libido.[34] Fibrates have absolute contraindications in hepatic or severe renal dysfunction and preexisting gallbladder disease. Fibrates should also not be used in pregnant or nursing mothers.

Gemfibrozil is a potent inhibitor of the cytochrome P450 2C8 metabolic pathway and the glucuronidation of statins.[35] Cerivastatin is partially cleared by the CYP 2C8 pathway and

Table 26–5 Fibrate Outcome Studies

Trial	Duration Yrs	N	Treatment	Primary Endpoint	RRR	ARR	NNT
Primary Prevention							
HHS	5	4081	Gemfibrozil 600 mg bid	Fatal, nonfatal MI and cardiac death	34%	1.4%	71

undergoes significant glucuronidation. Gemfibrozil's inhibitory effect on both metabolic pathways for cerivastatin explains the fivefold to sixfold increase in the area under the curve (AUC) for cerivastatin when combined with gemfibrozil.[36] Fenofibrate, which does not inhibit the CYP 2C8 metabolic pathway or statin glucuronidation, has a minimal impact on cerivastatin levels. All statins including rosuvastatin require varying degrees of glucuronidation for metabolism, and the AUC for all statins evaluated, except for fluvastatin, are increased when combined with gemfibrozil (Table 26–6). This explains gemfibrozil's greater propensity to increase the risk of rhabdomyolysis when combined with statins, as compared with fenofibrate.[37]

CYP 2C8 is a common metabolic pathway for many of the diabetic treatments, such as glimepiride, rosiglitazone, and repaglinide. Gemfibrozil, as an inhibitor of the CYP 2C8 metabolic pathway, raises the AUC for all these drugs significantly. Therefore, gemfibrozil should only be used rarely in combination with CYP 2C8 metabolized drugs.[38,39] Alternatively, fenofibrate can be used as a substitute for gemfibrozil without adversely affecting the AUC of CYP 2C8 metabolized drugs.

Although gemfibrozil and fenofibrate are both fibrates and activate PPAR-alpha, resulting in similar lipoprotein changes (fenofibrate may more potently decrease LDL), these drugs have very different pharmacokinetic profiles. Gemfibrozil is a competitive inhibitor of the cytochrome P450 2C8 metabolic pathway, organic anion transport protein 2 (OATP2), and statin glucuronidation.[40] Fenofibrate is a substrate for the cytochrome P450 2C9 metabolic pathway but is not an inhibitor and is also a mild inhibitor of P-glycoproteins. These metabolic pathways appear to result in little known drug interactions for fenofibrate. The gemfibrozil-statin interaction is most problematic because a fibrate is frequently necessary to add to a statin to improve the lipoprotein profile. Both fenofibrate and, perhaps less commonly, gemfibrozil may rarely increase serum creatinine by an unknown mechanism. The most likely explanation appears to relate to increases in creatinine production in muscle tissue, but renal filtration changes are also possible. The homocysteine level is increased by both fenofibrate and gemfibrozil. Although the clinical significance of increased homocysteine level with fibrate therapy is uncertain, on the basis of a correlation between increased homocysteine levels and CHD risk and the demonstrated benefit of folic acid supplementation as a means of decreasing the fenofibrate-associated increase in homocysteine, it appears prudent to consider folic acid supplementation for

Table 26–6 Statin/Fibrate Combination Therapy: Pharmacokinetic Interactions

	Gemfibrozil	Fenofibrate
Atorvastatin	↑ in C_{max} (expected)	No effect
Simvastatin	↑ in C_{max} by 2-fold	No effect
Pravastatin	↑ in C_{max} by 2-fold	No effect

C_{max}, maximum concentration.

patients on fibrate therapy.[41] Both fenofibrate and gemfibrozil lower the fibrinogen level, but neither fibrate significantly alters Lp(a) level.

Gemfibrozil is usually dosed at 1200 mg at two divided doses 30 minutes before the morning and evening meals. Micronized fenofibrate, 145 mg, is given with a meal. The pharmacokinetic profile of micronized fenofibrate is markedly affected by food, and unless a patient takes the capsule with a meal, its absorption may be suboptimal. A new formulation of micronized fenofibrate is available that does not require intake with food and therefore should improve patient compliance. The recommended dose of bezafibrate is 400 g once daily as a sustained-release tablet, and ciprofibrate is given at 100 g daily.

CLINICAL SIGNIFICANCE OF NONSTATIN PLEIOTROPIC EFFECTS

Nonstatin therapies also have a multitude of potential pleiotropic effects. Niacin lowers Lp(a) and fibrinogen while increasing HDL and modifying LDL particle size. Ezetimibe lowers plant sterol levels and alters the cholesterol composition of postprandial chylomicrons. Both bile acid sequestrants and ezetimibe may affect FXR (bile acid receptor) or LXR (oxysterol receptor), or both, by altering bile salts/biliary cholesterol absorption.

As PPAR-alpha agonists, fibrates affect the expression of numerous genes that alter lipoprotein metabolism or the development of atherosclerosis (Fig. 26–4). PPAR-alpha agonism upregulates the genes involved in reverse cholesterol transport. Fenofibrate has been shown to upregulate macrophage ABCA1, which increases efflux of free cholesterol into nascent HDL[42] and enhances the uptake of HDL by the hepatic SRBI receptors, which results in increased biliary cholesterol excretion. PPAR-alpha agonists also appear to have numerous anti-inflammatory and antithrombotic effects that may reduce plaque rupture vulnerability to induce clinical events (Fig. 26–5). Although the clinical benefits of these pleiotropic effects of nonstatin therapies remain speculative, intriguing posthoc analyses from fibrate trials support additional clinical benefits of PPAR-alpha agonism in patients with metabolic syndrome or diabetes. In the fibrate outcomes trials, Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT)[43] and the Helsinki Heart Study (HHS),[44] the subset of patients with diabetes had a greater risk reduction than did the patients without diabetes (Fig. 26–6). In the VA-HIT trial[43] the occurrence of a new cardiovascular event and the benefit of fibrate therapy were much less dependent on levels of HDL-C or TGs than on the presence or absence of insulin resistance.

RATIONALE OF COMBINATION THERAPY

In light of the residual risk of CHD events in statin trials within certain subgroups, combination therapy appears most appropriate in patients with a high rate of events despite optimal statin treatment. These subgroups include patients with LDL-C levels >70 mg/dL, diabetics, those with metabolic syndrome, those with elevated hs-CRP, and cigarette smokers.

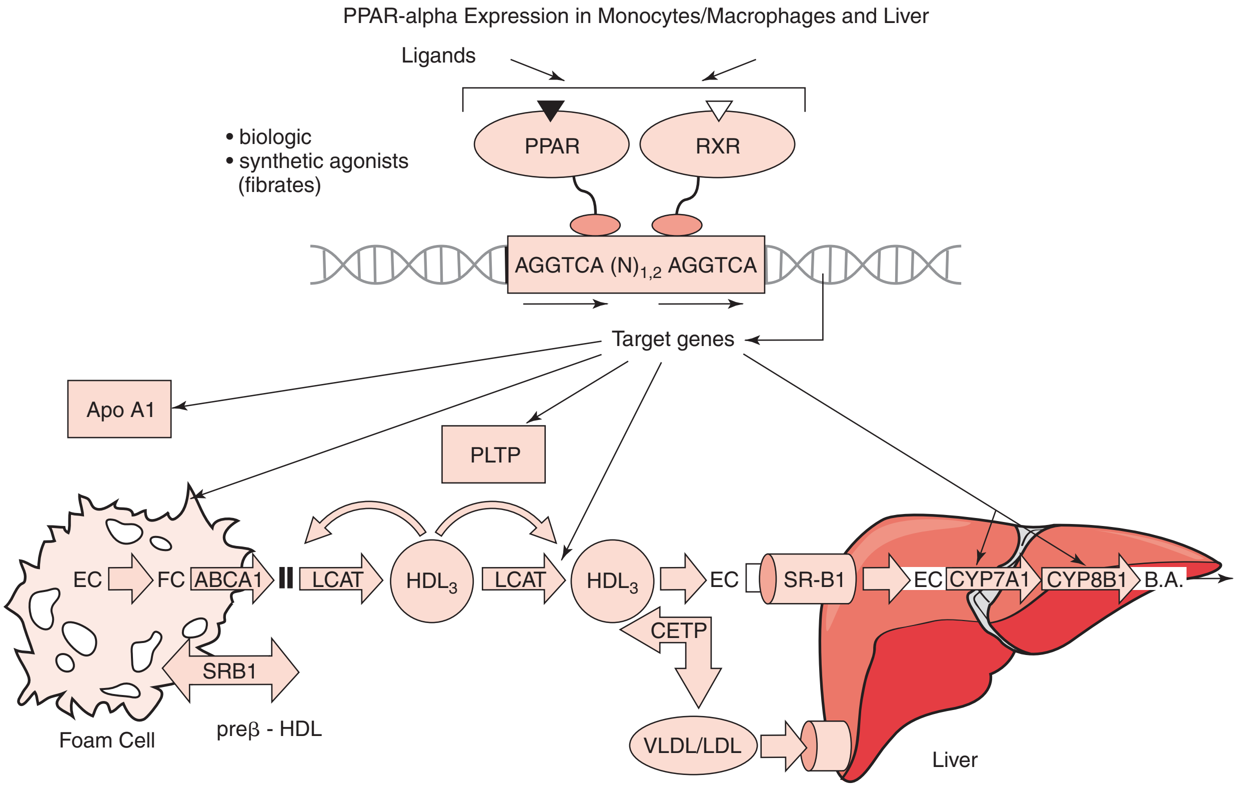

Figure 26–4 PPAR-alpha expression in monocytes/macrophages and liver.

A survey demonstrated that 75% of patients with CVD met the definition of "very high risk" according to the NCEP ATP III update report.[3] In this survey only 18% of patients at "very high risk" had an LDL <70 mg/dL and only 4% had an LDL <70 mg/dL and a non-HDL <100 mg/dL if TGs were >200 mg/dL. These data support the use of more aggressive statin therapy and the implementation of combination therapy as needed to achieve these optional targets in the "very high risk" patient population.

Although further LDL-C lowering may provide additional clinical benefits to patients with diabetes or metabolic syndrome, or both, the posthoc analysis of clinical trials has

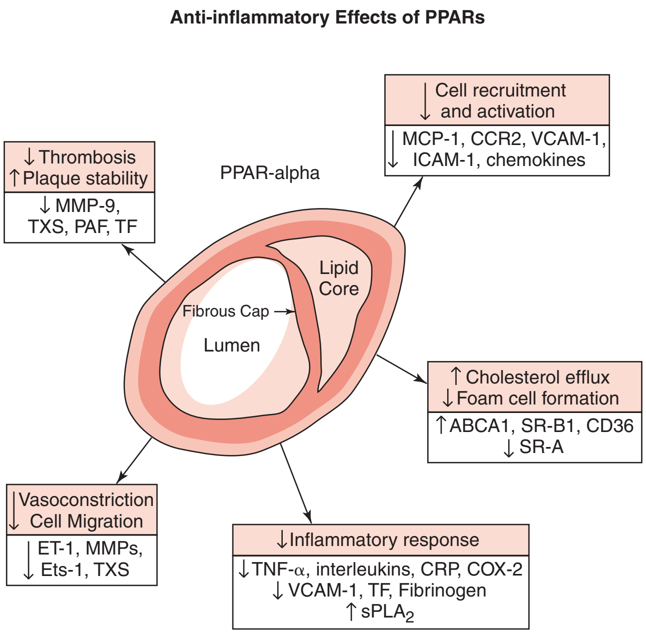

Figure 26–5 Anti-inflammatory effects of PPARs.

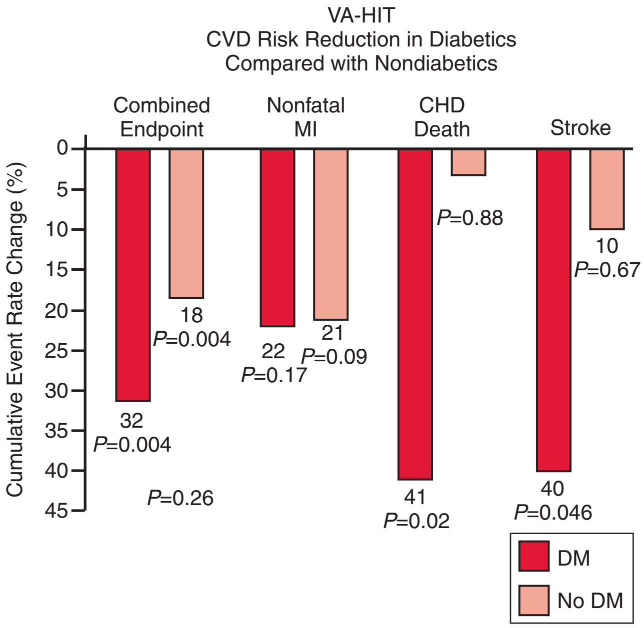

Figure 26–6 CVD risk reduction in diabetics compared with nondiabetics in Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT).

demonstrated a very high residual risk even with low LDL-C levels. Surrogate endpoint trials also demonstrate significant atherosclerotic progression in diabetics on statins or on a combination of statins and niacin. Because fibrates appear to have unique benefits in patients with insulin resistance, the combination of a statin and a fibrate is potentially most appropriate in this patient population. The Action to Control Cardiovascular Risk in Diabetes (ACCORD)[45] trial is testing this hypothesis in approximately 10,000 diabetics on simvastatin randomized to fenofibrate or placebo to evaluate CHD outcomes.

The additive effects of simvastatin and fenofibrate on lipid parameter have been documented in the Simvastatin Plus Fenofibrate for Combined Hyperlipidemia (SAFARI) trial.[46] Simvastatin monotherapy (20 mg/d) was compared with combination therapy (simvastatin 20 mg/d plus fenofibrate 160 mg/d) in patients with combined hyperlipidemia (fasting TG levels >150 and <500 mg/dL and LDL-C >130 mg/dL). Mean LDL-C levels decreased significantly with combination therapy compared with monotherapy (31.2% and 25.8%, respectively, $P < 0.001$). In addition, mean HDL-C levels significantly increased with combination therapy compared with monotherapy (18.6% and 9.7%, respectively, $P < 0.001$) and no drug-related serious adverse events occurred.[46]

THE SAFETY OF COMBINATION THERAPY

Although combination therapy is widely used and, in fact, recommended by expert panels for the management of hypertension and diabetes, combination treatment of dyslipidemia is seldom clinically applied in practice. In the National Cholesterol Education Program Evaluation Project Utilizing Novel E-Technology (NEPTUNE)[3] survey, only 5% of patients on treatment were on combination therapies. The major reason combination therapy has not been widely used in practice is the perception of adverse safety associated with combining a statin with niacin or a fibrate. In the labeling for all statins are cautionary notes regarding the combination with niacin or a fibrate, stating that the benefits should outweigh the increased risk of myopathy. The concern about the combination of niacin with a statin is based on the early case reports that documented myopathy with lovastatin in combination with high doses of niacin (≥2.5 g/d). Because niacin does not alter the pharmacokinetics of lovastatin and because excessive doses of niacin have documented hepatotoxicity, the most likely explanation for the cases of myopathy that are associated with combination statin-niacin therapy is that the liver impairment associated with niacin toxicity results in delayed clearance of the statin, leading to an increased risk of myopathy. Statin-induced myopathy is almost always associated with factors that increase the AUC, such as increased dosage, hypothyroidism, renal or hepatic impairment, or drugs that interfere with statin metabolism, such as cytochrome P450 3A4 inhibitors. In the absence of hepatotoxicity, it is unlikely that niacin would increase the risk of statin myopathy, and since the time of the first two reports of niacin and lovastatin myopathy, there have been no additional reports in the medical literature. Adverse event reports (AERs) under the Med Watch program to the FDA have also documented a very low incidence of statin myopathy associated with niacin.[47] Extended-release niacin, which has a very low rate of hepatoxocity, especially when compared with sustained-release niacin, has very few reports of myopathy in the AER database despite several hundred thousand prescriptions written in combination with a statin. Therefore the AER data, although not conclusive, support the safety of doses of extended-release niacin up to 2 g/d in combination with a statin.

In regard to fibrate therapy, there appears to be a clinically significant difference in safety with the combination of gemfibrozil compared with fenofibrate plus a statin. At least 60 case reports of gemfibrozil-statin myopathy have been in the medical literature compared with 2 cases of fenofibrate in combination with a statin. Reviews of the FDA AER database have documented that after correcting for prescription use, the rate of myopathy for gemfibrozil compared with a statin is 30 times more than combination therapy with fenofibrate (Table 26–7).[48,49] Cerivastatin, in combination with gemfibrozil, was associated with more than 4000 times the rate of rhabdomyolysis compared with statin therapy alone, and numerous fatalities were reported, resulting in the removal of cerivastatin from the worldwide market. An analysis of several managed care prescription and hospitalization event data has estimated that the rate of rhabdomyolysis requiring hospitalization from cerivastatin in combination with gemfibrozil was at least 1 in 10 patients. The Lipid and Diabetes Study (LDS),[50] a 2 × 2 factorial design, used cerivastatin/fenofibrate combination therapy or placebo in diabetics and enrolled more than 2000 patients (more than 1000 for more than 12 weeks) on cerivastatin and fenofibrate before the study was discontinued when cerivastatin was withdrawn from the market. In the more than 2000 patients on the combination of cerivastatin and fenofibrate, there were no case reports of myopathy. In the FIELD trial approximately 1000 patients were on both fenofibrate and a statin, and no cases of rhabdomyolysis were reported. In a Veterans Administration database evaluation during a 2-year period (October 1, 2002 to September 30, 2003), there were 93,677 patients on a combination of gemfibrozil and statin and 1830 patients on

Table 26–7 Reported Cases of Rhabdomyolysis with Fenofibrate + Statin Versus Gemfibrozil + Statin

Medication	No. Cases Reported	No. Prescriptions Dispensed	No. Cases Reported per Million
Fenofibrate + any statin	16	3,519,000	4.55
Fenofibrate + cerivastatin	14	100,000	140.00
Fenofibrate + other statins	2	3,419,000	0.58
Gemfibrozil + any statin	590	6,757,000	87.32
Gemfibrozil + cerivastatin	533	116,000	4,594.83
Gemfibrozil + other statins	57	6,641,000	8.58

fenofibrate with a statin during the evaluation period. During the 2 years of evaluation, there were 149 cases of rhabdomyolysis or acute tubular necrosis in the 93,677 patients on gemfibrozil with any statin for an overall rate of .16%. No cases of rhabdomyolysis or acute tubular necrosis were reported in 1830 patients on fenofibrate with any statin.[51] Therefore the AER data or the information from the LDS study support a much greater safety margin for combining fenofibrate with a statin than gemfibrozil.

The reason for the much greater propensity for gemfibrozil to increase the risk of myopathy with a statin is most likely due to the difference in the pharmacokinetic interactions between the two fibrates. Lipophilic statins are hydrolyzed by the cytochrome P450 enzymes to increase water solubility for renal excretion. Statins are also metabolized by another secondary pathway known as *glucuronidation.* Gemfibrozil uses the same family of glucuronidation enzymes as the statins, but fenofibrate uses a different enzyme family. This explains the marked increase in AUC for statins in conjunction with gemfibrozil, although fenofibrate has no significant effects on statin blood levels. Gemfibrozil is also a potent cytochrome P450 2C8 inhibitor, which is a metabolic pathway for cerivastatin. The more prominent increase in the AUC for gemfibrozil and cerivastatin may be due to both the effect of CYP 2C8 and glucuronidation. Rosiglitazone and repaglinide are also CYP 2C8 metabolized, and blood levels are increased in combination with gemfibrozil but not with fenofibrate. Therefore gemfibrozil is problematic not only for combination therapy with statins but also for use with the antidiabetes drug that uses the CYP 2C8 pathway. In diabetic patients who have documented benefits from statin therapy but a high residual risk, combination therapy with fenofibrate appears the most appropriate add-on treatment to further improve the lipid profile, if necessary, and avoid the significant safety problems associated with gemfibrozil therapy. The Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial is underway to determine the enhanced clinical benefit of adding fenofibrate to the regimen of patients with simvastatin therapy, and the Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides and Impact on Global Health Outcomes (AIM-HIGH) trial is evaluating the potential clinical benefits of increasing HDL-C with niacin in patients with CHD and the metabolic syndrome.

OMEGA-3 FATTY ACIDS

Since the observation of the marked TG-lowering effects of salmon feeding in patients with severe hypotriglyceridemia, marine omega-3 fatty acids have been used clinically as a therapy for dyslipidemia.[52] In a comprehensive review of human studies, Harris reported that 4 g/d of marine omega-3 fatty acids decreased serum TGs by 25% to 30% with modest increases in LDL of 5% to 10% and a neutral effect on HDL cholesterol (+1% to 3%).[53] A dose-response relationship exists between omega-fatty acid intake and TG-lowering, but even small intakes can produce significant reductions.[54,55] Postprandial triglyceridemia is especially sensitive to chronic fish oil consumption.[56] The mechanisms for other TG-lowering therapies, such as fibrate or niacin, are fairly well established, but for omega-3 fatty acids, the hypotriglyceridemia is not well understood.

Omega-3 fatty acids regulate at least four metabolic nuclear receptors that result in the repartitioning of metabolic fuel (i.e., fatty acids) away from TG storage and toward oxidation (Fig. 26–7). This effect is mediated by a marked reduction in SREBP1-c, the main genetic switch controlling lipogenesis. With reduction in TG synthesis and increase in fatty acid oxidation in the hepatocyte, there is a decreased substrate for VLDL synthesis and secretion. Additionally, omega-3 fatty acid, as an unsaturated fat, may undergo peroxidation that appears to stimulate the degradation of APO B, also resulting in the reduction in VLDL secretion. A reduction in VLDL secretion allows enhanced postprandial chylomicron clearance, but also omega-3 fatty acids appear to directly stimulate lipoprotein lipase activity.[57]

A highly purified, pharmaceutical-grade omega-3 fatty acid, marine fish oil formulation contains high concentrations of eicosahexaenoic acid and docosahexaenoic acid (440 mg EPA and 360 mg DHA, respectively, for a total of 800 mg EPA + DHA), along with 4 mg (6 International Units) vitamin E in each 1 g capsule. Prescription omega-3 fatty marine oils are indicated for treatment of hypertriglyceridemia and have been shown in clinical trials to significantly reduce serum TGs by 19% to 55% at doses of 4 capsules/d when administered over periods from 6 weeks to several years. Marine oil also modestly increases LDL-C, increases HDL-C levels, and favorably affects lipoprotein particle size and subclass distribution. When combined with gemfibrozil and simvastatin, marine oil reduces TG levels an additional 37% and 46%, respectively. Marine oil is well tolerated with few side effects other than mild gastrointestinal-related symptoms. Specifically, no adverse effects have been reported regarding hyperglycemia, abnormal bleeding, elevations in muscle or liver enzymes, or abnormalities in kidney or nerve function.

TORCETRAPIB

Torcetrapib is the first in the class of cholesteryl ester transfer protein (CETP) inhibitors. CETP assists the equal mass gradient transfer of cholesteryl ester from HDL to the ApoB-containing particles (LDL and VLDL) for TGs. In the presence of hypertriglyceridemia, CETP, by transferring TG into HDL and LDL in exchange for cholesteryl ester, results in TG-enrichment of these lipoproteins, which undergo further hydrolysis by lipoprotein and hepatic lipases to form a smaller, more dense LDL and HDL. Therefore the inhibition of CETP results in a marked increase in HDL mass and size by reducing HDL metabolism and also increasing LDL particle size.

The observation of high levels of HDL-C in Japanese populations with deficiencies in CETP[58,59] has led to the concept of CETP inhibition as a potential new strategy for substantially elevating HDL-C and for the treatment of CVD,[60] although it is unclear if families with elevated HDL due to CETP deficiency have a lower rate of CVD. In rabbit models both biologic and chemical techniques have been employed to suppress CETP activity, resulting in increases in HDL-C levels and reductions in atherosclerotic lesions.[61-64] In preliminary trials, torcetrapib, administered alone to healthy young individuals[65] and with or without background statin therapy to individuals with low levels of HDL-C,[66] has been shown to produce substantial elevations in HDL-C, modest decreases in LDL-C, and increases in lipid particle size.

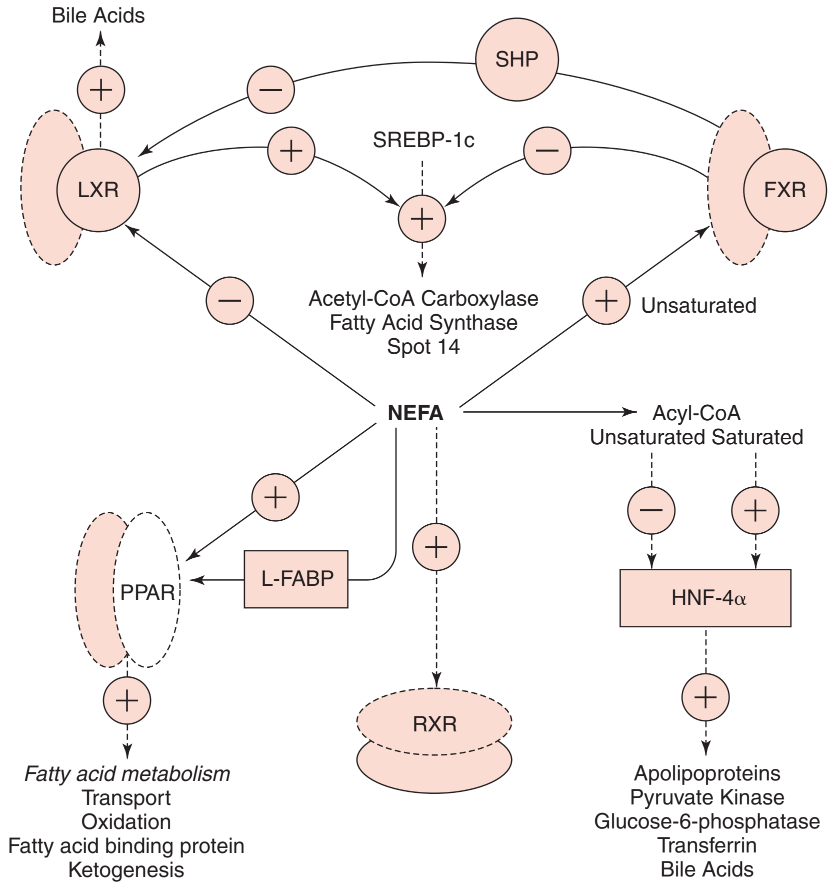

Figure 26–7 Omega-3 fatty acid regulation of metabolic nuclear receptors. NEFA refers to nonesterified fatty acids that are omega-3 polyunsaturated fatty acids but also applies to omega-6 polyunsaturated fatty acids. These fatty acids activate nuclear receptors and cofactors that in turn activate or repress genes that regulate metabolism of lipids, carbohydrates, and bile acids. LXR = liver X receptor; FXR = farnesoid X receptor; PPAR = peroxisomal proliferator activator receptor; HNF-4 = hepatic nuclear factor-4; RXR = retinoid X receptor; FABP = fatty acid binding protein; SHP = small heterodimer partner; SREBP-1c = sterol regulatory element binding protein-1c.

A 60-mg dose of torcetrapib was shown to increase HDL by 45% and lower LDL by 8%.[67] Torcetrapib is generally well tolerated, but there is a dose-related increase in blood pressure. The 60-mg dose, which is the single dose that is being evaluated in a large phase II program, is associated with an approximate 2-mm mean increase in systolic blood pressure. The clinical benefits of torcetrapib on atherosclerosis, as assessed by intravascular coronary ultrasound and by carotid ultrasound and a large cardiovascular morbidity trial, are presently underway to test the hypothesis that raising HDL by CETP inhibition results in a cardiovascular benefit.

CONCLUSION

Reducing the residual CHD risk for patients on statin therapy remains an important clinical challenge. The "lower is better" hypothesis has been well documented by clinical trials, but even with low levels of LDL cholesterol, patients with diabetes, metabolic syndrome, and other uncontrolled risk factors continue to have a relatively high CV event rate. Combination therapy that further improves the lipid profile appears to be frequently necessary for very high-risk patients who have not yet achieved the optional therapeutic target. The use of combination therapy has been tainted by the history of increased risk of myopathy with gemfibrozil in combination with a statin. However, other lipid-altering agents, such as bile acid sequestrants, extended-release niacin, ezetimibe, and fenofibrate, do not have a pharmacokinetic interaction with statins and appear to have a low risk for increasing statin-related side effects. The improved safety of these agents with a statin has stimulated a new era of clinical trials evaluating the potential clinical benefits of combination therapy.

Drugs for Elevated LDL-Cholesterol

Neil J. Stone

CHAPTER CONTENTS

HMGCoA-REDUCTASE INHIBITORS

HMGCoA-reductase inhibitors, or "statins," are competitive inhibitors of the rate-limiting step of hepatic cholesterol synthesis. This leads to a reduction in hepatocyte cholesterol concentration with subsequent upregulation of low-density lipoprotein (LDL) receptors that enhance clearance of LDL.[1] Statins lower both large and small LDL subclasses.[2] In addition to effects on LDL, intermediate-density lipoprotein (IDL) and very-low-density lipoprotein (VLDL) are decreased by statin therapy.[3] Both fractions are decreased to similar percentages by statin therapy. Thus, statins are effective drugs for lowering both elevated LDL-C and triglyceride-rich lipoproteins. They are indicated in those individuals with elevations of these lipoproteins due to genetic reasons, as in familial hypercholesterolemia, familial defective apo B, familial combined hyperlipidemia, and type 3 (remnant removal disease). They are also indicated in most adults with diabetes,[4] renal failure,[5] and for the dyslipidemia found in renal and cardiac transplantation recipients.[6] The Adult Treatment Panel III (ATP III) recommends statins as the most effective class of drugs for lowering LDL-C in reducing the risk for CHD in both primary and secondary prevention.[7]

Effects on Lipids and Lipoproteins

All members of the statin class reduce LDL-C levels in a dose-dependent fashion. This dose-response relationship is log-linear. This means that although the initial dose lowers LDL-C from 25% to 45%, additional doublings of the statin dose result in only an additional 6% to 7% of LDL-C lowering.[8] Responsiveness to statins by individuals varies, however, and individuals who are hypo- or hyper-responsive to one statin maintain that response with other statins.[9] In familial combined hyperlipidemia, using a moderate dosage of a potent statin generates lowered cholesterol not only in LDL but also in triglyceride-rich remnant lipoprotein (TGRL) in the fasting and fed states.[10] This allows attainment of both LDL and non–HDL-C goals.

The initially available statins (lovastatin, pravastatin, and simvastatin) were derived from fungal fermentation.[11] Subsequently, synthetic forms (fluvastatin, atorvastatin, cerivastatin, and rosuvastatin) became available.[12] Cerivastatin, the most potent of all the statins introduced to date, was withdrawn from the market after it was found to have an unacceptable incidence of myositis and rhabdomyolysis.[13,14] The latter reaction was more likely when cerivastatin was combined with gemfibrozil.

A review of clinical trial data indicated that initial doses of statins (Table 27–1) should provide at least a 30% reduction in LDL-C.[12] Triglycerides are lowered with statins approximately proportional to the degree of LDL-C lowering, 15% to 30%, an effect size that is usually not adequate to normalize moderate elevations of triglycerides.[15] Statin therapy does not result in removal of triglyceride-laden chylomicrons. Thus, statins should not be used when severe hypertriglyceridemia suggesting chylomicronemia is present. Statins affect HDL-C levels to a variable degree, and there is no relationship between degree of LDL-C lowering and change in HDL-C.[16] Rosuvastatin, simvastatin, and pravastatin appear to raise HDL-C more than atorvastatin, for example. In the PROVE-IT-TIMI 22 trial, standard LDL-C lowering with pravastatin in subjects with acute coronary syndrome was associated with a greater percent increase in HDL-C than that seen with the intensive LDL-C lowering with atorvastatin. In PROVE-IT-TIMI 22, those individuals with the greatest LDL-C lowering had the greatest event reduction.[17] Statins in moderate doses do not lower Lp(a), although a study of heterozygous subjects with familial hypercholesterolemia (FH) showed a decrease in Lp(a) levels with 80 mg of atorvastatin.[18] Statins lower markers of inflammation and oxidation, such as high-sensitivity CRP, as well as lipoprotein-associated phospholipase A2 (Lp-PLA2).[19] Statins lower hs-CRP in primary and secondary prevention patients, and the result is seen as early as 12 weeks.[20] For hs-CRP, the lowering is mainly independent of LDL-C lowering, unlike that seen with Lp-PLA2, which is largely mediated by the statin-induced reduction in LDL-C. Lovastatin was effective among those individuals with a ratio of total to HDL-C that was lower than the median and a hs-CRP level higher than the median in a primary prevention trial.[21] In contrast, lovastatin was ineffective among subjects in this trial with a ratio of total to HDL-C and a hs-CRP level that were both lower than the median. Also, patients with acute coronary syndrome who have low hs-CRP levels after statin therapy have better clinical outcomes than those with higher hs-CRP levels, regardless of the resultant level of

LDL-C.[22] Whether hs-CRP should be a co-equal target with LDL-C for CHD risk reduction awaits definitive clinical trial results.

Pharmacokinetic Properties

The available statins differ in terms of lipid solubility, half-life, and hepatic and renal clearance[23,24] (Table 27–2). Several of the statins are metabolized extensively by the CYP pathways of the P450 cytochrome system. Fluvastatin is metabolized by 2C9, whereas atorvastatin, lovastatin, and simvastatin are metabolized by 3A4. Rosuvastatin is only weakly metabolized by 2C9, and pravastatin is not metabolized at all. These properties can have clinical importance. For example, in patients with impaired renal function, atorvastatin and fluvastatin may have advantages because they are essentially not renally cleared. Likewise, for those patients who require prolonged treatment with erythromycin or clarithromycin, antibiotics that inhibit the metabolism of statins by the 3A4 P450 system, such as atorvastatin, simvastatin, and lovastatin, clinicians should consider an alternative statin.

Drug Interactions

Safety is not a class effect because statins vary in their routes of excretion and the impact on their metabolism by other drugs, especially those that affect the P450 system.[25] Statins, especially simvastatin, must be used in low doses and monitored regularly if coadministered with amiodarone or verapamil. Physicians should be aware that erythromycin; clarithromycin; azole antifungals, such as ketoconazole; protease inhibitors; and large quantities of grapefruit juice may increase steady state concentrations of statins. Fluvastatin is metabolized by the 2C9 pathway, and concentrations of fluconazole and warfarin may increase statin concentrations. Because rosuvastatin is only weakly metabolized by 2C9, it does not interact significantly with fluconazole. Pravastatin is not metabolized at all by the P450 system, but protease inhibitors may decrease its concentration. All statins may interact with cyclosporine and with other lipid-lowering drugs, such as fibrates and nicotinic acid; warfarin; and digoxin.[26] Cyclosporine is used extensively in transplant patients. Cyclosporine is highly lipid soluble, and a significant portion is bound to lipoproteins. It increases LDL-C and Lp(a) concentrations. It affects fluvastatin less so.[27] Gemfibrozil affects glucuronidation of statins, resulting in a higher concentration of statin and increased toxicity in turn, which results in an unacceptably high incidence of rhabdomyolysis when combined with cerivastatin. Coadministered fenofibrate does not raise statin concentrations and is now the fibrate of choice when fibrate and statin therapy are combined. Both fluvastatin and warfarin are metabolized by the P450 2C9 pathway. Because case reports have indicated changes in warfarin levels with other statins not metabolized this way, until more definitive data are available, patients on warfarin should monitor their INR closely after starting statin therapy.[28] Statins may increase digoxin concentrations by inhibiting P-glycoprotein transport.[29]

Although there were early reports of myositis with statin and nicotinic acid combinations, this has not been reported in studies of an extended-release form of nicotinic acid.[30] This may relate to the higher incidence of hepatotoxicity with long-acting forms of nicotinic acid and the resultant increased levels of statins that result from hepatic damage.

Efficacy

Angiographic Trials

A decade of double-blind, randomized, controlled angiographic trials demonstrated that treatment with statins could significantly decrease progression of atherosclerosis.[31] Thompson emphasized the importance of statins in lowering non-HDL lipoproteins and LDL-C in these trials. The Post Coronary Artery Bypass Graft Trial (Post CABG) demonstrated the value of lower LDL-C attained with more intensive statin (lovastatin) therapy in those subjects who had undergone coronary bypass surgery.[32] The higher-dose lovastatin group attained an LDL-C of approximately 100 mg/dL as compared

Table 27–1 Statins–Effective Clinical Dosages

Statin Name	Daily Dose to Lower LDL >30%	Maximal Daily Dose
Lovastatin	40 mg	80 mg
Pravastatin	40 mg	80 mg
Simvastatin	20 mg	80 mg
Fluvastatin XL	80 mg	80 mg
Atorvastatin	10 mg	80 mg
Rosuvastatin	5 mg	40 mg

Table 27–2 Statin Pharmacokinetics

Modified from: Ballantyne CM, Corsini A, Davidson MH, et al: Risk for myopathy with statin therapy in high-risk patients. Arch Intern Med 2003;163(5):553-64 and Corsini A, Bellosta A, Davidson MH: Pharmacokinetic interactions between statins and fibrates. Am J Cardiol 2005;96:44K-49K.

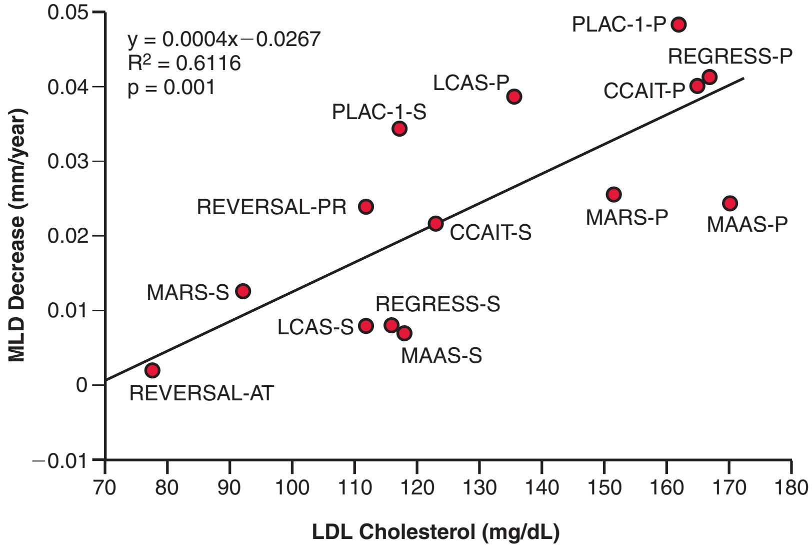

Figure 27–1 Atherosclerosis progression varies directly with low-density lipoprotein (LDL). This regression line indicates that atherosclerosis does not progress when LDL is 67 mg/dL or below. Data from randomized placebo-controlled trials using statins for preventing atherosclerosis progression or preventing coronary heart disease events in primary or secondary prevention were used for computation of the univariate regression lines correlating LDL with outcomes. Regression estimates, model R^2, and *P* values for LDL effect were obtained from the unweighted regression lines. AT, atorvastatin; CCAIT, Canadian Coronary Atherosclerosis Intervention Trial; LCAS, Lipoprotein and Coronary Atherosclerosis Study; MAAS, Multicentre Anti-Atheroma Study; MARS, Monitored Atherosclerosis Regression Study; MLD, mean luminal diameter; P, placebo; PLAC, Pravastatin Limitation of Atherosclerosis in the Coronary Arteries study; PR, pravastatin; REGRESS, Regression Growth Evaluation Statin Study; REVERSAL, Reversal of Atherosclerosis with Aggressive Lipid Lowering; S, statin. (From O'Keefe JH, Cordain L, Harris WH, et al: Optimal low-density lipoprotein is 50 to 70 mg/dL; lower is better and physiologically normal. J Am Coll Cardiol 2004;43:2142-46.)

with the reduction of LDL-C to only 132 to 136 mg/dL. The investigators found delayed atherosclerotic progression in the grafts at 4 to 5 years. An informative angiographic trial enrolled 341 subjects with stable coronary disease, relatively normal left ventricular function, and an LDL-C higher than 115 mg/dL who were referred for angioplasty.[33] Those assigned to the high-dose statin therapy (atorvastatin) had a significantly longer time to the first ischemic CHD event as compared with those who were assigned to angioplasty and usual medical care.

Although the CHD event rate was 36% lower in the statin group, the P value obtained was not statistically significant due to the adjustment for multiple on-trial analyses. On closer inspection, the intensive statin therapy had its greatest effect in reducing revascularization procedures and hospitalizations for worsening angina. Using intravascular ultrasound, a multi-center study showed that intensive statin therapy (atorvastatin 80 mg/d) had a significantly greater effect on the primary endpoint (percentage change in atheroma volume) than a moderate dose of a statin (pravastatin 40 mg/d).[34] Importantly, progression did not occur in those assigned to atorvastatin 80 mg/d, whereas it did in those assigned to pravastatin 40 mg/d. Of note, those assigned to atorvastatin 80 mg/d had significantly lower hs-CRP levels than those assigned to pravastatin 40 mg/d. O'Keefe and coworkers plotted out the results of major angiographic trials showing the increasing benefit of LDL-C lowering down to an LDL-C of less than 80 mg/d (Fig. 27–1).[35]

Surface/transesophageal MRI has been used to monitor statin-induced atherosclerotic plaque (AP) reduction.[36] AP regression and reverse remodeling was detected accurately by MRI in just 6 months after statin therapy initiation, and not surprisingly, it was associated with LDL-C reduction.

Large-Scale Clinical Trials

Statins have proven effective in primary prevention and secondary prevention trials (Tables 27–3 and 27–4). As might be expected, the absolute risk reduction is greater in the secondary prevention trials, resulting in a steeper LDL-C-event reduction curve than that seen in primary prevention trials. The large Heart Protection Study demonstrated significant benefit for total mortality and CHD events in subjects at high risk of a coronary event assigned to simvastatin 40 mg daily compared with placebo.[37] This substantial benefit occurred regardless of baseline LDL-C and in all subgroups including women and the elderly. Benefit increased with duration of therapy. Ischemic stroke incidence was also substantially reduced by statin therapy.[38] No significant increase in liver or muscle toxicity occurred, and statin therapy was not associated with an increase in cancer, respiratory disease, or suicide.

The Cholesterol Treatment Trialists' collaboration produced a prospective meta-analysis of data from 90,056 subjects in 14 randomized trials of statins (Fig. 27–2).[39] During a mean of 5 years 8186 subjects died, 14,348 had major vascular events, and 5103 developed cancer. Mean LDL-C differences at 1 year ranged from 14 mg/dL to 69 mg/dL with a mean of 42 mg/dL in these trials. The results mirrored those seen in the Heart Protection Study. A highly significant reduction occurred in all-cause mortality, as well as a significant 19% reduction

Table 27–3 Cardiovascular Benefits of Statins in Secondary Prevention Clinical Trials

Study	Statin Dose; Numbers of Subjects	LDL-C Reduction (%)	Efficacy Against CHD	Efficacy Against Stroke
HEART PROTECTION STUDY (HPS) subjects 40-80 yr old with coronary disease, other occlusive disease, diabetes	Simvastatin 40 mg/d (10,269) vs. placebo (10,267)	–37	Significant reductions in total mortality, fatal and nonfatal MI, revascularization	Yes
PROSPER—subjects 70-82 yr old with history of or risk factors for vascular disease	Pravastatin 40 mg/d (2891) vs. placebo (2913); mean follow-up was 3.2 yr	–32	No reduction in total mortality, but significant reduction in fatal and nonfatal CHD	No, though a decrease in TIA (low rate of stroke in placebo group)
PROVE-IT-TIMI 22—4162 subjects with acute coronary syndrome; mean age 58 yr	Atorvastatin 80 mg (2099) vs. pravastatin 40 mg (2063); mean follow-up was 2.0 yr	Prava 40: –10; Atorva 80: –42	Greater reduction in combined endpoint with atorvastatin 80 mg than with pravastatin 40 mg	No
Cholesterol and Recurrent Events (CARE) Study—4159 subjects post-MI; mean age 59	Pravastatin 40 mg vs. placebo; mean follow-up was 5 yr	–28	Significant reduction of primary endpoint	Yes
Long Term Intervention in Ischaemic Patients (LIPID)—9014 subjects, 31-75 yr old MI and acute coronary syndrome	Pravastatin 40 mg/d (4512) vs. placebo (4502); mean follow-up was 5 yr	–25	Significant reduction of primary endpoint	Yes

in coronary mortality. Nonsignificant reductions occurred in noncoronary vascular mortality and nonvascular mortality. Statin therapy substantially reduced myocardial infarction or CHD death and coronary revascularization by about 25%. The rates for fatal or nonfatal stroke were reduced by 17% on average. The proportional reduction in major vascular events differed significantly ($P < 0.0001$) according to the absolute reduction in LDL-C achieved but remained similar throughout the range of LDL-C studied. These benefits were significant within the first year but were greater in subsequent years. Moreover, statin therapy was found to be safe with no increase in cancer risk. Taken as a whole, this large dataset suggests that in those with known CHD or greatly at its risk, prolonged statin treatment with substantial LDL-C reductions should provide benefit to all patients irrespective of the initial LDL-C. Using ATP III guidelines with LDL-C goals based on CHD risk is still reasonable, however, because the benefits, risk, cost, and feasibility issues must be considered in various patient groups to determine the intensity of therapy.

MECHANISM OF BENEFIT OF STATINS

Although LDL lowering appears to be the major reason why statins produce cardiovascular benefit, some investigators hold that there are “pleiotropic effects” on endothelial dysfunction, inflammation, coagulation, and plaque regression that more fully explain how statins work[40] (Table 27–5). They argue that pleiotropic effects may explain the early benefit seen with statins in the acute coronary syndrome[41] as compared with beneficial but delayed effects in nondrug trials of LDL-C lowering by partial ileal bypass.[42] Whether these effects are truly cholesterol independent and mediated by their ability to block the synthesis of isoprenoid intermediates is actively debated.[43] Others argue that LDL-C reduction may serve as a marker for the pleiotropic effects seen with statins. This is supported by increasing benefit from statins at the higher dosage range.

Safety

As can be seen from the large-scale meta-analysis, in clinical trials, statins are well tolerated. The two major side effects that clinicians encounter are those involving the liver and muscles.

Liver

An ACC/AHA/NHLBI Clinical Advisory on Statins noted that statin-induced elevated hepatic transaminases generally occur infrequently with rates below 2%.[12] These elevations were dose dependent and more likely at the highest dosages. The setting may be important as well. In the PROVE-IT-TIMI 22 Trial, the incidence of significant liver transaminase elevation was 3.3% in the atorvastatin group versus 1.1 in the pravastatin group.[17] In the setting of chronic stable coronary disease, the Treat to New Targets (TNT) trial showed a low order of

Table 27–4 Cardiovascular Benefits of Statins in Primary Prevention Clinical Trials

Primary Prevention Clinical Trials	Statin Dosage	LDL-C Reduction (%)	Efficacy against CHD	Efficacy against Stroke
AFCAPS/TEXCAPS; 5608 men 45-73 yr old and 997 women 55-73 yr old with lipid entry criteria (low HDL-C required)	Lovastatin 20 mg and 40 mg/day (3304) vs. placebo (3301)	-25	Yes	Not mentioned
WOSCOPS; high risk men 45-64 yr old without prior myocardial infarction; follow-up for 4.9 years	Pravastatin 40 mg/d (3302) vs. placebo (3293)	-26	Yes	No
ASCOT-LLA 10,305 hypertensive patients (aged 40-79 yr) with at least 3 other cardiovascular risk factors followed for 3.3 yr before study stopped by DSMB	Atorvastatin 10 mg/d (5168) and placebo (5137)	-29	Yes	Yes
ALLHAT-LLA; 10,355 subjects, aged 55 yr or older who met lipid criteria and were followed for up to 8 yr	Pravastatin 40 mg/d	-16.7 (this small reduction related to drop-ins in placebo + drop-outs in treatment groups)	No; difference in LDL-C between statin and usual care was only 18% due to high cross-over and drop-out rate	No
CARDS; 2838 men and women with type 2 DM and at least one other risk factor[29]	Atorvastatin 10 mg/d	-40	Yes	Yes

liver toxicity and did not differentiate between the low- and high-dose atorvastatin regimens employed. Indeed, it has been questioned whether low-level transaminase elevation (<2× the upper limit of normal) constitutes true hepatotoxicity.

Statin-associated hepatotoxicity has several characteristic features.[44] Elevations of liver transaminases usually are noted within the first 12 weeks of therapy. Unlike the situation with nicotinic acid hepatotoxicity, in which symptoms often herald liver damage, statin-associated elevations of liver transaminases are usually asymptomatic. Evidence of cholestasis with jaundice and hyperbilirubinemia is rare. Progression to liver failure shown to be specifically due to statins is rare; indeed, despite the large number of subjects assigned to statins in large-scale clinical trials, statin-induced liver failure was not seen. When the statin dose is reduced or there is rechallenge with another statin, elevations of liver transaminases often do not occur. When statin therapy is stopped, elevated liver transaminases return to normal. An experience from a large HMO of severe cases of hepatic transaminase elevation (defined as >10× the upper limit of normal) indicated that in 14 of 17 cases in which hepatotoxicity was directly attributable to statin use, there was a drug interaction.[45] Although they concluded that less frequent liver enzyme monitoring was reasonable for most patients on statins, they acknowledged that continued monitoring was warranted for patients who were receiving concomitant medications or who had comorbidity that increased their risk of hepatic toxicity.

Cholestasis and active liver disease are listed as contraindications to statin use. Patients with acute liver disease, such as acute viral hepatitis or alcoholic hepatitis, should not take statins until they have recovered. The review cited earlier noted that statins have not been shown to worsen the outcome in persons with chronic transaminase elevations due to hepatitis B or C, and treatment of hyperlipidemia may actually improve transaminase elevations in individuals with fatty liver.

A reasonable screening approach for those on statins is to check a liver panel 6 or 12 weeks after starting statin therapy and then yearly or after a change in either dosage or the patient's condition. More frequent testing should be considered if there are concerns over the patient's condition, associated drug therapy (e.g., nicotinic acid, fibrates, or other drugs that affect the liver), alcohol habit, or the medical setting (hospital). If the patient has known stable liver disease, such as fatty liver, and merits statin therapy, low doses of statins can be employed initially, but screening should be more frequent. Statin therapy should be stopped if transaminase elevations exceed 2× the upper limit of normal. In the Heart Protection Study there was no significant difference from placebo in liver transaminases >4× the upper limit of normal. However, an important caveat is that subjects in this trial were prescreened for simvastatin tolerability.

Muscle

The ACC/AHA advisory defined several of the terms used to describe muscle problems with statins.[12] These included the following:

Endpoint	Events (%) Treatment (45,054)	Events (%) Control (45,002)	RR(CI)
Nonfatal MI	2001 (4.4%)	2769 (6.2%)	0.74 (0.70–0.79)
CHD death	1548 (3.4%)	1960 (4.4%)	0.81 (0.75–0.87)
Any major coronary event	**3337 (7.4%)**	**4420 (9.8%)**	**0.77 (0.74–0.80)**
CABG	713 (1.6%)	1006 (2.2%)	0.75 (0.69–0.82)
PTCA	510 (1.1%)	658 (1.5%)	0.79 (0.69–0.90)
Unspecified	1397 (3.1%)	1770 (3.9%)	0.76 (0.69–0.84)
Any coronary revascularization	**2620 (5.8%)**	**3434 (7.6%)**	**0.76 (0.73–0.80)**
Hemorrhagic stroke	105 (0.2%)	99 (0.2%)	1.05 (0.78–1.41)
Presumed ischemic stroke	1235 (2.8%)	1518 (3.4%)	0.81 (0.74–0.89)
Any stroke	**1340 (3.0%)**	**1617 (3.7%)**	**0.83 (0.78–0.88)**
Any major vascular event	**6354 (14.1%)**	**7994 (17.8%)**	**0.79 (0.77–0.81)**

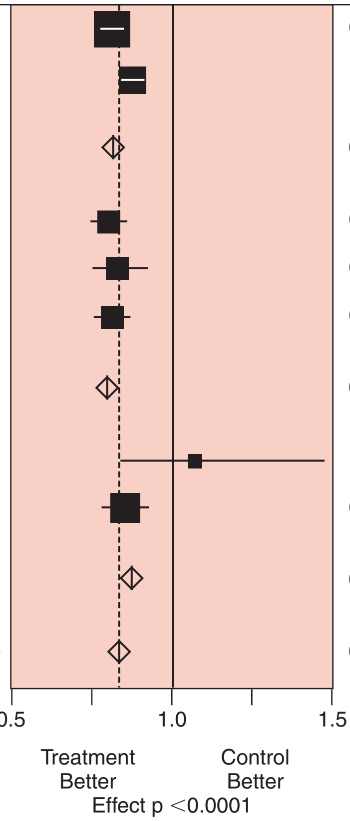

Figure 27–2 Proportional effects on major vascular events per mmol/L LDL cholesterol reduction. The *broken vertical line* indicates overall RR for any type of major vascular event. CABG, coronary artery bypass graft; PTCA, percutaneous transluminal coronary angioplasty. The Lesol Intervention Prevention Study (LIPS) only provided data on fatal strokes and so does not contribute to the stroke analyses. *Diamonds* represent totals and subtotals (95% CI). *Squares* represent individual categories (horizontal lines are 99% CIs). The area of square is proportional to the amount of statistical information in that category. RRs are weighted to represent reduction in rate per 1 mmol/L LDL cholesterol reduction achieved by treatment at 1 year after randomization. (From Cholesterol Treatment Trialists' (CTT) Collaborators. Efficacy and safety of cholesterol-lowering treatment: prospective meta-analysis of data from 90,056 participants in 14 randomised trials of statins. Lancet 2005;366:1267.)

- Myopathy—a general term referring to any disease of muscles; myopathies can be acquired or inherited and can occur at birth or later in life
- Myalgia—muscle ache or weakness without creatine kinase (CK) elevation
- Myositis—muscle symptoms with increased CK levels
- Rhabdomyolysis—muscle symptoms with marked CK elevation (typically substantially greater than 10 times the upper limit of normal and with creatinine elevation (usually with brown urine and urinary myoglobin).

One concerning report detailed four subjects with statin-associated weakness, no CK elevation, and abnormal findings on muscle biopsy.[46] How often this occurs is not clear, but it does indicate that patients with objective measures of statin-associated weakness, irrespective of their CK level, should have their statin stopped until they can be carefully evaluated for other causes of muscle weakness including hypothyroidism and polymyalgia rheumatica. Grundy reviewed the data as to whether statins can cause a low-grade myopathy.[47] He argued that although a small fraction of patients do develop myopathy, the likelihood that there will be progression to rhabdomyolysis and death is small, and this must be balanced against the need for risk reduction with statins in high-risk patients. He emphasized the need for clinicians to look for predisposing conditions of myopathy as listed by the ACC/AHA/NHLBI panel that included advanced age, relatively low body weight, elderly females, certain medications, use of multiple medications, multisystem disease, and acute illnesses or major surgery. The use of combination therapy with gemfibrozil results in additive improvements in the lipid and lipoprotein profile but often with an unacceptable increased risk. Fenofibrate is shown not to affect statin glucuronidation

Table 27–5 Pleiotropic Effects of Statin Drugs[40]

Improve impaired endothelial vasodilation
Produce antithrombotic effects
Decrease vascular inflammation
Decrease vascular smooth muscle proliferation
Increase plaque stability

as is seen with gemfibrozil. This has made fenofibrate the fibrate of choice if it is believed that combination therapy with a statin is beneficial. Additional provocative factors for myopathy are alcohol use, compromised liver or renal function, hypothyroidism, and diabetes (Table 27–6).[48]

Several practical considerations should be noted. First, CK measurements are highly variable. Getting a CK at baseline is useful, but it should be repeated only when symptoms suggest myositis. Second, patients who exercise intensively can have marked asymptomatic excursions in their CK. Moreover, statins magnify the exercise-related increase in CK.[48] The low rate of muscle complications seen in clinical trials may reflect, in some instances, the highly selected nature of the populations studied (e.g., the Heart Protection Study had an "active drug" run-in as compared with the "placebo" run-in phase with the CARE trial).

One useful clinical maneuver for those with vague muscle complaints that are not clearly due to the statin therapy is to provide a 2- to 3-week holiday off statins with a view toward rechallenging with either the same or a lowered dose of the statin to see if the statin is truly causing the symptoms noted. An analysis of the TNT trial showed that discontinuing statins for a short time during the run-in phase did not result in an increased risk of CHD events.[49] For patients with familial muscle disorders or those presenting with new-onset weakness, a work-up should include an inquiry into exogenous substances (alcohol, grapefruit juice, or drugs that increase statin concentrations) and systemic causes (hypothyroidism, collagen vascular disease) and primary myopathy (consider muscle biopsy) should ensue before a consideration of whether to start statin therapy is undertaken.

Fibrates and nicotinic acid can lower LDL-C, but they are mainly used to treat atherogenic dyslipidemia. Fenofibrate can reduce LDL-C by at least 20% in those with normal triglyceride levels.[50,51] In patients with elevated triglyceride levels at baseline, LDL-C lowering is much less and may actually increase. Nicotinic acid lowers LDL-C in a dose-related fashion, but substantial LDL-C lowering of more than 25% usually occurs at doses that exceed 1500 mg per day.[52]

For those patients who require LDL-C lowering above and beyond what statins can provide (e.g., those with familial hypercholesterolemia) or whose intolerance of statin therapy (most often due to muscle symptoms) prevents them from reaching goal levels for LDL-C, drugs that have a primary effect on the gastrointestinal (GI) tract are recommended.

Three classes of drugs are available: bile acid sequestrants (resins, such as cholestyramine and colestipol, and a polymer, such as colesevelam); cholesterol absorption inhibitors, such as ezetimibe; and plant stanol esters.

Table 27–6 Suggestions for Statin Usage

1. Use statins to lower LDL-C with intensity of therapy based on severity of CHD risk. In those at highest CHD risk, statins provide benefit even in those patients with LDL-C lower than 100 mg/dL.
2. If you use statins, lower LDL-C at least 30-40%.
3. Do not consider safety or properties a class effect. Statins differ in pharmacologic properties that can be helpful in deciding which statin to use in an individual patient.
4. Consider muscle and liver toxicity in all patients, even though the overall risk of such a reaction is low. Get a baseline liver panel and if possible, a total CK before starting therapy. Obtain CK and TSH if the patient develops muscle symptoms. Do not measure CK routinely on follow-up blood tests as CK varies widely, especially in those who exercise regularly. Remember that statins can exacerbate exercise-induced skeletal muscle injury.
5. Consider patient characteristics, magnitude of change necessary to reach a goal, associated medications, and comorbidity as factors when you choose a statin. Consider older age, (especially women > 80 yr), small body frame, frailty, multisystem disease, multiple medications, and high-risk clinical situations (perioperative period of major surgery) as factors that might affect the decision regarding statin dosage and the advisability of combined therapy with a fibrate or nicotinic acid.
6. If a nonserious adverse reaction occurs with a patient on a statin, consider rechallenging with a lower dose after the patient is back to baseline, especially if that dose was well tolerated in the past. GI active drugs can be used to obtain the additional LDL-C lowering required if lower-dose statins can be safely taken.
7. Use combinations to optimize effects on lipoproteins. Add GI active medication (bile acid sequestrants, cholesterol absorption inhibitors, stanol ester margarines) to gain additional LDL-C lowering. Add nicotinic acid to raise HDL-C and lower triglycerides, as well as LDL and Lp(a). Add fibrates (fenofibrate is the fibrate of choice for treating high triglycerides/low HDL-C or metabolic syndrome in a patient on statins).

Modified from Stone NJ: Strategies for Treating Abnormal Lipid Profiles with Drugs. In Grundy S (ed): Atlas on Atherosclerosis. Philadelphia, Current Science, 2005, pp 143-166.

BILE ACID SEQUESTRANTS

Bile acid sequestrants (BAS) lower LDL-C by interfering with bile acid absorption in the ileum. They promote the fecal excretion of the bound bile acids resulting in a compensatory increased LDL receptor synthesis to replenish hepatic cholesterol pools, thus producing enhanced LDL clearance. They are nonsystemic drugs for LDL-C lowering either singly or in combination with statins.

Effects on Lipids and Lipoproteins

BAS lower LDL-C in a dose-related fashion (Table 27–7). They are an essential part of a multidrug regimen in patients with FH who have marked elevations of LDL-C because their effects are additive to those seen with statins. BAS allow those who cannot tolerate a higher dose of statin to obtain further LDL-C lowering that is more substantial than that seen with doubling the statin dose. BAS should not be given to those with triglycerides higher than 250 mg/dL due to an increased secretion of triglyceride-rich particles that can produce marked hypertriglyceridemia in some cases. HDL-C levels are increased to a mild degree with BAS. BAS do not lower Lp(a).

For decades, the only BAS available were cholestyramine and colestipol. Before the introduction of statins, these BAS were given in higher dosages than are used currently. They were difficult drugs to use at high dosages due to the limiting gastrointestinal side effects. These resins bound other drugs avidly, especially thyroid replacement hormone, digoxin, and antibiotics. Colesevelam, a polymer gel, was introduced in tablet form.[53] It has the advantage of greater specificity for bile acids and, except for verapamil, has markedly fewer drug interactions than the resins.[54] Combining colesevelam with a low dose of simvastatin 10 mg/d resulted in a mean reduction in LDL-C of 42% that exceeded the reduction usually seen with simvastatin 40 mg/d alone.[55] The effects of combination therapy on serum HDL-C and triglyceride levels were similar to those for simvastatin alone.

Efficacy

In primary prevention, cholestyramine was used in the Lipid Research Clinics Primary Prevention Trial (Table 27–8). It reduced rates of fatal and nonfatal MI, but the trial was not powered to reduce the total mortality rate.[56] In two small angiographic trials, the NHLBI Type II Intervention Study[57] and the STARS[58] trial, hypercholesterolemic men with CHD on cholestyramine had reduced progression on serial angiograms. In the FATS trial, colestipol was added to either nicotinic acid or lovastatin and contributed to the decreased progression on angiography, as well as to the event reduction seen in that trial when compared with a placebo group.[59]

Table 27–7 Bile Acid Sequestrants (BAS)

BAS	Initial Dosage	Maintenance Dosage	LDL-C Lowering Seen (Dosage)	Comments
Cholestyramine resin	8 g/d in divided doses	16-24 g/d as monotherapy; lower doses if used with statins	Varies from 8.7% to 28% depending on dosage of resin	Take other drugs 1 hr before or 3 hrs after; psyllium augments action
Colestipol resin	10 g/d in divided doses	16-24 g/d as monotherapy; lower doses if used with statins	Similar to cholestyramine, varies with dosage of resin	Take other drugs 1 hr before or 3 hrs after; psyllium augments action
Colesevelam	625 mg × 2 or 3 tablets twice daily (7 daily is maximal)	625 mg × 3 bid; can be used as 7 tablets daily if required	LDL-C lowering 19% (3.8 g/d)	Take with a large glass of water

Table 27–8 Clinical Efficacy of Bile Acid Sequestrants (BAS)

Clinical Trials with BAS	Subjects	Drugs (Dosage)	LDL-C Reduction Seen (%)	Efficacy Against CHD
LRC PPT	3806 men	Cholestyramine (16-24 g/d)	-20.3	Yes; 19% reduction in fatal, nonfatal MI at 7.4 yr
STARS	26 men	Cholestyramine 16 g/d	-35.7	Yes; improvement on angiography at 2 yr
NHLBI Type 2 Trial	116 men and women	Cholestyramine 16 g/d average	-26	Yes, if narrowing >50% at baseline at 5 yr
CLAS	162 men	Colestipol 30 gm/d + nicotinic acid 4.3 g/d	-43	Yes; those patients treated had significantly more regression noted on angiography at 2 yr
FH-SCOR	72 men and women	Colestipol, nicotinic acid, and lovastatin	-39	Yes, angiographic change correlated with change in LDL-C at 2 yr
FATS		Colestipol 30 g/d; and either lovastatin 20 mg bid or nicotinic acid 4 g/d	-46 (lovastatin) -36 (nicotinic acid)	Nicotinic acid group had higher HDL than lovastatin group; significant angiographic, clinical improvement at 2.5 yr

Safety/Compliance Issues

BAS are not absorbed and should not be considered systemic drugs. Indeed, GI side effects such as constipation and aggravation of hemorrhoidal bleeding can be limiting. Resins, such as cholestyramine and colestipol, are available as powders that must be mixed with water or applesauce. Colestipol is also available in tablet form. Colesevelam is available in tablet form and should be taken twice daily with a large glass of water. These drugs require detailed patient instruction to be sure that patients take measures to minimize constipation and, in the case of resins especially, guard against drug interactions.

Ezetimibe (Cholesterol Absorption Inhibitors)

Ezetimibe, a 2-azetidione, is a potent inhibitor of cholesterol absorption. Using a genetic approach, investigators identified Niemann-Pick C1-Like 1 (NPC1L1) as a critical mediator of cholesterol absorption and the direct target of this drug.[60] After absorption, ezetimibe is rapidly glucuronidated by the liver and recycled by the enterohepatic circulation to its target site in the brush border of the small intestine. It prevents the absorption of cholesterol from both dietary and especially biliary sources. It markedly reduces absorption of plant sterols.

Defects of either of two cotransporters (ABCG5 and ABCG 8) responsible for resecreting absorbed plant sterols back into the intestinal lumen lead to the rare inherited disease of phytosterolemia. Phytosterolemia is characterized by hyperabsorption and diminished biliary excretion of plant sterols. Because ezetimibe interferes with NPC1L1, reducing the intestinal uptake of cholesterol and plant sterols, it is a novel treatment for this rare disorder.[61]

Effect on Lipids/Lipoproteins

Ezetimibe is used at a single dosage of 10 mg/d. It lowers LDL-C approximately 20%, and its LDL-C lowering effects are additive to those obtained with statins. Although it has been proposed as monotherapy in subjects who are intolerant to statins, no outcome data have confirmed that the combination of a lower dose of statin plus ezetimibe is as efficacious as a larger dose of statin. For statin-intolerant patients or in those with FH, a combination of ezetimibe and a BAS, such as colestipol, results in an additional 20% reduction in LDL-C than seen with either one alone.[62] Patients should avoid taking BAS and ezetimibe at the same time for optimal efficacy.

Efficacy

As note earlier, no randomized clinical trials of ezetimibe with CHD endpoints are available. Although patients with the homozygous form of FH are often resistant to statins, they respond to ezetimibe.[63] Thus ezetimibe becomes a valuable fourth drug alongside statins, BAS, and nicotinic acid.

Safety

For most patients, ezetimibe is remarkably well tolerated with a profile similar to that seen with placebo. In patients who previously had experienced myalgia with statin therapy (with or without elevated CK levels), myalgia has occurred with ezetimibe. Patients with a history of statin intolerance should be monitored for adverse muscle events during treatment with ezetimibe.[64] Elevations of liver transaminases and cases of hepatitis have been reported in patients treated with ezetimibe. Patients who begin ezetimibe should have a liver panel at baseline. After 6 to 12 weeks, measurement of hepatic transaminases is recommended. This should be repeated if combined with a statin. Statins or ezetimibe, or both, are contraindicated for patients with active liver disease or unexplained persistent elevations of liver transaminases.

PLANT STANOL ESTERS

Plant sterols are ubiquitous in nature and have the familiar multi-ring nuclear structure of the sterol family. They differ from cholesterol (found in animals as a key component of cell membranes, vitamin D, adrenal and gonadal steroids) only in the structure of their side chain. Saturated sterols, termed *stanols,* lack the 5 double bond in their B-ring.[65] Saturation of sitosterol, the most commonly occurring plant sterol, gives rise to sitostanol; saturation of campesterol gives rise to campestanol. Plant sterols and cholesterol are consumed approximately in equal amounts, but phytosterols occur in human plasma in a concentration that is normally <0.5% that of cholesterol. Plant stanols are even less well absorbed from the intestine and have a plasma level that is only one tenth as high (i.e., 0.05% that of cholesterol). The ATP III report suggested that the addition of plant stanol or sterol esters and fiber could help patients reach LDL-C goals without having to resort to medications. Because there had been no rigorous comparison of plant stanol and sterols, ATP III recommended either one.[66] Data that became available subsequent to the ATP III report indicate that there may be an advantage to using plant stanol esters rather than plant sterols to lower LDL-C.[67] LDL-lowering efficacy of plant sterol esters tends to diminish over time, whereas in contrast, plant stanol esters maintain their LDL-C lowering efficacy of about 10% from baseline. Also, plant stanols were found not to affect bile acid synthesis, unlike plant sterols. Finally, dietary plant stanol esters reduce statin-induced elevations of serum plant sterol levels, whereas serum plant sterol levels are not lowered when dietary plant sterol ester is fed.[68]

Effect on Lipids/Lipoproteins

An important practical observation is that the margarine-based stanol ester is as effective in a single dose as it is when taken in three divided doses.[69] The persistence of the single-dose effect suggests that stanols not only compete with cholesterol for micellar solubilization but also have an additional, longer-lasting effect on intestinal mucosal cells. There are practical limits to how much margarine an individual can ingest. Maximal LDL-C lowering with plant stanols occurs with 2 g/d of plant stanol esters.[70] In a study of post-menopausal women, LDL-C levels were lowered 13%, which might allow low-risk patients to avoid drug therapy. Older patients appear to be more responsive than younger ones to the effects of plant stanol esters.[71]

Efficacy Against CHD

No CHD endpoint studies are available. Some researchers have raised concerns that elevated plant sterol concentrations could increase CHD risk. To determine whether plasma levels of plant sterols were associated with coronary atherosclerosis in humans, 2542 subjects, aged 30 to 67 years, who underwent electron beam computed tomography had plasma levels of cholesterol and plant sterols measured.[72] Plasma levels of cholesterol, but not sitosterol or campesterol, were significantly higher in subjects with coronary calcium. In addition, in the same paper, investigators could not show that elevated plasma levels of plant sterols (sitosterol and campesterol) were associated with atherosclerosis in genetically modified mice.

Safety

A meta-analysis presented at a workshop on plant stanol esters indicated that levels of vitamins A and D are not affected by stanols or sterols.[73] Alpha carotene, lycopene, and vitamin E levels are carried on LDL particles and remained stable relative to LDL levels. Although beta carotene levels declined, the panel did not expect adverse health outcomes. Indeed, there are adverse health outcomes from beta carotene supplementation.[74] Some experts have suggested that sources of carotenoids be ingested at meals other than when plant sterol esters are eaten.

Cardiovascular Disease and Lifestyle Modification

Frank M. Sacks and Kathy McManus

CHAPTER CONTENTS

Because of the difficulty many of our patients have in improving their diet, physicians are tempted to lose faith in a nonpharmacologic approach. In this chapter we describe the strong scientific base that supports our continued enthusiasm in clinical practice for healthy nutrition and regular exercise and provide practical approaches to illustrate how to achieve lifestyle modification on a daily basis for our patients.

Epidemiology worldwide shows a pattern of cardiovascular disease (CVD) prevalence that points directly at poor nutritional quality, too much food, and erosion of a healthy lifestyle as the causes of high rates of CVD worldwide. Very low rates of CVD still exist in Mediterranean countries, Japan, and China, where traditional diets and lifestyles are often maintained. During the transition to a developed economy typical of North America and Europe, CVD and diabetes increase rapidly, as has been evident worldwide, notably in South Asia and Latin America.

Although drug therapy for hyperlipidemia has enjoyed huge success in decreasing CVD, national guidelines rightfully still call for nutrition and exercise for primary prevention.[1] For secondary prevention, nutrition and drug therapy should be used together. Diet and drug treatments are additive in improving risk factors, such as LDL cholesterol, blood pressure, and insulin resistance, and reducing CVD. Improved quality of the diet reduces CVD whether body weight remains in excess.[2,3] However, weight loss has its own benefits to raise HDL cholesterol, lower triglycerides, improve insulin sensitivity, and lower blood pressure. When adopted intensively, diet and weight loss, taken to their full potential, may eliminate the need for drug therapy for hyperlipidemia, hypertension, or type 2 diabetes, or simplify the evermore complex multidrug regimens necessary to control these conditions.

DIETARY FATS AND BLOOD LIPIDS

Saturated fats, trans-unsaturated fats from partially hydrogenated vegetable oils, and cholesterol itself increase blood LDL cholesterol.[4,5] Saturated fat and cholesterol are present mainly in dairy fat and red meat, whereas trans fats are present in most fried foods and baked products in the United States. Trans fatty acids are also present in dairy and meat fat, formed in the ruminant gut by bacteria during digestion. All guidelines call for reduction in these dietary lipids. When saturated fat, trans fats, and cholesterol are all reduced, LDL cholesterol decreases. This happens with whatever nutrient replaces it, and this is the rationale for traditional guidelines to recommend a low-fat, carbohydrate-rich diet as a pragmatic way to reduce unhealthy fats.[1] The remaining question is whether nutrients and foods other than those that are carbohydrate-rich could replace the unhealthy fats. The possibilities are unsaturated fats and oils and protein. Beneficial potentials of unsaturated fats are long established, and new mechanisms are still being discovered.[6,7] Moreover, the benefits of protein to improve CVD risk are now just coming to light.[8,9]

The effects on blood lipids and blood pressure of these approaches that emphasize either carbohydrate, unsaturated fats, or protein were compared in the OmniHeart trial, which is discussed later.[8]

High-Carbohydrate, Low-Fat Diets to Reduce LDL Cholesterol and Blood Pressure

Low-fat, high-carbohydrate diets reduce LDL cholesterol generally by a modest amount, 5% to 10%, in proportion to adherence.[5] Very low-fat, low-cholesterol diets can reduce LDL cholesterol more, but acceptability by the general public may be limited. Very low-fat diets may be deficient in essential fatty acids.

Low-fat, high-carbohydrate diets not only reduce LDL cholesterol but also reduce HDL cholesterol and raise triglycerides (Fig. 28–1).[5,6] Because the LDL/HDL ratio is unchanged, CVD risk cannot be assumed to decrease.

The DASH Diet: A Type of Low-Fat, High-Carbohydrate Diet to Control Blood Pressure and LDL Cholesterol

The Dietary Approaches to Stop Hypertension (DASH) study attempted to combine information from epidemiology and animal studies on possible new dietary means to prevent and treat hypertension.[10] Whereas weight loss and dietary sodium reduction had long been shown to lower blood pressure,

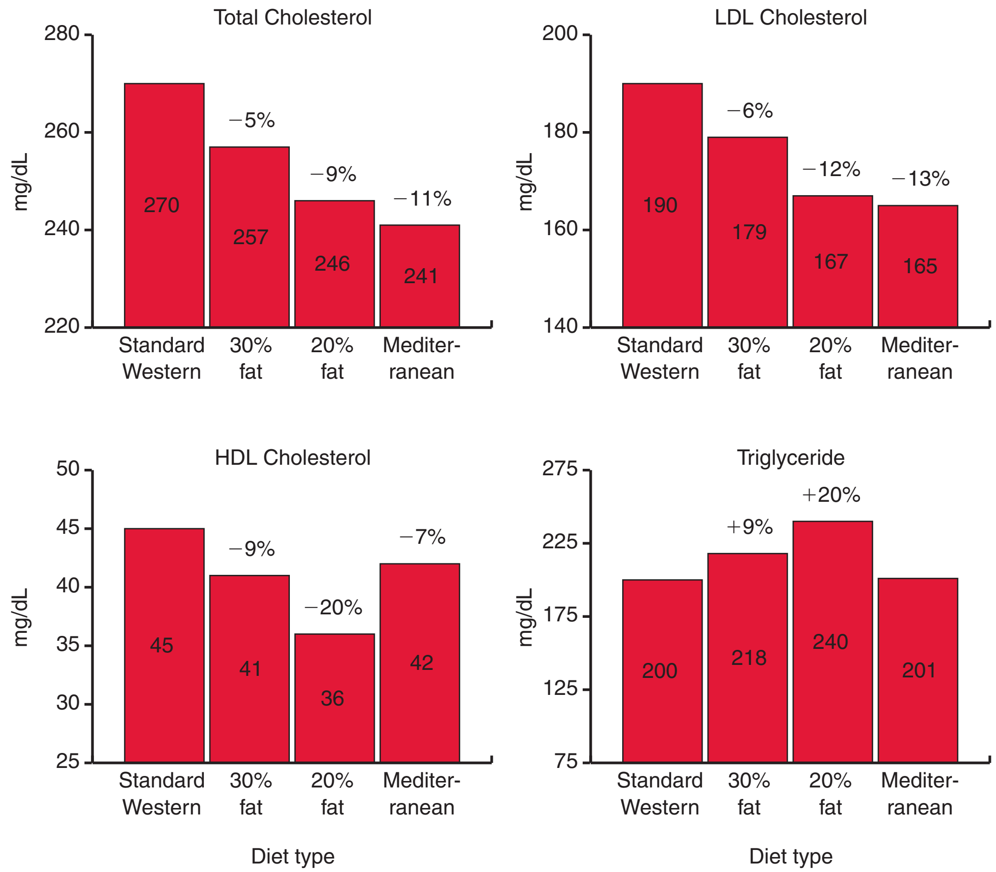

Figure 28–1 Effect of cholesterol-lowering diets on blood lipid risk factors. (Modified from Sacks FM, Katan M: Randomized clinical trials on the effects of dietary fat and carbohydrate on plasma lipoproteins and cardiovascular disease. Am J Med 2002;113[Suppl 9B]:13S-24S.)

population studies suggested that other nutrients also may have beneficial effects. The DASH research group designed a dietary pattern that was rich in fruits and vegetables and low-fat dairy products, included nuts and whole grains, and was low in red meat and sugar-containing desserts and beverages. The DASH diet substantially reduced blood pressure and extended the potential for nutritional control of hypertension.[10] When the DASH diet was combined with reduced sodium, the beneficial effects were even stronger (Fig. 28–2).[11] In the typical older patient population in clinical practice, the DASH diet with low-sodium content reduced systolic blood pressure by 15 mm Hg in those with mild hypertension and 10 mm Hg in those with above-average blood pressure (120 to 139 mm Hg),[12] now termed "prehypertension" by Joint National Committee 7.[13]

The DASH diet also reduced LDL cholesterol, as would be predicted from its low content of saturated fat and cholesterol.[14] However, HDL cholesterol also decreased predictably by about the same percentage as LDL cholesterol, and the ratio did not change. Interestingly, triglycerides did not increase on the DASH diet, as they often do on a high-carbohydrate diet. Perhaps this is because of the relatively good type of carbohydrates used in the diet, causing reduced blood glucose response (i.e., having low glycemic index).[15] Overall, predicted CVD risk was reduced on the DASH diet due to its benefits of lower blood pressure and LDL cholesterol outweighing the reduced HDL cholesterol.[14] With low sodium, CVD risk on the DASH diet improved more. DASH is considered the benchmark dietary pattern recommended by the U.S. Dietary Goals Committee.[16]

Low-Fat Diets and Cardiovascular Disease: Clinical Trials and Epidemiology

Low-fat diets have not yet had a satisfactory test in a randomized clinical trial with clinical endpoints. The Women's Health Initiative (WHI) was such a trial in 160,000 women in the United States. These women were randomized to either a low-fat, high-carbohydrate diet rich in fruits and vegetables or to a no-intervention comparison group and followed for 7.5 years. No effect on CVD endpoints and cancer occurred.[17] Although the WHI set a goal for reducing total fat to 20%, it was clear from lack of HDL reduction or triglyceride increase, both biomarkers of dietary fat reduction, that the participants were able to reduce fat only minimally. Previous small-scale trials did not find reduction in CVD with low-fat diets.[5] Ornish and colleagues[18] used a very low-fat, vegetarian diet as a major part of overall lifestyle change that included intensive exercise in a small group of patients with CHD. Meals were provided to the patients. Coronary stenosis improved in the treated group, although the study was not large enough to evaluate an effect on clinical events. A less intensive program of a low-fat diet and exercise in Heidelberg, Germany, also found benefits on coronary stenosis.[19] Epidemiologic data generally have not

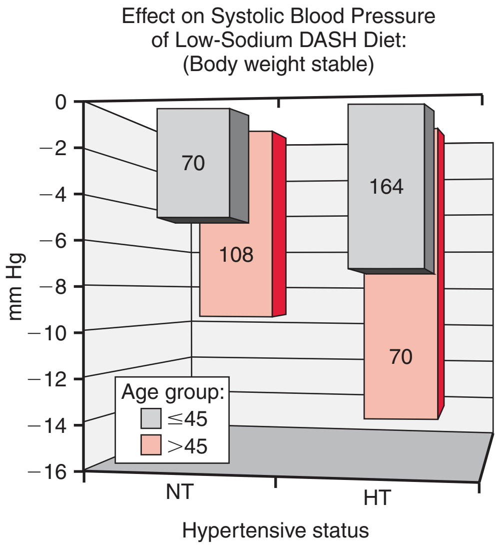

Figure 28–2 Effect of the low-sodium DASH diet on systolic blood pressure. (Modified from Vollmer WM, Sacks FM, Ard J, et al: Effects of diet and sodium intake on blood pressure: Subgroup analysis of the DASH-sodium trial. Ann Intern Med 2001;135:1019-28.)

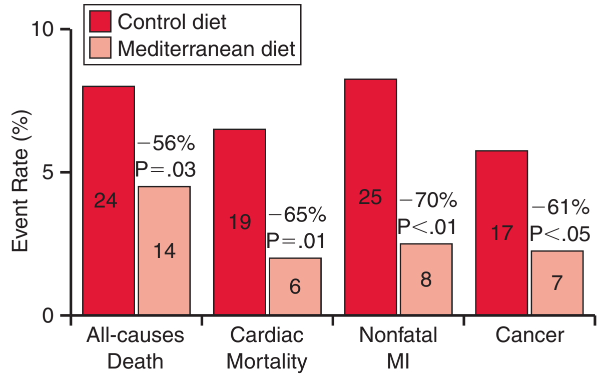

Figure 28–3 The Lyon Heart Study. A trial of a Mediterranean diet in patients after myocardial infarction. (Modified from de Lorgeril M, Renaud S, Mamelle N, et al: Mediterranean alpha-linolenic acid-rich diet in secondary prevention of coronary heart disease. Lancet 1994;343:1454-9.)

found a relationship between amount of total fat and CHD.[20] A low-fat dietary pattern can be based on healthy foods, such as whole grains, fruits and vegetables, low-fat dairy products, fish and lean meats, or it can have plenty of high-carbohydrate, high-calorie foods, such as refined flour products, desserts, and sugar-containing drinks. The type of low-fat diet may be critical to its success or failure for risk factor improvement.

Effects of low-fat, high-carbohydrate diets on the CVD risk factors and CHD are as follows:

- Reduction in blood pressure
- Reduction of LDL cholesterol concentration
- Reduction of HDL cholesterol concentration
- No effect on the LDL-to-HDL cholesterol ratio
- Increase in triglycerides, unless low glycemic index foods predominate
- Improvement in coronary stenosis (with an intensive exercise program)
- No reduction in CHD in epidemiologic studies or small-scale, short-duration trials
- No reduction in CVD in the definitive WHI

Moderate Unsaturated Fat Diets

Replacing saturated fat with unsaturated fat has a long history in cardiovascular disease prevention. In the 1950s and 1960s, polyunsaturated vegetable oils from corn, soybeans, and safflower seeds were used essentially as medicine, lacking effective and well-tolerated drugs, to lower blood cholesterol. These polyunsaturated oils are the most potent LDL-lowering nutrients, and several clinical trials demonstrated significant reduction in CVD.[5] A different type of unsaturated oil is canola (rapeseed) oil, which is mainly monounsaturated fat but also has an omega-3 fatty acid, α-linolenic acid. The Lyon Heart Study used this type of oil with a Mediterranean diet in a secondary prevention study that found reduction in CVD (Fig. 28–3).[21] α-Linolenic acid, also prevalent in soybean oil and some vegetable products, is strongly protective against CHD in epidemiologic studies.[22] Finally, olive oil and high-monounsaturated varieties of sunflower and safflower oils have primarily monounsaturated oils. This class of vegetable oil improves risk factors, although a clinical endpoint trial has not been done.

Whatever unsaturated fat is used to replace saturated and trans fat, whether unhydrogenated liquid vegetable oils (e.g., canola, olive, sunflower, safflower, peanut, soybean) or from nuts, total fat intake can be made to remain the same or it can be increased to replace some carbohydrate. Currently, there is uncertainty whether polyunsaturated or monounsaturated fat is superior for preventing CHD, although current evidence tends to favor polyunsaturated oils. Polyunsaturated fats have slightly more effect than monounsaturated fat in lowering LDL levels[4,5] and perhaps in reducing serum inflammatory markers.[6] Any type of fat raises HDL cholesterol and lowers triglycerides compared with carbohydrate. However, as discussed later, the type of carbohydrate food may relate to its metabolic effects.[15] High unsaturated fat diets improve the lipid profile not only compared with saturated fat but also with carbohydrate.

Randomized trials definitively show the benefits of polyunsaturated fats. Three[23-25] out of four[23-26] randomized trials showed significant benefits on coronary rates (Table 28–1). In addition to lowering LDL, polyunsaturated fats may reduce the vascular inflammatory response and limit the propensity of LDL particles to bind to vascular cells and deposit their cholesterol in vascular intima.[6,7] In monkeys, polyunsaturated fats from vegetable oils actually regressed coronary atherosclerosis.[27] Polyunsaturated fats also have anti-arrhythmogenic actions.[28] Thus, much evidence exists for the use of polyunsaturated oils to replace saturated fats to prevent coronary disease.

Monounsaturated fat has less of a direct relationship to coronary prevention compared with polyunsaturated fat. Epidemiology shows modest reduction of CHD at the borderline of statistical significance.[20] A clinical trial that specifically raised monounsaturated fats to prevent CHD has not occurred. Monkey models of atherosclerosis do not show a benefit of monounsaturated fats.[27] However, in humans,

Table 28–1 Clinical Trials of Diet Therapy with Polyunsaturated Vegetable Oils to Reduce Coronary Events: Substitution of Polyunsaturated Fat for Saturated Fat

	N	Dietary Fat	Duration	▲Cholesterol	▲CVD
Finnish Mental Hospital	676	34%	6 yr	–15%*	–43%*
Oslo	412	39%	5 yr	–14%*	–25%*
MRC Soy Oil	393	46%	4 yr	–15%*	–12%
Los Angeles	846	40%	8 yr	–13%*	–34%*

*$P \leq 0.05$.
▲Cholesterol, percentage change in serum cholesterol in the treatment group compared with the change in the control group; ▲CVD, percentage difference in coronary event rates in the treatment compared with the control group.
CVD is defined as myocardial infarction or sudden death for the Finnish, Oslo, and MRC trials and myocardial infarction, sudden death, or stroke for the Los Angeles trial.
Trials with at least 2 years of average follow-up were included.

Table 28–2 Beneficial Effects on Blood Pressure and Blood Lipids of Replacing Carbohydrate with Either Protein or Unsaturated Fat (Omni Heart Study)

	Mean Change from Baseline in Each Diet			
	Baseline	CARB	PROT	UNSAT
LDL (≥130)	157	–20	–24	–22
HDL	50	–1	–3	0
TG	102	0	–16	–9
SBP	146	–13	–16	–16
Risk Reduction		16%	21%	20%

CARB, carbohydrate; HDL, high-density lipoprotein; LDL, low-density lipoprotein; PROT, protein; SBP, systolic blood pressure; TG, triglyceride; UNSAT, unsaturated fat.

monounsaturated fats decrease LDL and preserve HDL and TG levels nearly as much as polyunsaturated fats. Monounsaturated oils, particularly olive oil, have been an integral part of the centuries-old traditional Mediterranean diet, which has been associated with very low coronary rates.[29] Thus, there are reasons to advocate increased intake of unsaturated oils from a variety of sources, monounsaturated and polyunsaturated.

Reduced-Carbohydrate, Higher Unsaturated Fat, and Protein Diets: A New Twist to the DASH Dietary Approach

The DASH diet, considered the benchmark diet for health in the United States,[16] is low in fat and high in carbohydrate. Although it reduced blood pressure and LDL cholesterol, it reduced HDL cholesterol and did not affect triglycerides.[14] In view of the favorable evidence on unsaturated fats and HDL and triglycerides, it was hypothesized that the DASH diet could be improved in its overall effects on CVD risk factors by replacing some of the carbohydrate with unsaturated fats. In addition, higher protein intake, replacing carbohydrate, was predictive of reduced blood pressure and CVD in epidemiologic studies, and small-scale studies found favorable effects on lipid risk factors. The OmniHeart study (Optimal Macronutrient Intake) designed three healthful diets, one high in carbohydrate like the DASH diet, another high in unsaturated fat, and a third high in protein, from mixed sources.[8] All three were low in saturated fat and cholesterol and high in potassium, fruits, vegetables, nuts, and low-fat dairy products, thereby building on the dietary approach of DASH. All three diets substantially improved blood pressure and LDL cholesterol. However, lowering carbohydrate intake by either raising unsaturated fat or protein further reduced blood pressure and reduced triglycerides. The unsaturated fat diet raised HDL cholesterol, whereas the protein diet lowered LDL cholesterol and HDL cholesterol (Table 28–2).[8] Taken together, moderate reduction in carbohydrate intake, from 58% to 48% of total calories, produced 11% to 13% further reduction in estimated CVD risk beyond the 20% effect of the DASH-type diet.

Type of Carbohydrate

The usual mix of carbohydrates in the Western diet contains much refined polysaccharides, such as in bread and baked goods, and sugars in juices and soda. These have a high glycemic index, causing glucose and insulin to rise substantially.[15] Other types of carbohydrates that are in whole grains and vegetables have a lower glycemic index because the digestion and absorption of the glucose are slow. These cause less of a rise in blood glucose and hence insulin. The low glycemic index of grains and vegetables is partly explained by the fiber content of these foods but also by the intrinsic digestibility of the food. These foods also cause less of a rise in plasma triglycerides than the more commonly eaten higher glycemic index carbohydrates. Some of the concerns about a low-fat diet can be set aside if a patient truly eats low-glycemic index foods rather than the ubiquitous less-desirable, high-carbohydrate

foods that all too often are a major part of low-fat diets. This concept needs to be put to a definitive test, however.

Effects of reduced-carbohydrate, high unsaturated fat diets on CVD are as follows:

- Reduction in blood pressure
- Reduction in LDL cholesterol concentration
- Preservation of HDL cholesterol concentration
- Reduction in the LDL-to-HDL cholesterol ratio
- Decrease in triglycerides compared with low-fat diets
- Reduction in CVD events (polyunsaturated fats)

The effects of increased protein and lower carbohydrate intakes are as follows:

- Lowered blood pressure
- Lowered LDL cholesterol
- Lowered HDL cholesterol
- Lowered triglycerides
- Lowered CVD risk in epidemiologic studies
- CVD not directly studied in a randomized trial

Fish Oil to Prevent CHD

In the early 1980s, two lines of evidence coalesced to engender widespread excitement on the potentially cardioprotective effects of omega-3 fatty acids, particularly those from fish oil (EPA, DHA). Populations eating large amounts of fatty fish had low rates of CVD, and in many epidemiologic studies, n-3 PUFA intake or blood levels are inversely related to CVD.[30,31] Omega-3 fatty acids are metabolized to prostaglandins and leukotrienes that are anti-thrombotic, anti-inflammatory, and vasodilating. The most established benefit of fish oil is to reduce blood triglycerides. A large dose is necessary, requiring 10 to 15 1-g capsules of fish oil that contain between 20% and 50% omega-3 fatty acids. A prescription version of fish oil that is 90% omega-3 fatty acids is available. This requires fewer capsules. Use of fish oil for hypertriglyceridemia is discussed in Chapter 26.

Polyunsaturated fatty acids either from fish or plants have other anti-inflammatory properties that are still being discovered.[7] Epidemiologic studies show that omega-3 fatty acids are associated with reduced CVD events, both fatal and nonfatal.[30,31] Fish oil and other polyunsaturated fatty acids have potentially anti-arrhythmic effects, increasing the depolarization threshold of ion channels.[28] Reduction in fatal CHD events has been reported in epidemiologic studies often attributed to reduced sudden death. However, a broader view of the benefits of omega-3 fatty acids is necessary because sudden death cannot account for all CVD event reduction, nonfatal as well as fatal, found in epidemiologic studies and clinical trials.

The Diet and Reinfarction Trial (DART) tested the effect of increased intake of fatty fish or fish oil (1.5 g/day) for 2 years in 2033 Welsh men who had had an acute myocardial infarction.[32] This small amount of fatty fish or fish oil significantly reduced total and coronary mortality. Nonfatal myocardial infarction was not affected significantly, however. These results have been reinforced by the GISSI Prevenzione trial, which tested 1 g/day of n-3 polyunsaturated fatty acids in 11,324 Italian patients surviving a recent myocardial infarction.[33] In both trials the death rate began to lessen in the fish oil group as early as 3 months after treatment was started. Recent trials to specifically test the effect of fish oil on cardiac arrhythmia produced mixed results.[34,35] In November 2005, results were reported from a Japanese trial of primary prevention of CVD with fish oil showed striking reduction in nonfatal CVD events.[36] Thus, relatively low doses of fish oil, 1 to 2 g/day, may be cardioprotective due to several mechanisms yet to be determined specifically.

Effects of fish oil intake are as follows:

- Large doses (>5 g/day omega-3 fatty acids)
  - Reduction in blood triglycerides
  - Reduction in blood pressure
  - Anti-thrombotic
- Small doses (1 to 2 g/day omega-3 fatty acids)
  - Prevent CVD events, fatal or nonfatal

OBESITY

In this section we briefly discuss the increasing problem of obesity and then provide a practical approach for evaluating obesity and its treatment. We cover energy intake requirements for weight loss and weight stability, the influence of carbohydrate, fat and protein on success in weight loss, and specific dietary approaches.

The prevalence of obesity and overweight continues to increase despite public health education on healthy eating and exercise. The achievement and maintenance of a healthy weight can contribute to the reduction of risk factors for cardiovascular disease including dyslipidemia, diabetes, and high blood pressure. However, the role of excess dietary fat, protein, and carbohydrate in causing excess weight and in its treatment continues to be debated. To date, most of the published research has involved short-term trials (<1 year duration). Current available data on long-term weight loss are limited. Typically reported weight losses remaining after 4 to 5 years are about 3% to 6% of initial body weight.[37] A 5% weight loss does have health benefits including reduction in lipids and serum glucose levels. Research that supports healthy eating patterns and lifestyle modification to attain and sustain weight over an extended period of time is necessary. Strategies aimed at reducing obesity, and the morbidity and mortality from the chronic diseases associated with it, may be more effective if success also includes quality of life.

Two thirds of adults in the United States are overweight, and 32% are obese according to the 2003-2004 National Health and Nutrition Examination Survey (NHANES).[38] Overweight is defined as an excess of body weight compared with height. Obesity is defined by the National Institutes of Health consensus panel as an abnormally high proportion of body fat.

Body Mass Index as a Measure of Overweight

A variety of methods are used to determine if someone is overweight or obese. Some are based on the relationship between height and weight; others are based on measurements of body fat. The most commonly used method is body mass index (BMI). BMI can be used to screen for both overweight and obesity in adults. It is a calculation based on height and weight, and it is not gender specific. BMI does not measure percent of body fat.

BMI is determined by dividing a person's weight in kilograms by height in meters squared:

$$\frac{\text{weight (kg)}}{\text{height (m}^2\text{)}}$$

The BMI of an individual who weighs 160 lb and is 5′5″ tall is calculated as follows:

$$160 \text{ lb} \div 2.2 \text{ kg/lb} = 72.7 \text{ kg}$$

$$65 \text{ inches} \times 2.54 \text{ cm} = 165.1 \text{ cm} = 1.65 \text{ m}$$

$$(1.65 \text{ m})^2 = 2.72 \text{ m}^2$$

$$\text{BMI} = 72.7 \text{ kg} \div 2.72 \text{ m}^2 = 26.7 \text{ kg/m}^2$$

Table 28–3 illustrates calculated BMI values.

An expert panel convened by the National Heart, Lung, and Blood Institute (NHLBI) in cooperation with the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) further classified the categories for BMI (Table 28–4).

Determining BMI is inexpensive, simple, and quick, but it does have limitations. In very muscular adults, using BMI as a measurement tool may categorize them as "overweight" when they are fit and healthy. Another problem with using BMI is in adults who have lost muscle mass, such as the elderly. The tool may indicate they are in the "healthy" weight category when they may be at risk due to reduced nutritional reserves.

Waist Circumference

Waist circumference is positively correlated with abdominal fat content. It provides an acceptable measurement for assessing a patient's abdominal fat content and is most useful when the BMI is less than 35. Waist circumference is more predictive of illness risk than BMI after age 65 and in Asian-American populations. High risk for the development of hypertension, diabetes, and cardiovascular disease is associated in women with a waist circumference >35 inches (>88 cm) and in men > 40 inches (>102 cm).

Clinical Assessment of Obesity

The medical assessment of obesity should be done by the physician and include height, weight, and waist circumference. Medical examination should rule out other physiologic causes and assess overall risk status. In addition to a medical evaluation, a psychological assessment may be beneficial. This may include assessment for barriers to treatment including eating disorders, addictions, depression, and other mental disorders.

The nutritional assessment consists of an evaluation of current eating patterns including number and timing of meals and snacks, food preparation methods, and frequency of eating away from home. A history of weight and dieting should be assessed, along with weight changes after the age of 18. An assessment of motivation for weight loss and barriers to treatment including knowledge support systems, financial concerns, and physical limitations should be ascertained.

Physical activity level including type of exercise, duration, and intensity, as well as the patient's commitment to a program, should be determined.

Goals for Weight Loss and Management

The general goals of weight loss and management are: (1) prevent further weight gain; (2) reduce body weight; (3) maintain lost weight over a long term; and (4) reduce risk factors associated with obesity. Good evidence from randomized clinical trials indicates that the overweight and obese can successfully reduce health risks with a weight loss of 10% of baseline weight. With success, further weight loss can be attempted, if warranted, through further assessment.

Determination of Calorie Levels for Weight Loss

The focus of diet intervention for weight loss in overweight or obese patients is a low-calorie diet. No eating plan produces weight loss without a planned reduction in calories. This was demonstrated convincingly by the WHI.[39] A high-carbohydrate, low-fat diet taught without calorie reduction failed to produce sustained weight loss, thereby upending certain dogma that low-fat eating will "automatically" cause reduced calories and weight loss. Randomized trials suggest that weight loss at the rate of 1 to 2 lb per week is achievable by reducing calorie intake. Numerous methods to determine calorie needs for weight loss exist. One method for determining calorie needs is to calculate resting energy requirement by the Harris-Benedict Equation:[40]

For women: $\text{REE} = 655 + (9.56 \times \text{wt [kg]}) + (1.85 \times \text{Ht [cm]}) - (4.67 \times \text{age})$

For men: $\text{REE} = 66.5 + (13.75 \times \text{wt [kg]}) + (5.0 \times \text{ht [cm]}) - (6.8 \times \text{age})$

After determining resting energy requirement, add an activity factor and finally subtract kilocalories for weight loss.

Example:

Woman, 40 years old. Ht: 5′5″ (165 cm), Wt: 165 lb (75 kg), Activity Level: light

Step 1: REE using Harris-Benedict Equation

$\text{REE} = 655 + (9.56 \times 75) + (1.85 \times 165) - (4.67 \times 40)$

REE = 1491

Step 2: Add activity factor to REE and determine kilocalories for weight maintenance

Activity Level Description Multiplier

Bedrest: bedridden, sedentary = 1.0

Light: daily routine activities = 1.3

Moderate: regular exercise program in addition to daily activities = 1.5

Vigorous: heavy construction worker or athlete = 1.7

REE $1491 \times 1.3 = 1938$

Estimated calories for weight maintenance = 1938

Step 3: For weight loss, subtract 500 kcal* per day from kcal for weight maintenance

1938 calories - 500 kcal/day = 1438 kcal for weight loss of 1 lb/week

*3500 calories = 1 lb fat. By subtracting 500 calories/day from maintenance calories, patient can lose 1 lb/week (–500 kcal/day × 7 days/week = –3500 kcal or 1 lb fat).

To use the table, find the appropriate height in the left-hand column labeled "Height." Move across to a given weight. The number at the top of the column is the body mass index at that height and weight. Pounds have been rounded off.

Table 28–4 Classification of Overweight and Obesity by Body Mass Index

	Obesity Class	BMI (kg/m^2)
Underweight		<18.5
Normal		18.5-24.9
Overweight		25.0-29.9
Obesity	I	30.0-34.9
Obesity	II	35.0-39.9
Extreme obesity	III	≥40

BMI, body mass index.

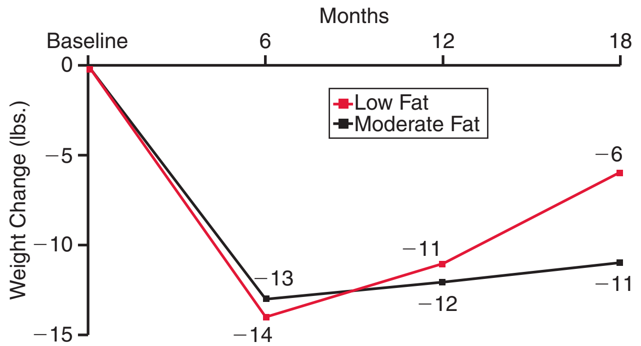

Figure 28–4 Comparison of a Mediterranean-style, high-unsaturated fat diet with a low-fat diet for weight loss. (Modified from McManus K, Antinoro L, Sacks F: A randomized controlled trial of a moderate-fat, low-energy diet compared with a low fat, low-energy diet for weight loss in overweight adults. Int J Obesity 2001;25:1503-11.)

Another simpler method to determine the calorie level for a weight loss diet is to select a standard calorie level that has been used in many clinical trials on weight loss. Diets containing 1000 to 1200 kcal/day can be selected for most women; a diet between 1200 kcal/day and 1600 kcal/day can be chosen for men. The higher levels may be appropriate for women who weigh 165 lb or more or who exercise. A daily caloric deficit of 500 kcal will produce a weight loss of 1 lb per week. More gradual rates of weight loss can be achieved by more modest, sustained reduction of calories.

Macronutrient Contents of Diet Intervention for Weight Loss

Published clinical trials of long-term results for dietary treatment of obesity are limited. The debate continues as to the most effective macronutrient content of the diet to support weight loss and maintenance of lost weight.

Low-Fat versus Moderate-Fat Diet for Weight Loss

The conventional diet for weight loss is low in fat, which has a rational basis because fat is energy dense compared with carbohydrate. The low-fat hypothesis is that decreasing energy-dense fat in the diet will result in an overall reduction of calories. A meta-analysis of trials of low-fat diets showed a mean dietary reduction from 38% to 27% and resulted in a mean 3.2 kg weight loss.[41] These studies were mostly short term and have been challenged by other researchers, citing methodologic concerns for certain studies used in the analysis, including the often greater intensity of interventions in the low-fat compared with no-intervention control groups and the lack of randomized control groups.[42]

An alternative hypothesis to reducing fat to assist reduction in energy and thus weight loss is to reduce intake of all macronutrients but leave the usual dietary proportions of fat, carbohydrate, and protein unchanged. In some clinical trials with fully controlled dietary intake, the macronutrient composition did not affect the rate or total amount of weight loss over the short run.[43-45] The crucial factor for weight loss is reduction in calorie intake.

Nonetheless, it remains to be determined over the long run whether there is any relative advantage to diets that are reduced in fat (high carbohydrate) compared with those that are reduced in carbohydrate and higher in fat and protein. We compared these two approaches in a randomized trial and found that a moderate-fat diet based on the diets of southern Europe and the Mediterranean allowed for a greater variety of foods that are considered appetizing compared with a more bland, low-fat diet and had better long-term success.[46] In 101 overweight men and women, one half were instructed to eat a low-fat diet (20% calories from fat) and one half to eat a moderate-fat diet (35% calories from fat, mostly monounsaturated from peanut butter, nuts, olive and canola oils). After 18 months, only one in five study participants could stick to the low-fat diet, whereas more than one half stuck to the moderate-fat diet. Both groups lost an average of 11 pounds in the first 6 months. The moderate-fat group maintained significant weight loss for 18 months, whereas the low-fat group gained more than one half of it back (Fig. 28–4). After $2\frac{1}{2}$ years, the moderate-fat group still maintained this weight reduction. Surprisingly, those on the moderate-fat diet increased consumption of vegetables and fiber compared with the low-fat group. We attribute the success of a moderate-fat, energy-restricted diet to the fact that patients could include favorite foods if they carefully watched portion sizes. For example, they could use full-fat salad dressings, eat nuts for snacks, and sauté vegetables and meats.

High-Protein, Low-Carbohydrate Diets

A high-protein, low-carbohydrate diet for weight loss has been touted in the press. However, a review by Freedman, King, and Kennedy in 2001 concluded that a careful, scientific evaluation of these approaches to weight loss is necessary.[47] Subsequently, two studies reported that low-carbohydrate diets that increased protein or fat reduced body weight more than conventional low-fat diets over 6 to 12 months. However, at the 12-month point, the difference in weight loss lost statistical significance.[48,49]

Comparison of Popular Diets

Four diets popularly touted for weight loss in bestselling books were compared in a randomized trial lasting 1 year.[50] The diets were Ornish (very low fat, high carbohydrate), Weight Watchers (balanced calorie reduction), Zone (moderate reduction in carbohydrate, low glycemic index, increased protein and unsaturated fat), and Atkins (low carbohydrate, high

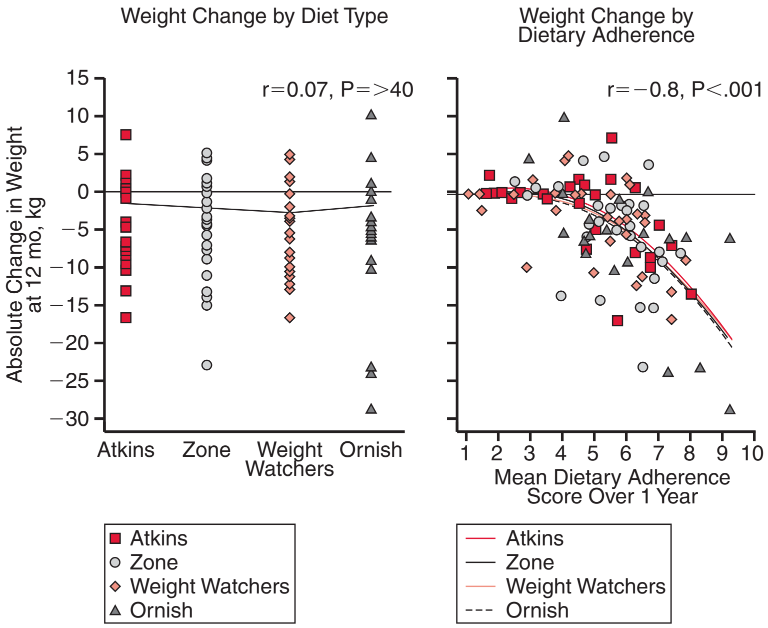

Figure 28–5 Comparison of popular weight loss diets. (Modified from Dansinger ML, Gleason JA, Griffith JL, et al: Comparison of the Atkins, Ornish, Weight Watchers, and Zone diets for weight loss and heart disease risk reduction: A randomized trial. JAMA 2005;293:43-53.)

protein and fat). The diet instruction was minimal and based on the popular books; there was no sustained counseling or group support. Thus, the researchers mimicked one "real world" scenario that overweight people try. All four diets produced modest initial weight loss, which was not sustained (Fig. 28–5). Although there was no statistically significant difference in weight loss among the groups, the less extreme diets produced slightly better results (i.e., Weight Watchers and Zone). Interestingly, no matter what diet was assigned to a participant, good adherence produced better weight loss. Several participants in each group lost more than 25 lb at 1 year. A minority of overweight people can follow a weight loss diet with minimal support and sustain clinically meaningful weight loss at least to 1 year. However, as shown by other studies, adherence declines in the absence of continued supervision and support.

Healthy Eating Patterns

In determining appropriate diets to reduce risk of cardiovascular disease, one approach is to base food plans on healthy dietary patterns. A large body of epidemiologic and metabolic data indicates that a diet high in vegetables, fruit, legumes, and whole grains but low in animal foods, particularly red meat, provides a healthy alternative to typical U.S. and northern European diets that contain large amounts of meat, high-fat dairy products, highly refined carbohydrates, hydrogenated fats, and low amounts of vegetables and fruit.

Mediterranean Diet

One example of a healthful eating pattern is the Mediterranean diet. The traditional Mediterranean diet reflects food patterns typical of Crete, much of the rest of Greece, and southern Italy in the 1960s. The selection of this specific time and these geographic areas is based on evidence that adult life expectancy for populations in these areas was among the highest in the world and that rates of coronary heart disease, major cancers, and some other diet-related chronic diseases were among the lowest in the world.

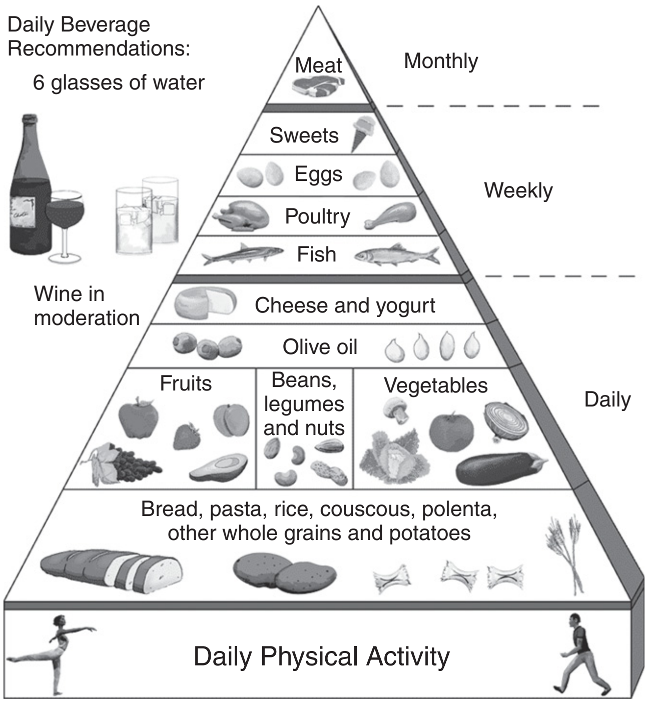

Figure 28–6 The traditional Mediterranean diet pyramid, developed in collaboration with the Nutrition Department of Harvard School of Public Health, the World Health Organization Regional Office for Europe, and the Oldways Preservation and Exchange Trust of Boston.

The Mediterranean diet of the early 1960s is described by the following broad characteristics:

- Abundance of plant foods that are minimally processed including vegetables, fruit, breads, beans, potatoes, nuts, seeds
- Olive oil as the principal fat
- Cheese and yogurt eaten daily in low to moderate amounts

- Fresh fruit as daily dessert—sweets containing sugar or honey eaten a few times per month
- Red meat eaten infrequently
- Wine in moderation with meals

In the traditional Mediterranean diet the percentage of calories from fat varies from 28% to 40% depending on the region. The majority of the fat is monounsaturated, with saturated fat being < 8% of total kilocalories.

The Mediterranean pyramid illustrated in Figure 28–6 is designed to convey a general sense of the relative proportions and frequency of consumption of foods that contribute to this overall dietary pattern. At the base of the pyramid, the diet features many different types of grains, bread, pasta, rice, bulgur (cracked wheat), and potatoes. Daily consumption of fruits, vegetables, beans, legumes, and nuts is encouraged, along with olive oil and moderate amounts of cheese and yogurt. Fish, poultry, and eggs are the main protein sources. Red meat is limited to a few times a month.

Table 28–5 Mediterranean-style Sample Menus

1500-Calorie Diet	2000-Calorie Diet
Breakfast 1 cup oatmeal 3/4 cup skim milk 2 Tbsp raisins 1 slice whole wheat toast 1 Tbsp peanut butter **Lunch** 3 oz skinless chicken breast 1 1/2 cups fresh spinach 1 Tbsp olive oil 1 Tbsp balsamic vinegar 2 whole wheat crackers 1 cup skim milk 1 medium orange **Snack** 1 oz almonds **Dinner** 4 oz broiled cod 1 baked sweet potato 5 mushrooms 1/2 cup asparagus 1 cup mixed greens 1 Tbsp. olive oil 1 Tbsp. vinegar 1/2 cup strawberries Calories: 1480 Protein: 90 g/24% Carbs: 165 g/45% Fat: 57 g/35% Sat: 9 g/5% Mono: 33 g/20% Poly: 10 g/6% Cholesterol: 119 mg Sodium: 940 mg Fiber: 28 g	**Breakfast** Egg white omelet with 2 egg whites and 1/8 cup each peppers, onions, mushrooms 1/2 Tbsp canola oil 1 slice whole wheat toast 3/4 cup blueberries 1/2 cup orange juice **Snack** 2 whole wheat crackers 1 Tbsp almond butter **Lunch** 1 cup vegetable soup, no added salt 3 oz turkey breast 2 slices whole wheat bread 1/4 cup avocado 3 slices tomato 1 cup 1% milk 1 apple **Snack** 1/2 cup carrots 1/8 cup hummus **Dinner** 4 oz broiled salmon 3/4 cup brown rice Mixed green salad 1/2 Tbsp olive oil 1 Tbsp vinegar Stir fry 1/2 cup broccoli and 1/2 cup cauliflower in 1/2 Tbsp olive oil **Snack** 3/4 cup low-fat vanilla yogurt 1 1/2 cups cantaloupe melon Calories: 2010 Protein: 107 g/21% Carbs: 240 g/48% Fat: 78 g/35% Sat: 15 g/7% Mono: 39 g/18% Poly: 17 g/8% Cholesterol: 163 mg Sodium: 1433 mg Fiber: 36 g

A Mediterranean-style diet can be successfully incorporated into the American diet using the main principles but substituting foods readily available and acceptable to the American palate. Table 28–5 illustrates a 1500-calorie meal plan and 2000-calorie meal plan that are patterned after the Mediterranean diet. The 1500-calorie meal plan can be used for a general weight loss plan for many adults, whereas a 2000-calorie meal plan is designed for weight maintenance. Table 28–6 shows an example of an alternative low-fat eating plan based on the DASH diet.[10]

Overall, the main objective in selecting healthful diets is to choose those that will not only reduce the risk of chronic disease but that are palatable and acceptable for long-term health. The Mediterranean-style diet and the DASH diet are approaches to eating that have proven to be acceptable and healthy. The OmniHeart study showed the superiority of a high unsaturated fat and protein diet on the basis of the principles established in DASH.[8] The OmniHeart unsaturated fat diet has strong similarities to the Mediterranean diet.

PHYSICAL ACTIVITY

Numerous scientific studies have demonstrated that physical activity prevents and treats many established risk factors including hypertension, insulin resistance and glucose intolerance, elevated triglyceride concentrations, low HDL cholesterol levels, and obesity.[51] The effect or benefit of exercise is influenced by the specific exercise, individual variation, and whether weight loss occurred. Physical activity can be an important adjunct to diet for obtaining and maintaining weight loss. The National Weight Control registry identified 3000 men and women who lost a minimum of 30 kg and maintained their weight loss for at least 1 year.[52] The average weight loss for these individuals was 30 kg, and the average amount of time that they maintained their lost weight was 5.5 years. Eighty-one percent of the participants reported physical activity. Women reported expending an average 2445 kcal per week, whereas men reported expending 3298 kcal per week. The physical activities most often recorded were walking, cycling, weight lifting, aerobics, running, and stair climbing.

Definition of Terms

Physical activity is defined as bodily movement produced by skeletal muscles that results in energy expenditure beyond resting expenditure.[52,53] Exercise is a subset of physical activity that is scheduled, repetitive, and has a goal of improving or maintaining physical fitness. Physical fitness includes cardiorespiratory fitness, muscle strength, body composition, and flexibility, comprising a set of attributes that people achieve and that relate to the ability to perform physical activity.

In describing physical activity or exercise, three components are assessed:

- Type—actual activity (i.e., walking, swimming, weight training)
- Duration—length of time
- Intensity—rate of energy expenditure

Recommendations for Primary Prevention

Type and Duration

The Centers for Disease Control and Prevention (CDC) and the American College of Sports Medicine (ACSM) recommend that individuals should engage in 30 minutes or more of moderate-intensity physical activity on most (preferably all) days of the week.[53] Patients should be encouraged to engage in a variety of physical activities and increase their activities as tolerated. Table 28–7 illustrates examples of a variety of moderate amounts of physical activity.

Intensity

The recommendation for maximum efficiency for cardiovascular health is to work at an intensity level equal to 65% to 85% of maximum heart rate (defined as Maximum Heart Rate = 220 – age of person).

Recommendations for Secondary Prevention

An American Heart Association consensus statement on preventing heart attack and death in patients with coronary disease suggested a minimum of 30 to 60 minutes of moderate-intensity activity 3 to 4 times weekly supplemented by an increase in daily lifestyle activities (e.g., using stairs, parking further from one's destination, taking walk breaks at work, performing household tasks); 5 to 6 hours a week were suggested for maximum benefits.[54]

Regular physical activity can improve heart function, reduce stress, and increase energy levels. The goal of 30 minutes of moderate-intensity activity most days of the week can be achieved by most people through a regular program of brisk walking. The public health challenge lies in promoting and supporting an active lifestyle early in life, which can be maintained throughout adulthood to reduce the risk of cardiovascular disease and other chronic diseases.

THE OVERALL EFFECT OF DIET AND LIFESTYLE

With full adherence, diet and exercise have strong potentials for major improvements in risk factors, dyslipidemia, high blood pressure, diabetes, and obesity. For example, strict vegetarians in Boston in the early 1970s showed very low cholesterol and blood pressure and near absence of overweight.[55] However, a more realistic approach is to simultaneously target more modest changes in several aspects of lifestyle. Together, these adjustments would be projected to reduce CHD markedly,[56] even if individual risk factors would be expected to change only mildly (Table 28–8).

Table 28–6 A Low-Fat Eating Plan Based on the DASH Diet, 2000 Calories a Day

Food Group	Daily Servings (except as noted)	Serving Sizes	Examples and Notes	Significance of Each Food Group to the DASH Eating Plan
Grains and grain products	7-8	1 slice bread 1 oz dry cereal* ½ cup cooked rice, pasta, or cereal	Whole wheat bread, English muffin, pita bread, bagel, cereals, grits, oatmeal, crackers, unsalted pretzels and popcorn	Major sources of energy and fiber
Vegetables	4-5	1 cup raw leafy vegetable ½ cup cooked vegetable 6 oz vegetable juice	Tomatoes, potatoes, carrots, green peas, squash, broccoli, turnip greens, collards, kale, spinach, artichokes, green beans, lima beans, sweet potatoes	Rich sources of potassium, magnesium, and fiber
Fruits	4-5	6 oz fruit juice 1 medium fruit ½ cup dried fruit ½ cup fresh, frozen, or canned fruit	Apricots, bananas, dates, grapes, oranges, orange juice, grapefruit, grapefruit juice, mangoes, melons, peaches, pineapples, prunes, raisins, strawberries, tangerines	Important sources of potassium, magnesium, and fiber
Low-fat or fat-free dairy foods	2-3	8 oz milk 1 cup yogurt 1½ oz cheese	Fat-free (skim) or low-fat (1%) milk, fat-free or low-fat buttermilk, fat-free or low-fat regular or frozen yogurt, low-fat and fat-free cheese	Major sources of calcium and protein
Meats, poultry, and fish	2 or fewer	3 oz cooked meats, poultry, or fish	Select only lean, trim away visible fats, broil, roast, or boil instead of frying, remove skin from poultry	Rich sources of protein and magnesium
Nuts, seeds, and dry beans	4-5/wk	⅓ cup or 1½ oz nuts 2 Tbsp or ½ oz seeds ½ cup cooked dry beans, peas	Almonds, filberts, mixed nuts, peanuts, walnuts, sunflower seeds, kidney beans, lentils	Rich sources of magnesium, protein, and fiber
Fats and oils†	2-3	1 tsp soft margarine 1 Tbsp low-fat mayonnaise, 2 Tbsp light salad dressing 1 tsp vegetable oil	Soft margarine, low-fat mayonnaise, light salad dressing, vegetable oil (e.g., olive, corn, canola, safflower)	DASH has 27% of calories as fat including fat in or added to foods
Sweets	5/wk	1 Tbsp sugar 1 Tbsp jelly or jam ½ oz jelly beans 8 oz lemonade	Maple syrup, sugar, jelly, jam, fruit-flavored gelatin, jelly beans, hard candy, fruit punch, sorbet, ices	Sweets should be low in fat

*Equals ½-1¼ cups, depending on cereal type. Check the product's Nutrition Facts label.
†Fat content changes serving counts for fats and oils. For example: 1 Tbsp of regular salad dressing equals 1 serving; 1 Tbsp of a low-fat dressing equals ½ serving; 1 Tbsp of a fat-free dressing equals 0 servings.
The number of daily servings in a food group may vary from those listed, depending on your caloric needs. Use this chart to help you plan your menus or take it with you when you go to the store.
From the U.S. Department of Health and Human Services, National Institutes of Health, National Heart, Lung, and Blood Institute.

Table 28–7 Examples of Moderate Amounts of Physical Activity*

Common Chores	Sports Activities	
Washing and waxing a car	Playing volleyball for 45-60 min	Less vigorous More time†
Washing windows or floors for 45-60 min	Playing touch football for 45 min	
Gardening for 30-45 min	Walking 1¾ miles in 35 min (20 min/mile)	↑
Wheeling self in wheelchair for 30-40 min	Basketball (shooting baskets) for 30 min	
Pushing a stroller 1½ miles in 30 min	Bicycling 5 miles in 30 min	
Raking leaves for 30 min	Dancing fast (social) for 30 min	
Walking 2 miles in 30 min (15 min/mile)	Water aerobics for 30 min	
Shoveling snow for 15 min	Swimming laps for 20 min	↓
Stairwalking for 15 min	Basketball (playing a game) for 15-20 min	More vigorous Less time
	Jumping rope for 15 min	
	Running 1½ miles in 15 min (15 min/mile)	

*A moderate amount of physical activity is roughly equivalent to physical activity that uses approximately 150 calories of energy per day, or 1000 calories per week.
†Some activities can be performed at various intensities; the suggested durations correspond to expected intensity of effort.

Table 28–8 Major Reduction in Cardiovascular Disease Risk by Making Modest Improvements in Lifestyle: The Nurses' Health Study

Primary Prevention of CVD: Five Attributes to Define Low Risk in the Nurses Health Study

1. Diet in upper 40% of population
   Good fat: Low saturated and trans fat, high polyunsaturated fat, high fish oil
   Good carbohydrates: Low-glycemic load, high fiber (whole grains)
   High folate (vegetables, fruit)
2. Not currently smoking
3. Moderate alcoholic beverage drinking (1 drink every other day to daily)
4. Regular exercise (½ hr daily, e.g., 2 miles/hr walking)
5. Body mass index < 25 kg/m^2 (optimal < 21 kg/m^2)

Three Low-Risk Attributes:
Good diet, no smoking, regular exercise
51% of coronary events and strokes could be avoided, but only 13% of nurses had this lifestyle

Four Low-Risk Attributes:
Good diet, no smoking, regular exercise, BMI < 25 kg/m^2
60% of events could be avoided; only 7% of nurses had these attributes

Five Low-Risk Attributes:
Above, plus moderate alcohol
74% CVD events, 82% coronary events in the population avoided, only 3% of nurses had these attributes

Chapter 29

The Steps Beyond Diet and Drug Therapy for Severe Hypercholesterolemia

Bruce R. Gordon and Lisa Cooper Hudgins

CHAPTER CONTENTS

A small subset of patients with hypercholesterolemia have an inadequate lipid-lowering response to maximum diet and drug treatment and should be considered for additional therapy to come as close as possible to the therapeutic targets of the National Cholesterol Education Program (NCEP).[1] Most candidates for treatment beyond diet and drugs are patients with familial hypercholesterolemia (FH) including all individuals with homozygous FH and patients with heterozygous FH who do not attain NCEP goals.

Treatment options alone or in combination include plasmapheresis, low-density lipoprotein (LDL) apheresis, portacaval shunt, liver transplantation, partial ileal bypass (PIB) surgery, and gene therapy. *Plasmapheresis* is a nonspecific, extracorporeal procedure that removes all plasma proteins including high-density lipoprotein (HDL) from the blood. A superior method that specifically lowers LDL cholesterol (LDL-C) in these patients is *LDL apheresis*. Methods for performing LDL apheresis include dextran sulfate cellulose adsorption, immunoadsorption, heparin-induced extracorporeal precipitation (HELP), and perfusion through whole blood–compatible columns. Time-averaged LDL lowering of 40% to 50% is achieved with weekly or every-other-week LDL apheresis therapy. The U.S. Food and Drug Administration (FDA) has approved LDL apheresis therapy for patients who, despite maximal tolerated diet and drug therapy, have an LDL-C concentration above 300 mg/dL without coronary artery disease (CAD) or an LDL-C concentration above 200 mg/dL with CAD. Dextran sulfate cellulose adsorption using the Liposorber System (Kaneka Pharma America) and HELP (B Braun) are the two systems available in the United States.

Surgical procedures for lowering LDL-C are more invasive than LDL apheresis and should only be considered if LDL-apheresis therapy does not provide adequate LDL-C lowering. *Portacaval shunts* have been used to achieve LDL-C lowering of about 40% as adjunctive therapy to LDL apheresis in patients with homozygous FH. *Liver transplantation* can achieve near normal LDL-C levels but is associated with considerable morbidity and the need for long-term immunosuppressive therapy. *Partial ileal bypass surgery* has slowed the progression of CAD, but it has appreciable morbidity rates and is not appropriate for patients with homozygous FH. *Gene transfer* has been used in a few patients with homozygous FH, with limited success. This therapy is not ready for widespread application in this patient population.

Increasing evidence indicates that LDL apheresis is beneficial in patients with refractory hypercholesterolemia and CAD and is clearly the therapy of choice for patients who require treatment beyond diet and drugs. The rapidity of clinical improvement in patients who receive LDL apheresis suggests mechanisms in addition to the regression of plaque. Whole blood–compatible systems for the performance of LDL apheresis will hopefully increase the acceptance of this therapy and decrease the cost. These systems have been used extensively in Europe but have not been introduced in the United States.

DEFINITION OF THE TARGET POPULATION

Because nondietary, nonpharmacologic therapy for hypercholesterolemia entails a major commitment from the patient and medical community, and in some instances substantial risk, clear guidelines for considering such therapy are necessary. All patients should have therapeutic lifestyle changes (TLC) instituted and be treated with maximum combination lipid-lowering drug therapy including (as tolerated) a reductase inhibitor, ezetemibe, and nicotinic acid. The FDA has approved LDL apheresis for patients with LDL-C concentrations substantially higher than levels recommended for initiation of lipid-lowering drug therapy.

Criteria for additional therapy should include the degree of LDL-C elevation and whether the patient has CAD or multiple risk factors for CAD. The FDA has approved LDL apheresis for the management of patients with CAD and LDL-C concentrations of more than 200 mg/dL or patients without CAD but an LDL-C concentration of more than 300 mg/dL. Table 29–1 summarizes this approach and incorporates selection criteria with those from the NCEP. Individuals with extremely high triglyceride concentrations or secondary causes of hypercholesterolemia are generally not candidates for the therapies described in this chapter.

Table 29–1 LDL-C Levels (mg/dL) and Initiation of Therapy

Categories	Diet + Drugs	LDL Apheresis + Diet/Drugs
Homozygous FH	All levels	All levels
High risk: CAD present or CAD equivalents	100 (70 optional)	200 (CAD only)
Moderate risk	130 or 160	300
Low risk	160 or 190	Not applicable

The recommendations of the third report of the National Cholesterol Education Program's Expert Panel (updated in 2004)[1] are combined with the recommendations for treating patients with severe hypercholesterolemia using LDL apheresis as approved by the FDA.
CAD, coronary artery disease; FH, familial hypercholesterolemia; LDL-C, low-density lipoprotein cholesterol.

DESCRIPTION OF THE PATIENT POPULATION

Homozygous Familial Hypercholesterolemia

The clearest indication for nondietary, nondrug therapy is in patients with homozygous FH. This disorder is caused by the inheritance of two mutant genes at the LDL receptor locus. The clinical expression occurs in approximately 1 in 1 million persons. The defect in LDL receptor function causes a marked elevation in the plasma concentration of LDL-C, which typically exceeds 500 mg/dL but can reach as high as 1000 mg/dL.[2] HDL cholesterol (HDL-C) concentrations tend to be substantially below normal. Clinical features include the presence of xanthomas, severe aortic root disease including aortic stenosis, and the premature onset of CAD. Angina pectoris, myocardial infarction, or sudden death frequently occurs between the ages of 5 and 20 years. Mabuchi et al.[3] followed 10 patients with homozygous FH for a period of approximately 14 years. During that time, six of the patients died from sudden death or heart failure at an average age of 26. Similar observations were reported in patients from South Africa.[4]

The severity of the clinical expression depends to a great extent on the percentage of functioning LDL receptors. In the study by Goldstein and Brown[5] of 57 homozygotes, more than one fourth of receptor-absent patients died before the age of 25 compared with 1 of 26 individuals with residual LDL receptor activity. Because of the very high risk of premature CAD and the poor response to diet and drug therapy, all patients with homozygous FH require alternative therapy.

Patients with Low-Density Lipoprotein Cholesterol Concentrations of More Than 200 mg/dL and Coronary Artery Disease

The majority of patients in this group will have the heterozygous form of FH. This disorder has a prevalence of approximately 1 in 500 persons and is typically manifested by the occurrence of premature CAD by the fifth decade for men and the sixth decade for women. Clinically similar syndromes are produced by defects in the LDL receptor and defective apolipoprotein B (apoB) structure with impaired receptor binding. The presence of both CAD and elevated LDL concentrations is an important risk factor for subsequent coronary events, and therefore patients with CAD require intensive LDL-C concentration control. The reinfarction rate found in seven secondary prevention trials reviewed by Pekkanen et al.[6] was about 6% annually in contrast to a 1% to 2% rate of first infarction in four primary prevention trials. Trials in patients with marked hypercholesterolemia[7,8] have reported regression or a lower rate of progression of coronary lesions when the elevated LDL-C concentration is lowered with diet and drugs. Coupled with the impressive results from the trials that used the statins, a very persuasive case can be made for the aggressive treatment of subjects with familial hypercholesterolemia to achieve NCEP LDL-C targets.

Patients with Low-Density Lipoprotein Cholesterol Concentrations of More Than 300 mg/dL without Coronary Artery Disease

The decision of whether to use nondietary, nondrug therapy for primary prevention in asymptomatic adults is never as easy as it is in homozygotes. The risk of premature CAD is most apparent in patients with FH due to the presence of lifelong elevated LDL-C concentrations. In addition, the presence of risk factors other than LDL-C helps determine which patients are most likely to develop CAD. For example, a lipoprotein(a) [Lp(a)] concentration of more than 20 mg/dL has been recognized as an independent risk factor in patients with FH.[9,10] The use of noninvasive screening procedures for CAD, such as quantitation of coronary artery calcium, provides additional guidance for determining whether patients with elevated LDL-C will develop clinically significant disease.[11]

Based on current FDA guidelines, it is reasonable to consider nondietary, nondrug therapy for primary prevention in patients with an LDL-C concentration of more than 300 mg/dL despite diet and maximal tolerated lipid-lowering drug therapy.

EXTRACORPOREAL THERAPIES FOR THE TREATMENT OF SEVERE HYPERCHOLESTEROLEMIA

Background

Plasmapheresis and the more specific LDL apheresis procedures have provided safe and efficient methods for LDL lowering in patients with severe hypercholesterolemia. These techniques are available around the world and have become the most common mode of therapy for patients with refractory hypercholesterolemia. The first report of plasma exchange for FH was published by de Gennes et al.[12] in 1967. The procedure was performed manually and was too cumbersome for prolonged use. In 1975 Thompson et al.[13] described

the use of plasmapheresis with an automated cell separator to treat patients with homozygous FH. Plasmapheresis therapy has been shown to improve the survival of treated homozygotes compared with their untreated control siblings.[14]

The nonselectivity of plasmapheresis led to the development of LDL apheresis for the specific removal of apoB-containing lipoproteins from the blood. It is most useful in patients who respond incompletely to diet and lipid-lowering drug therapy because of drug intolerance or extremely high baseline LDL-C concentrations. The specific removal of apoB-containing lipoproteins was first described in 1976 by Lupien and colleagues[15] using heparin agarose beads. LDL apheresis has grown from a cumbersome laboratory procedure to a routine therapy with automated equipment. Methods for performing LDL apheresis include heparin-induced extracorporeal LDL precipitation (HELP),[16] columns that contain immobilized antibodies to LDL,[17] and columns that contain dextran sulfate cellulose.[18,19] Whole blood–compatible systems using columns containing either a modified polyacrylate gel (DALI System; Fresenius AG, St. Wendel, Germany)[20] or dextran sulfate (Liposorber-D; Kaneka Pharma, Osaka, Japan)[21] have been developed and have shown promise in initial investigations.

Studies to date have focused on the use of LDL apheresis in patients with severe hypercholesterolemia and CAD. The use and clinical acceptance of the procedure have increased worldwide, including approval in 1996 by the FDA.

Vascular Access

The primary consideration is achieving a sufficient blood flow rate for the patient. Fortunately, venous access from an antecubital fossa vein is most often sufficient for plasmapheresis and LDL apheresis because of the lower blood flow rates required (50 to 100 mL/min) compared with hemodialysis (400 mL/min). Should access from antecubital fossa veins provide insufficient blood flow, the placement of a fistula or graft may be necessary.

Anticoagulation

Some form of anticoagulation is necessary for all extracorporeal procedures. Heparin and acid citrate dextrose (ACD) are the anticoagulants most commonly used in extracorporeal therapies. Heparin is typically used for extracorporeal procedures that involve a membrane to separate whole blood into plasma and cells or in the whole blood–compatible system. Typically, a heparin bolus of approximately 20 to 50 U/kg is administered, followed by a continuous infusion of approximately 1000 U/h. Heparin is a very effective anticoagulant. However, its effects are still apparent several hours after completion of the procedure. ACD, which is also an effective anticoagulant, has the advantage of rapid metabolism and little residual effect after the procedure. Side effects due to ACD administration include symptoms of hypocalcemia, which may include perioral tingling; hypotension; or, very rarely, tetany.

Blood Separation

Most forms of LDL apheresis require the separation of blood into cells and plasma before the plasma is processed to specifically remove apoB-containing lipoproteins. Whole blood–compatible systems use direct adsorption of lipoproteins on columns and thereby eliminate the requirement for cell separation. For systems that require cell separation, either a membrane or centrifuge is used to separate blood into plasma and cellular elements. Membrane separation of blood is simpler and requires less extracorporeal volume, but it is less efficient than centrifugal techniques.

Frequency of Therapy, Lipid Lowering, and Volume of Blood Processed

Most patients are treated with LDL apheresis at a treatment frequency of approximately every 2 weeks. This is based on the rebound of the LDL-C, as well as the observation that most patients prefer to be treated no more often than every other week. At a treatment frequency of every 2 weeks there is usually a stepwise reduction in pretreatment LDL-C level until a new plateau is reached.

Cholesterol reduction can be quantified by measuring the achievement in either the acute or time-averaged lowering (Fig. 29–1). The acute lowering is the difference between preprocedure and postprocedure lipid values as a percent of the initial value and is a function of the amount of plasma or blood processed during a single treatment. Most plasmapheresis treatments process approximately a single plasma volume and achieve approximately 50% lipid lowering. Because nonspecific depletion of plasma proteins is not a problem, LDL apheresis procedures can process 1.5 to 2.0 plasma or blood volumes and reduce LDL-C concentrations acutely by 70% to 80%. For a blood flow of 50 to 80 mL/min, it takes about 3 hours to process 1.5 to 2.0 plasma or blood volumes.

Although acute lowering is helpful in determining treatment efficiency, the time-averaged lipid value is a better indicator of the lipid concentration to which the patient's arteries are exposed over an extended period. The time-averaged lowering is related to the treatment frequency and rate of rebound. The time-averaged lipid value is estimated by the formula 0.73 (pre LDL-C – post LDL-C) + post LDL-C or can

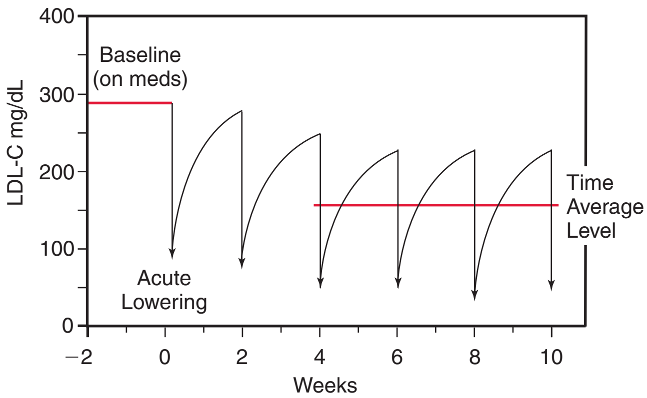

Figure 29–1 Acute and time average lowering of LDL-C for LDL apheresis treatments. The acute lowering is the difference in pretreatment and posttreatment levels as a percentage of the pretreatment level. The time average level is determined by measuring a "rebound" following a treatment.

be directly determined by measuring LDL-C daily after a treatment. The time-averaged LDL-C lowering is usually between 40% and 50%.

LDL apheresis has been reported to maintain or increase HDL-C concentrations over time.[22] The mechanism for this effect is unknown. The increase in HDL-C is seen most frequently in subjects with homozygous FH. In contrast, plasmapheresis lowers HDL-C through nonspecific depletion.

Plasmapheresis

Plasmapheresis was the original extracorporeal method for lowering LDL-C concentrations in individuals with FH. It has the advantages of being simple and safe. Unfortunately, HDL and other beneficial plasma proteins are also removed. This limitation makes plasmapheresis useful only in situations where LDL apheresis is not available. Because of the clear advantages of LDL apheresis compared with plasmapheresis, the remainder of this section is devoted to LDL apheresis.

Low-Density Lipoprotein Apheresis Using Dextran Sulfate Cellulose Columns

Dextran sulfate cellulose selectively binds apoB-containing lipoproteins on the basis of a charge attraction. Dextran sulfate cellulose columns were initially provided by the manufacturer as single, large-volume, nonregenerable columns that could be attached to any cell separator. Limited LDL-binding capacity resulted in the development of dual regenerable columns in a system that included a hollow-fiber primary cell separator (Fig. 29–2). Plasma is alternately perfused through each 150-mL column, permitting the regeneration of the off-line column with hypertonic sodium chloride solution. A computerized unit controls the process. The plasma, after passing through the adsorbent column, is recombined with the cells and returned to the patient. The advantage of this system is the almost unlimited LDL-binding capacity due to the on-line regeneration of the columns. The columns are discarded after each treatment.

Low-Density Lipoprotein Apheresis Using Immunoadsorption Columns

Immunoadsorption for the performance of LDL apheresis has been used to treat patients for approximately 25 years. Polyclonal monospecific or monoclonal antibodies to apoB are immobilized on a support, typically sepharose beads, and packed into glass columns. Each patient has two columns, which are reused during each procedure and reused from one procedure to the next because of the expense of making these columns. On-line regeneration of the columns is controlled by a column control unit (see Fig. 29–2). Typically, the columns are eluted with an acid solution, neutralized with a buffer solution, and then rinsed with saline. The procedure requires storage of the columns between treatments. All apoB-containing lipoproteins are removed [LDL, VLDL, and Lp(a)]. Because the columns are reused multiple times, they must be monitored for loss of activity that may occur after several months. In addition, sensitization of the patient to small quantities of shed antibody has been demonstrated.[23] Due to the cumbersome requirement of storing columns between uses, immunoadsorption LDL-apheresis is used less commonly than the other methods described in this chapter.

Low-Density Lipoprotein Apheresis Using Heparin-Induced Extracorporeal Low-Density Lipoprotein Precipitation

HELP-LDL apheresis specifically removes LDL, VLDL, and Lp(a) while minimally affecting HDL. HELP differs from other procedures in that it removes a substantial quantity of fibrinogen. The technique is based on the precipitation of positively charged LDL and other beta lipoproteins when heparin is added at a pH just above 5.0 (Fig. 29–3). A few

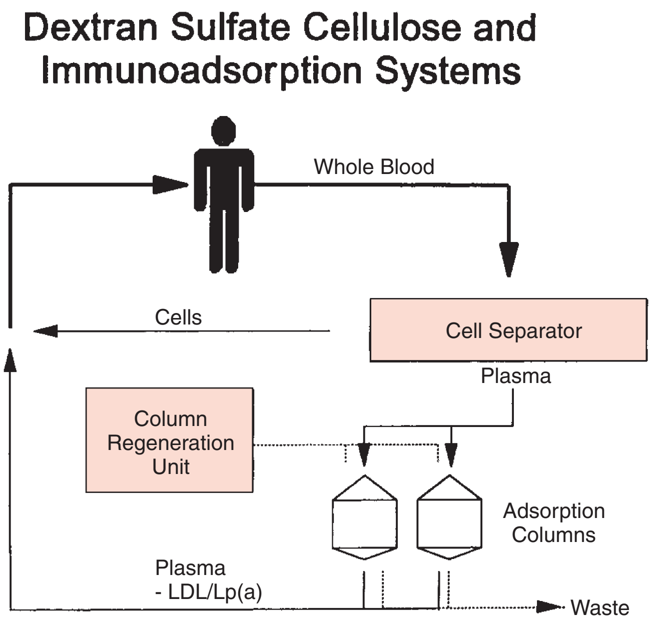

Figure 29–2 Schematic representation of dextran sulfate cellulose and immunoadsorption LDL apheresis systems.

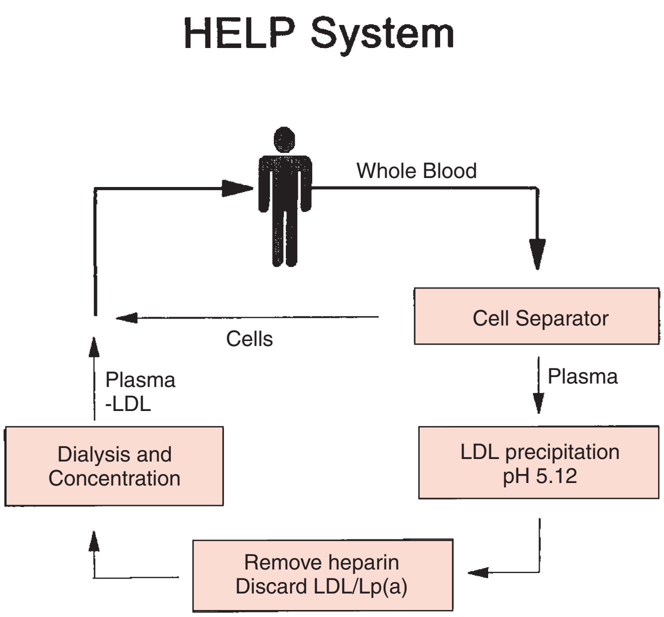

Figure 29–3 Schematic representation of the HELP-LDL apheresis system.

other plasma proteins precipitate to some extent with heparin, most notably fibrinogen. An anion exchange column removes excess heparin. The plasma is treated with bicarbonate dialysis and ultrafiltration to return pH to normal and remove excess fluid. The entire process is controlled by a microprocessor.

Low-Density Lipoprotein Apheresis Using Whole Blood–Compatible Systems

An important advance in the technology of performing LDL apheresis has been the development of whole blood–compatible systems. Potential cost savings and simplicity of use make a whole blood–compatible system very attractive for the performance of LDL apheresis. Two systems are currently available—The DALI System and Liposorber-D (Fig. 29–4). A comparison between the whole blood compatible systems and classic techniques for performing LDL apheresis is shown in Table 29–2. The DALI system uses a modified polyacrylate gel immobilized on a solid support. The mechanism of apoB binding is an electrostatic interaction between the positive charges of the apoB and the negatively charged carbohydrate moieties on the polyanionic gel.

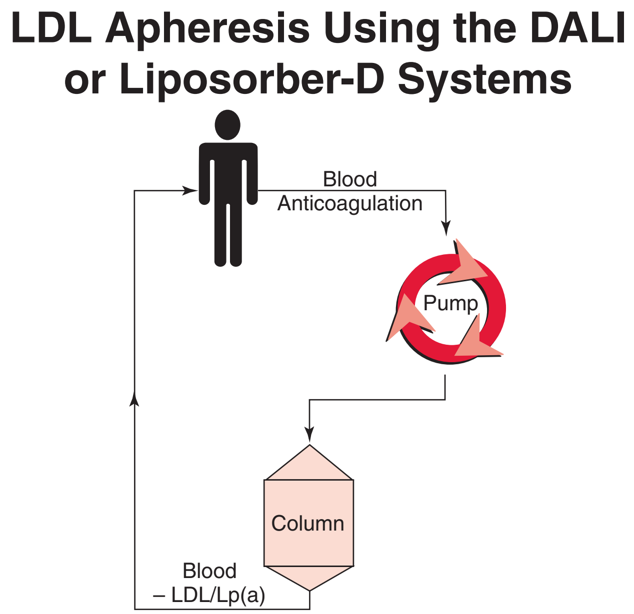

Figure 29–4 Schematic representation of the DALI and Liposorber-D whole blood–compatible LDL apheresis systems.

The initial two-center pilot study[20] reported on 12 hypercholesterolemic patients treated once each with columns containing 400 mL polyacrylate gel. No side effects were observed. A follow-up study reported the use of this technology in the therapy of three hypercholesterolemic subjects with atherosclerosis.[24] The acute reduction in lipids was 66% for LDL-C, 63% for Lp(a), and 29% for triglycerides. HDL and fibrinogen were lowered minimally. No clinically significant adverse events occurred, and the changes in biochemical and hematologic parameters were minor. The authors noted that the setup time for the procedure was only 30 minutes as opposed to 1 hour or more for other forms of LDL apheresis. The Liposorber-D system is based on binding of apo-B containing lipoproteins to dextran sulfate. The matrix has been modified to permit the safe interaction between whole blood and the column. The clinical experience in 10 subjects treated with this system was recently reported.[21] LDL cholesterol reduction was 62%. No significant side effects were observed. Whole blood–compatible systems are extremely promising despite the unknown long-term effects of whole blood interactions with the column. This form of LDL apheresis will hopefully be less expensive than established methods.

Risks of Low-Density Lipoprotein Apheresis

Adverse reactions due to LDL apheresis have been few. The extracorporeal volume is well tolerated even in patients with severe CAD. Hypotension requiring infusion of saline occurs in less than 5% of treatments. Unusual side effects include angina, hemolysis, and allergic or anaphylactic reactions. In immunoadsorption treatments, possible causes of adverse reactions include complement activation and sensitization of the patient to column constituents. An anaphylactoid reaction during dextran sulfate LDL apheresis has been described in patients taking angiotensin-converting enzyme (ACE) inhibitors.[25] The mechanism is related to release of bradykinin during LDL apheresis with concomitant decreased degradation of kinins by ACE inhibitors. The DALI system also activates the kallikrein-kinin system. Patients taking a short-acting ACE inhibitor should not take their ACE inhibitor for at least 24 hours before LDL apheresis therapy, whereas patients taking a long-acting ACE inhibitor should not take their medication for at least 48 hours before therapy. We have found that a better approach is to switch patients from ACE inhibitors to angiotensin II receptor blocking drugs before the initiation of LDL apheresis. Treatment with immunoadsorption

Table 29–2 Comparison of LDL-Apheresis Methods

Method	DALI	Liposorber-D	Liposorber	Immunoadsorption	HELP
Set-up time (approximate)	30 min	30 min	60 min	60 min	60 min
Reusable	No	No	No	Yes	No
Plasma/blood	Whole blood	Whole blood	Plasma	Plasma	Plasma
Principle	Polyacrylate	Dextran sulfate	Dextran sulfate	Antibodies	Heparin precipitation
Experience	Moderate	Limited	Extensive	Extensive	Extensive

Systems: DALI, direct adsorption of lipoproteins; Liposorber-D, dextran sulfate–based whole blood perfusion system; Liposorber, dextran sulfate cellulose column–based system; Immunoadsorption, low-density lipoprotein apheresis using columns containing immobilized antibodies on a support; HELP, heparin-induced extracorporeal low-density lipoprotein precipitation.

LDL apheresis or the HELP system are not associated with this clinical problem.

Benefits of Low-Density Lipoprotein Apheresis

Regression of tendon xanthoma and improvement in CAD have been demonstrated in patients with severe hypercholesterolemia when the LDL-C concentration is lowered through LDL apheresis protocols. In the LDL Apheresis Regression Study (LARS),[26] angiographic evidence for regression of CAD was observed in 10 of 30 patients treated with LDL apheresis and lipid-lowering drugs despite a baseline LDL concentration of 311 mg/dL. The HELP-LDL Apheresis Multicenter Study[27] was a 2-year investigation in 51 patients treated with weekly LDL apheresis and lipid-lowering drugs. Computer-assisted analysis of paired angiograms from 33 evaluable patients revealed that 23 patients had regression, 1 had little change, and 9 patients had progression. The German Multicenter LDL Apheresis Trial[28] was a four-center, 3-year prospective trial of 32 patients with FH. All patients who had symptomatic CAD experienced improvements in their symptoms by the end of the study. Improvement in electrocardiographic stress testing was demonstrated in 17 patients. Analysis of the paired angiograms did not reveal regression of disease, although definite progression of disease was observed in only five patients over 3 years.

An important study was the LDL-Apheresis Atherosclerosis Regression Study (LAARS), a prospective 2-year randomized one-center study in men with hypercholesterolemia and CAD.[29] This trial demonstrated that the addition of biweekly LDL apheresis to treatment with simvastatin improved regional myocardial perfusion and decreased myocardial ischemia. Of interest, there was little change in the coronary angiograms. Peripheral vascular disease was also found to improve in LAARS, as shown by standardized techniques including B-mode ultrasound.

Studies using intravascular ultrasound demonstrate that the angiogram may miss changes that occur in the blood vessel wall rather than the blood vessel lumen. The Low-Density Lipoprotein-Apheresis Coronary Morphology and Reserve Trial (LACMART) used intravascular ultrasound to compare change in coronary artery disease in 18 patients with familial hypercholesterolemia randomized to 1 year of either drug therapy or LDL apheresis combined with drug therapy.[30] Favorable changes in coronary artery minimal luminal diameter and plaque burden were observed in subjects receiving LDL apheresis plus drug compared with subjects receiving drug alone.

LDL apheresis with the HELP system has also been used to treat a patient with hypercholesterolemia and progression of CAD after heart transplantion.[31] The patient had clinical improvement documented by coronary angiography. LDL apheresis with the Liposorber system decreased the rate of restenosis in patients with elevated Lp(a) concentrations who had undergone coronary angioplasty.[32]

A multicenter study in the United States demonstrated the ability of LDL apheresis to decrease the number of clinical events in patients with CAD.[33] The rate of clinical events per 1000 patient-months decreased from 9.14 for the 5-year period before the initiation of LDL apheresis to 4.72 during the LDL apheresis period ($P = 0.037$). An analysis of data from the U.S. LDL Apheresis Registry established at the time of FDA approval of LDL apheresis confirmed the decrease in clinical events in a larger number of patients. In 1998 Mabuchi et al.[34] reported long-term outcome data in a study of 130 heterozygous FH patients with CAD. LDL apheresis combined with drug therapy produced a reduction in coronary events during a 6-year period. The rate of coronary events in the LDL apheresis-plus-drug group (n = 87) was 10% compared with 36% in the drug-alone group (n = 43).

Benefits of Low-Density Lipoprotein Apheresis Beyond Reducing Low-Density Lipoprotein Concentrations

The rapidity of clinical responses in some patients receiving LDL apheresis has suggested effects in addition to LDL lowering and regression of plaque. A number of mechanisms are likely for this observation including (1) decreased blood viscosity with improved blood rheology[35]; (2) improved coronary microcirculation; (3) lowered oxidized LDL concentrations[36]; (4) the removal of small, dense LDL particles; and (5) downregulation of leukocyte and endothelial adhesion molecules.[37] Tamai et al[36] measured forearm blood flow while infusing acetylcholine before and after a single LDL apheresis treatment and found that vasodilation responses were significantly augmented. The reductions in LDL and oxidized LDL correlated with the increase in acetylcholine-induced vasodilation.

SURGICAL PROCEDURES

Portacaval Shunt

Background

In 1963 a portacaval diversion was used to treat a child with a glycogen storage disease.[38] The observation by Starzl et al.[39] that the hyperlipidemia observed in these patients was improved by portacaval shunting provided the basis for using the procedure, starting in 1973, to treat severe forms of hypercholesterolemia.[40] The majority of reported cases had homozygous FH,[41,42,43] with a few cases of severe heterozygous FH also reported.

Technique

With the exception of the earliest procedures, all patients received end-to-side portacaval anastomoses. The portal vein is severed and connected with sutures to the suprarenal inferior vena cava, causing portal blood to completely bypass the liver (Fig. 29–5). The liver retains arterial flow through the hepatic artery.

Cholesterol Lowering

Table 29–3 shows the consistent and substantial total cholesterol and LDL-C lowering in 17 LDL receptor-negative patients. Nine were from Starzl's series,[42] and eight additional patients were treated at our center, of whom four had shunt surgery at the University of Pittsburgh and metabolic studies at the Rockefeller University. The average reductions in cho-

lesterol for the two groups were very similar, 37% and 42%, respectively, with all except one subject showing a better than 25% reduction. The decline in cholesterol began the week after surgery, with a plateau reached at about 6 months, and was sustained in all patients for the period of follow-up (4 months to 21 years), with no evidence of shunt closure. The HDL concentrations increased in every subject in our series (average of 36%) but had a more variable response in Starzl's series. Triglyceride concentrations, usually normal in this disease, decreased in all subjects except one. Two patients with heterozygous FH reported by Starzl et al.[42] had a similar lipid response to portacaval shunting. Less successful lowering was reported when the shunt was not fully patent or when collateral vessels were not completely tied off at the time of surgery.[43]

The hypocholesterolemic effect is coincidental with a marked decrease in cholesterol, bile acid, and LDL apoB synthesis and a decrease in cholesterol pool size.[44,45] Exogenous cholesterol absorption remains unchanged. In a 21-year-old receptor-negative homozygote patient, a liver biopsy 3 months after portacaval shunt revealed a marked decrease in the size of the hepatocytes, content of lipid and glycogen, and both rough and smooth endoplasmic reticula.[46] HMG-CoA reductase activity was decreased by 56%, and receptor-independent binding of LDL was significantly increased. These changes in the liver after a portacaval shunt have been attributed to loss of the first pass of portal blood containing high concentrations of hepatotropic substances, with the most important being insulin.[40] Many other synthetic functions of the liver, however, including the production of albumin, are unaffected.

Figure 29–5 End-to-side portacaval shunt. (From Zuidema GD, Cameron JL, Zeppa R: Portal hypertension. In Nora PF (ed): Operative Surgery: Principles and Techniques. Philadelphia, Lea & Febiger, 1980, p 694.

Risks and Benefits

Portacaval shunt surgery is generally well tolerated even in patients with symptomatic cardiac disease. The patient is typically discharged 3 to 4 days after surgery, with a single surgical follow-up visit 2 weeks later. In two of the larger series combined, 1 perioperative death occurred in 25 patients, most of whom had valvular or coronary disease at the time of surgery.[42,43] An NIH-sponsored registry of 45 shunted hypercholesterolemic patients reported three deaths within 30 days of surgery.[41]

The most feared adverse effect of the shunt is encephalopathy and intellectual deterioration. However, except for a single reported case of a brief period of coma 9 months after surgery in a 2 year-old child, there have been no reports of encephalopathy.[41,42,43] At our center, an adult heterozygote and four prepubertal homozygotes tested before and 1.5 to 2.5 years after surgery showed no changes in electroencephalographic, intelligence quotient, and other psychological parameters. One of these patients, age 25, who underwent portacaval shunt surgery at age 4, is a fully employed, healthy college graduate. Another patient with severe aortic stenosis developed a mild tremor 4.5 years after shunt surgery and then died suddenly of a myocardial infarction. At autopsy, he had mild cerebroventricular dilation and slightly thickened leptomeninges but no astrocyte proliferation or other changes typical of hepatic encephalopathy.

For the follow-up periods reported (generally <5 years), there has been no evidence of progressive hepatic dysfunction. However, mild liver enzyme abnormalities and elevated

Table 29–3 Effect of Portacaval Shunt Surgery on Lipid Profiles in Familial Homozygous Hypercholesterolemia

Average % Change [range]

	Starzl		Rogosin Institute	
Total cholesterol	–37	(–23 to –55)	–42	(–31 to –50)
LDL cholesterol	–36	(–21 to –44)	–43	(–36 to –50)
HDL cholesterol	–22	(–66 to +26)	+36	(+15 to +50)
Triglycerides	–19	(–63 to +80)	–35	(–12 to –63)

Data were obtained from 17 LDL receptor–negative patients before and at least 4 mo after shunting performed at ages 2-21. Nine patients were reported in Starzl TE, Chase HP, Ahrens EH Jr, et al: Portacaval shunt in patients with familial hypercholesterolemia. Ann Surg 1983;198:273-83, and the data from 8 patients are from our unpublished observations.
HDL, high-density lipoprotein; LDL, low-density lipoprotein.

ammonia concentrations occur.[39,42] We have also consistently seen a slight prolongation of prothrombin time and partial thromboplastin time and a reduction in several clotting factors after surgery, which thus far have not resulted in any clinically significant bleeding. The acceleration in growth in children after shunting has been attributed to improved health.[42] However, portacaval shunt surgery may alter growth by increasing blood levels of adrenal androgens. In two of our prepubertal male patients, rapid growth was associated with accelerated bone age; increased serum testosterone; and, in one case, precocious adrenarche that was successfully treated with hydrocortisone. One of our female patients also became amenorrheic with a high testosterone level, ovarian cysts, and other characteristics of the polycystic ovary syndrome after shunt surgery and was hyperinsulinemic after an oral but not intravenous glucose challenge. Case reports of increased serum testosterone have also occurred after shunting in post-menarchal females, although a survey of pituitary and thyroid function including testosterone before and 4 to 6 months after surgery failed to show changes in six homozygotes.[47] Clearly, the long-term effects of portacaval shunt surgery on liver function, growth, and sexual maturation need to be much better defined.

The follow-up of patients undergoing portacaval shunting has demonstrated that xanthomas regress and disease stabilization and improvement are possible. Starzl et al.[42] reported two cases of improved aortic stenosis, as evidenced by decreased aortic gradients 13 and 16 months after surgery. Coronary angiography in five patients from 7 months to 7 years after the procedure suggested improvement in one patient and disease stabilization in two. Disease stabilization over a similar time period for two patients who had also undergone coronary artery bypass graft surgery has also been reported.[48] However, coronary disease will often progress unless this surgery is combined with LDL apheresis to lower LDL-C sufficiently. We have treated an LDL receptor–negative patient without cardiovascular disease with a portacaval shunt at age 4 and LDL apheresis from the age of 6. He has continued biweekly LDL apheresis treatment for 19 years and has a time-averaged LDL-C concentration of 180 mg/dL, with no evidence of coronary or significant valvular disease.

Treatment Guidelines

Because of the uncertain, long-term hepatic and endocrine effects, portacaval shunt surgery should be reserved as adjunct therapy to LDL apheresis in the patient with an elevated LDL and significant cardiovascular disease. Portacaval shunt surgery is also an option for young children with significant valvular or coronary disease, or both, who are not large enough for treatment with LDL apheresis. The surgery should be performed before major clinical deterioration, at a time when the benefits of the surgery outweigh the risks of the operative procedure.

Liver Transplantation

Background

The first liver transplantation for homozygous FH was performed in a 6-year-old patient by Starzl in 1984.[49,50-52] Because of diffuse coronary atherosclerosis, heart transplantation was performed at the same time. Table 29–4 illustrates the dramatic increase in hepatic LDL clearance, decrease in LDL production, and plasma levels of LDL-cholesterol in this patient. Further LDL cholesterol lowering into the normal range was achieved with the addition of a statin. Similar results summarized in Table 29–5 have been reported for five other homozygous FH patients treated with combined heart-liver transplants (ages 6 to 46 years) and for 13 patients with liver-only transplants (ages 2.5 to 21 years). The longest follow-up has been 9 years after combined heart-liver transplant[53,54,55] and 13 years after liver-only transplant[56] (personal communication); nine patients were followed at least 4 years. Three patients previously had ileal bypass surgery or portacaval shunts, or both, that made the liver transplant surgery more technically difficult.[57,58] Four patients, ages $2\frac{1}{2}$ to 6, had normal coronaries and aortic valves at the time of liver transplant and were well 0.5 to 4 years later.[59-62] Two of these young patients each received a transplant from a heterozygote parent and thus required statin therapy to lower the LDL cholesterol further.[60,62]

Cholesterol Lowering

After transplantation, most homozygous FH patients met or exceeded NCEP guidelines (TC <225 mg/dL) within a few weeks of transplant. These excellent results were sustained over time and occurred despite treatment with steroids, cyclosporin, and other immunosuppressant agents that may increase lipid concentrations. Only four received additional therapy with statins. Lp(a) has also been reported to decrease,[63] and HDL-C may increase.

Risks and Benefits

Of the nine homozygous FH patients treated with heart-liver transplant, one died within a month of surgery after repeat heart-liver transplantation,[57] another died 4 years later of noncompliance with immunotherapy[59] (personal communication), and a third died 7 years later probably due to chronic rejection of the heart.[64] Of the 13 patients with liver-only transplants, just one death occurred from a myocardial infarction 2 years after surgery.[65] Four patients required retransplant of the liver due to infectious hepatitis, hepatic artery thrombosis, chronic hepatic rejection, or myocardial infarction. One 13-year-old patient had a myocardial infarction immediately after liver transplant surgery and required coronary artery bypass grafting.[66] Four reports documented by angiography the absence of progression[59,63,66,67] and regression[68] in coronary artery disease. Growth and development occurred normally.

Treatment Guidelines

For the treatment of some homozygous FH patients, the benefits of the sizable and sustained reduction in the level of LDL cholesterol may outweigh the risks of transplant surgery, chronic rejection, and immunosuppressive therapy. In practical terms, liver transplantation is often not a treatment option because waiting lists are long for cadaver livers and many family members including both parents have partial

Table 29–4 Response to Liver Transplant and Lovastatin in a Patient with Homozygous Familial Hypercholesterolemia

	Baseline	Liver Transplant	Transplant + Lovastatin
Total cholesterol (mg/dL)	1079	302	171
LDL-C (mg/dL)	988	184	107

Table 29–5 Summary of Liver and Heart-Liver Transplantation for the Treatment of Homozygous Familial Hypercholesterolemia

	Liver Transplant	Heart-Liver Transplant
Number of subjects	13	6
Date of surgery	1985-2002	1984-1996
Age at surgery (yr)	2.5-21	6-46
Length of follow-up (yr)	0.5-13	0.5-9
Preoperative cholesterol (mg/dL)	480-1170	700-1160
Follow-up cholesterol (mg/dL)	116-254	174-221
Number of deaths	1 (at 2 yr)	3 (at 1 mo, 4 and 7 yr)
Number with retransplants	2	2
Number on statins	2	2

Data from references 49-68. Includes 3 patients with prior ileal bypass or portacaval shunt surgery, or both. Follow-up cholesterol data include 2 patients with heterozygote living–related donors.

defects of the LDL receptor and therefore are not optimal liver donors. Until there is more information about the long-term health of liver transplant patients, liver transplantation should be reserved for the homozygous FH patient with established cardiovascular disease or evidence of progression despite maximum treatment with LDL-apheresis and drugs.

The liver transplant surgery should be performed before the vascular or valvular disease, or both, progresses to an unstable state. In the case of life-threatening heart failure, the liver and heart transplant can be combined, but with increased surgical complications and mortality.

Partial Ileal Bypass

Background

The PIB surgical procedure was introduced for the management of hypercholesterolemia in 1963.[69] More than 600 PIB procedures have been performed for this purpose.[70,71] The procedure lowers serum cholesterol by increasing the fecal loss of cholesterol and bile acids. A reduction in the absorption of cholesterol and bile acids stimulates an increase in hepatic cholesterol synthesis but also LDL receptor expression and the hepatic conversion of cholesterol to replenish the depleted bile-acid reservoir.[72] Its use has been best evaluated in patients with heterozygous FH. The lack of LDL receptors in homozygous FH may explain the minimal clinical response to PIB in this disorder.[73,74]

Technique

The PIB operation for lowering cholesterol bypasses the distal 200 cm or the distal third of the small intestine, whichever is greater. The ileum is divided, the proximal segment is anastomosed to the side of the cecum, and the closed distal segment is tacked to the cecum. This procedure is different from the weight-losing procedure, which includes a more extensive 90% jejunal-ileal bypass.

Cholesterol Lowering

The Program on the Surgical Control of the Hyperlipidemias (POSCH)[70,75,76] randomized 421 middle-aged survivors of a myocardial infarction and with an LDL cholesterol of at least 140 mg/dL to cholesterol-lowering therapy with PIB. The study began in 1975 before the general availability of HMG-CoA reductase inhibitors. At 5 years, surgery resulted in a 23% decrease in total cholesterol, a 38% decrease in LDL-C, a 4% increase in HDL-C, and a 20% increase in triglycerides. The responses were generally sustained for as long as surgical bypass was maintained (up to 20 years). Synergy with statins has been reported.[71]

Risks and Benefits

The operative and perioperative mortality rates are extremely low. The principal side effect of PIB surgery is more frequent and looser stools. During the first 5 years of follow-up, 6% to 8% of the surgically treated patients in the POSCH trial reported watery or frothy stools compared with 0% to 1% of controls. The average weight loss was 5.3 kg. Of PIB patients, 13.5% had at least one symptom of bowel obstruction (the majority occurred within the first year), but only 3.6% required surgical intervention. Surgically treated patients had a higher incidence of kidney stones (4% versus 0.7% per year) and gallstones (17% versus 5%). Twenty-three (6%) of the POSCH patients underwent reversal of surgery between 2 and 11 years after surgery, usually because of diarrhea.

The POSCH trial demonstrated that lipid lowering by PIB resulted in less progression and regression of coronary and peripheral vascular atherosclerosis compared with controls at 3, 5, 7, and 10 years after surgery.[75] Overall mortality was reduced by 20% at 18 years of follow-up.[76] There was no increase in colorectal cancer.

Gene Therapy

Background

Progress in molecular biology has provided hope for fixing the basic error in patients with severe FH through a technique called *gene transfer* (see Chapter 3). The foundation for this work was established by Goldstein and Brown,[5] who demonstrated that in the majority of patients, an absent or a defective LDL receptor was the cause of the marked elevation in LDL-C. Gene therapy would provide a normal copy of the missing or defective gene for the LDL receptor. In a single therapeutic trial, liver tissue from 5 patients, ages 7 to 41, with homozygous FH was harvested; the normal LDL receptor gene transduced with a recombinant retrovirus into the cells; and the hepatocytes reinfused into each patient through the mesenteric vein.[77] At 4 months a liver biopsy and in situ hybridization using an RNA probe specific for the recombinant-derived LDL receptor transcript revealed relatively few hepatocytes containing the transgene. In addition, only two of five subjects showed significant reductions in LDL-C (19% and 23%).

Although this attempt demonstrated the feasibility of correcting the LDL receptor abnormality in a limited number of hepatocytes, it was clear that better methods of gene therapy were necessary to correct this disorder. More appealing is intravenous delivery of the gene targeted specifically to the intact liver. Efficient and safe in vivo gene transfer has been difficult primarily because hepatocytes rarely divide without a stimulus, such as a partial hepatic resection. Fortunately, other viral vectors and nonviral approaches for gene transfer may be applicable. Adenoviruses have the capability of transducing genes into hepatocytes that are not dividing but may induce an immune response against the virus. Marked and sustained reduction of LDL cholesterol and atherosclerosis has been recently achieved in LDL receptor–deficient mice injected intravenously with novel, less immunogenic, liver-specific viral vectors, such as an adeno-associated virus from a nonhuman primate[78] and a helper-dependent adenovirus depleted of immunogenic viral genes.[79] Similar success has been obtained with a lentivirus vector in the Watanabe Heritable Hyperlipidemic (WHHL) rabbit model.[80]

CONCLUSIONS AND RECOMMENDATIONS FOR THERAPY

The treatment of patients with hypercholesterolemia who respond inadequately to diet and lipid-lowering drug therapy remains a challenge. Patients with homozygous FH are the clearest candidates for additional therapy because of their poor response to standard treatments. LDL apheresis has been the most commonly used treatment modality and is the safest alternative. This therapy should be initiated as early as possible and technically feasible. Generally age 5 or body weight of 15 kg is the lower limit because of difficulties with vascular access and the approximately 200 mL of blood in the extracorporeal circuit. An additional 10% to 20% cholesterol lowering can be achieved with the addition of atorvastatin and ezetimibe. Liver transplantation (and combined heart-liver transplantation when heart function is severely impaired) should be considered if LDL apheresis plus medication is technically difficult or inadequate at controlling the LDL-C concentration and progression of atherosclerosis. When a liver transplant, often limited by donor availability, is unfeasible or unacceptable, combination therapy with portacaval shunting, LDL apheresis, and medication may lower LDL-C sufficiently to prevent progression of atherosclerosis. Plasmapheresis is an alternative when LDL apheresis is not available. Gene therapy is not in use in clinical trials at present but is in active study in animal models.

The most frequent indication for LDL apheresis is the adult patient with heterozygous FH who has CAD and LDL-C concentrations higher than 200 mg/dL despite maximal diet and drug therapy. The use of nondietary, nonpharmacologic therapy as primary prevention in heterozygous patients without CAD but with LDL-C concentrations of more than 300 mg/dL and who are inadequately responsive to standard measures is more problematic. The standard risk factors should be used to segregate a small subset of individuals at the highest risk for the development of atherosclerosis in whom additional therapy is reasonable. The best alternative is LDL apheresis, but if this is not possible, PIB is also an option. Particularly for these patients, the decision to provide these therapies must be individualized.

Hypertension

Chapter 30

Initial Evaluation and Approach to the Patient with Hypertension

Marie Krousel-Wood, Barry J. Materson, and Paul K. Whelton

CHAPTER CONTENTS

An estimated 59 million people in the United States have hypertension (defined as having a systolic blood pressure [BP] ≥ 140 mm Hg or a diastolic BP ≥ 90 mm Hg, or both) or are taking antihypertensive medications. An additional 6 million people have been told at least twice that they have hypertension. This rising tide is due to an increase in and aging of the population and, more importantly, to an increase in the prevalence of obesity.[1]

No generally accepted definition of hypertension exists. One proposed definition is: *Hypertension is a disorder of intra-arterial pressure regulation such that the longer the duration and the higher the pressure, the greater the risk for target organ damage.* Some definitions include a statement that treatment reduces target organ risk. However it is defined, the reader must recognize that hypertension is heterogeneous in its pathophysiology and that its effect on target organs is also a function of associated risk factors, such as diabetes mellitus, dyslipidemia, and tobacco abuse. The current numeric definitions as promulgated by the Joint National Committee on Prevention, Evaluation, Diagnosis, and Treatment of Hypertension (JNC 7)[2] are displayed in Table 30–1.

The vast majority of patients with hypertension are treated in the ambulatory care setting. Table 30–2 displays general guidelines for follow-up. A few patients need to be treated urgently or emergently on the basis of the clinical presentation of complications of their hypertension rather than on the numbers alone (see Chapter 37). Most adult hypertensive emergencies are associated with very high levels of BP, often in excess of 240/130 mm Hg. What demands emergency treatment, however, is not the number, but an associated condition, such as acute pulmonary edema, acute myocardial infarction, or leaking abdominal aortic aneurysm. A stroke in process should not be treated with aggressive reduction of BP because it may cause brain tissue in the stroke penumbra to become nonviable.[3]

Patients who present repeatedly to Emergency Departments with very high BP but no other symptoms need not be hospitalized or treated emergently. Most of these patients are known hypertensives who have discontinued their medication. Placing them back on their previously prescribed medication is important, as well as adopting strategies to keep them from discontinuing them in the future. Those patients who continue to cycle through emergency departments, especially if they have established target organ damage, are at very high risk for experiencing an acute event.[4] Rapid reduction of BP in such patients with oral nifedipine is definitely contraindicated.

EVALUATION OF THE PATIENT

The subject of this chapter is hypertension, but it is one chapter in a book about cardiovascular therapeutics. One must not lose sight of the global picture of hypertension as part of the constellation of risk factors for cardiovascular, cerebrovascular, and renal disease.

Most medical problems are identified by obtaining a thorough history; performing a detailed physical examination that has, in part, been focused by the results of that history; and then obtaining additional laboratory or imaging data or performing relevant procedures. Hypertension is no exception.

On the other hand, few office-based practices could be self-sustaining if the practitioner asked every question and performed every examination listed in this chapter. The solution lies in a thorough approach that uses the patient and office staff to gather most of the data so that the practitioner

Table 30–1 Classification of Blood Pressure for Adults

BP Classification	SBP (mm Hg)	DBP (mm Hg)
Normal	<120	and <80
Prehypertension	120-139	or 80-89
Stage 1 hypertension	140-159	or 90-99
Stage 2 hypertension	≥160	or ≥100

BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure.
From Chobanian AV, Bakris GL, Black HR, et al, for the National High Blood Pressure Coordinating Committee: Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Hypertension 2003;42:1206-52.

Table 30–2 Recommendations for Follow-up Based on Initial Blood Pressure Measurements for Adults Without Acute End-Organ Damage

Initial Blood Pressure (mm Hg)*	Recommended Follow-up†
Normal	Recheck in 2 yr
Prehypertension	Recheck in 1 yr‡
Stage 1 hypertension	Confirm within 2 mo‡
Stage 2 hypertension	Evaluate or refer to a source of care within 1 mo
Higher BP (>180/110 mm Hg)	Evaluate and treat immediately or within 1 wk depending on clinical situation and complications

*If systolic and diastolic categories are different, follow recommendations for shorter follow-up (e.g., 160/86 mm Hg should be evaluated or referred to source of care within 1 mo).
†Modify the scheduling of follow-up according to reliable information about past BP measurements, other cardiovascular risk factors, or target organ disease.
‡Provide advice about lifestyle modifications.
From Chobanian AV, Bakris GL, Black HR, et al, for the National High Blood Pressure Coordinating Committee: Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Hypertension 2003;42:1206-52.

can convert this to information in short order and take the appropriate next steps. We address these issues as follows.

TAKING THE HISTORY

The history should provide clues as to whether the patient truly has hypertension; whether it is primary or secondary (Table 30–3); and, if secondary, the most likely cause or causes. The relevant questions should be incorporated in a history form that is to be completed by the patient or a knowledgeable family member before coming to the office. Many of the items are common to the history required for other disease entities covered in this book. Some practices may have electronic medical records or other computer capabilities so that patients may enter data at home and transmit them to the office. Use computer programs that require a positive or negative entry rather than defaulting to "negative" or "normal" when no entry is made. Figure 30–1 displays the pertinent elements of the history.

Table 30–3 Selected Causes of Secondary Hypertension

Chronic kidney disease
Coarctation of the aorta
Cushing's syndrome and other glucocorticoid excess states including chronic steroid therapy
Drug induced or drug related (includes nonsteroidal anti-inflammatory drugs, illicit pressor agents such as cocaine, sympathomimetics such as nasal decongestants and diet drugs, cyclosporine and tacrolimus, erythropoietin, licorice, alternative agents such as ephedra, ma haung and bitter orange)
Pheochromocytoma
Primary aldosteronism and other mineralocorticoid excess states
Renovascular hypertension
Sleep apnea
Thyroid/parathyroid disease

From Chobanian AV, Bakris GL, Black HR, et al, for the National High Blood Pressure Coordinating Committee: Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Hypertension 2003;42:1206-52.

Details of the Present Illness

Determining when the patient first became aware of having hypertension is important. Sudden or very recent onset or exacerbation may increase the likelihood of secondary hypertension. Ask about military, employment, insurance, and other past physical examinations. Determine what readings were obtained by other physicians, such as a gynecologist, or for a procedure like colonoscopy, or perioperatively. Someone who reports decades of being asked to rest before the BP determination is repeated or told that his or her BP is "borderline" (a meaningless term) is less likely to have a secondary cause.

Obtain a history of previous hypertension work-up with particular attention to data that may have already been reliably collected and need not be duplicated. If the patient has been previously treated for hypertension, a detailed list of medications used, their effect (or lack of same), and any adverse effects will be useful. Special attention must be paid to patients who report multiple, pharmacologically improbable and often bizarre "allergies" to medications. This may be a clue to anxiety syndromes or panic attacks. Some of these patients do not have hypertension at all. Furthermore, anxiety-induced hypertension generally does not respond to antihypertensive therapy. These patients require anxiolytic agents and care from a specialist in treating anxiety disorders.

Family History

Family history should be extended when possible to both maternal and paternal grandparents, aunts, and uncles in addition to siblings and children. If a woman has children, inquire about her BP during her pregnancy. Seek information

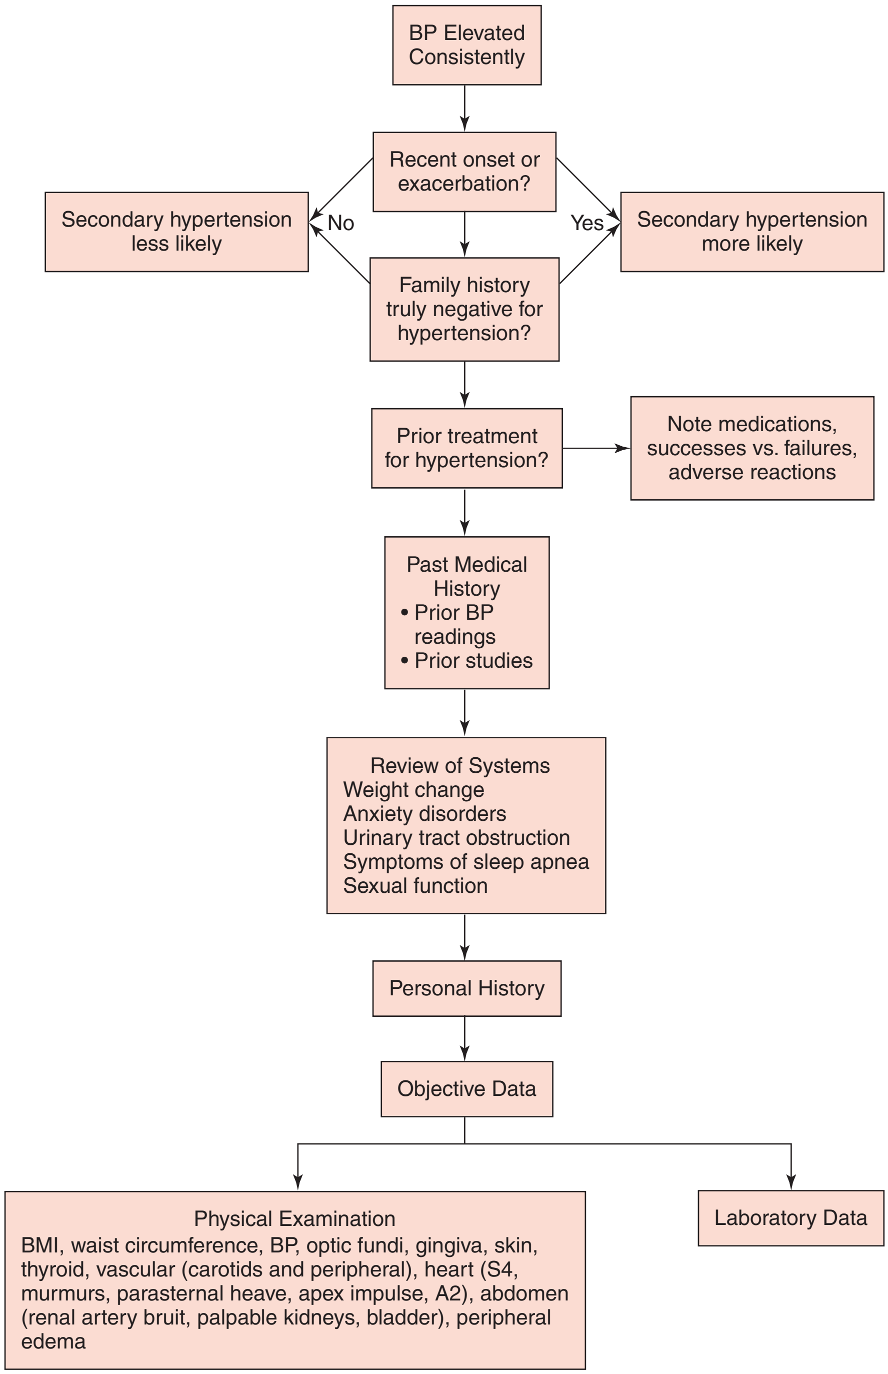

Figure 30–1 Flowchart for initial work-up of hypertension. A2, aortic component of second heart sound; BP, blood pressure; S4, fourth heart sound.

on strokes, premature cardiac death, and kidney failure in addition to heart failure and hypertension.

Past Medical History

Past medical history can reveal opportunities to review medical records for BP readings taken at the time of hospitalizations or procedures or for imaging studies, such as those of the brain or kidneys or laboratory data that may reveal a pattern of, for example, decreased serum potassium levels. A CT or MRI taken because of headaches might prove helpful by being totally normal or by showing signs of hypertension-associated brain lesions.

Review of Systems

The review of systems should focus on recent weight changes and on clues to anxiety disorders. Recent weight gain may be associated with new onset of hypertension. If the patient can lose the weight, it offers the opportunity to normalize the BP without medication. Weight loss may be a clue to hyperthyroidism or pheochromocytoma. Has the patient been previously diagnosed with panic attacks? Has the patient received formal psychological or psychiatric care? Has he or she taken anxiolytic medications? Both men and women should be asked about symptoms of urinary tract obstruction.

Daytime sleepiness or a history of loud snoring, especially when associated with long periods of apnea, is strongly suggestive of obstructive sleep apnea, a condition known to be associated with hypertension.[5]

Personal History

The personal history is often the key to establishing a diagnosis and in formulating a plan of treatment. Establish dietary intakes of sodium, potassium, and calcium. Tobacco abuse should be detailed because of its vasculotoxic effect. Alcohol abuse is an important factor in hypertension. Caffeine abuse, usually through high intake of coffee, can increase BP. Ask about use or abuse of nasal sprays and cold or allergy remedies, as well as weight loss potions that may have a pressor effect. Licorice abuse is an exceedingly rare cause of hypertension, but it is easily curable. People can be exposed to a variety of pressor agents in so-called health foods or herbal remedies. Determine whether patients are taking nonsteroidal anti-inflammatory drugs. Determine the patient's exercise pattern. If he or she does not exercise at all but has no physical contraindication, a prescription of daily walking is a good start.

A patient's education and occupation can provide important clues to the etiology of hypertension. Although industrial lead exposure is not common today, uncontrollable job-related stress is common.[6] Marital history may also give important clues to a patient's BP.

PHYSICAL EXAMINATION

Basic

The patient's weight and height should be determined. Calculating body mass index (BMI) is simple. Also measure the waist circumference. This simple measurement has significant predictive value for metabolic syndrome and coronary heart disease.[7]

Determination of correct diagnosis and treatment depends on accurate assessment of BP. Flawed decisions may result from inaccurate data. The BP guidelines for measurement of office BP outlined by the JNC 7[2] and the American Heart Association[8] are simple and easy to follow. In brief, the patient should be seated comfortably with feet on the floor and back supported and at rest for at least 10 minutes. The patient should not have consumed tobacco or caffeine in the past 30 minutes. The likelihood that the patient may have used illicit vasoactive drugs should be assessed. The bare arm should be fitted with a cuff of correct size, and the arm supported at heart level. The cuff should be inflated until either the radial or brachial pulse disappears from the palpating fingertip. The pressure should then be reduced by a few mm Hg per second until the first Korotkoff sound is heard.

With few exceptions, disappearance of the sounds marks the diastolic pressure. The initial reading should be repeated in both arms with the patient standing. The reading in each arm should be noted by arm side and position. A between-arm difference of more than 10 mm Hg will be seen in only 9% of the population.[9] These people tend to be hypertensive, older, more obese, and more likely to have decreased vascular compliance. Obstructive lesions are rare and should not be sought unless there are other clinical indications.[9] The systolic BP may be higher in one arm, and the diastolic higher in the other. Note the arm used, and use the one with the higher readings for future determination. This will prevent errors based on using inconsistent readings. Many offices use semi-automated BP equipment. Most of these devices use an oscillometric method of BP determination. If the instrument has been validated and the procedures for patient positioning described earlier have been followed, these devices eliminate observer error and free up staff time. Check *www.dableducational.org* to determine whether the instrument has been validated.

When BP values are reported to you by others, be suspicious of numbers that have terminal zeros for both systolic and diastolic pressures. Assuming that the instrument is calibrated in 2-mm Hg intervals, the odds of having a reading such as 160/100 are 1 in 25. If many similar readings are presented, you can safely assume that they were taken or recorded incorrectly or fabricated.

"White Coat" or Clinic Hypertension

Up to 25% of patients will have higher BP readings in the office than at home. This has been termed "white coat" or "clinic" hypertension. Its true impact on cardiovascular morbidity and mortality remains unknown. These patients should not be considered "normal" because they may have some differences (e.g., higher heart rate, less nocturnal fall in BP) from truly normotensive patients and because they tend to develop fixed hypertension later in life.[10] They should be followed and prescribed adoption and maintenance of a healthy lifestyle. Patients or family members who have been trained to use validated instruments may provide valuable data on home BP readings. If home BP readings are used, the criterion for hypertension is 135/85 rather than 140/90.[11] Be aware of the few patients whose fixation on their BP readings does more harm than good. The use of a 24-hour ambulatory BP recording device may be of value for patients who cannot take reliable home BP readings. Recently, patients have been described who have normal readings in the clinic and high readings at home.[12] In contrast to patients with white coat hypertension, patients with masked hypertension may have an increased risk of cardiovascular morbidity and mortality.

Other Physical Findings

All of the following points are parts of the routine physical examination but require special attention for the patient with hypertension. The patient's gait, posture, ability to stand from a supine or seated position, eye movements, facial expressions, and hearing can exclude gross neurologic abnormalities for patients who have no historical clues to neurologic disease. The patient's affect, goal-directed responses (or not) to questions, and body language can give important clues to anxiety, depression, or hostility.

Examination of the skin for café-au-lait spots, neurofibromatomata, hair pattern changes, factitious lesions, and signs of domestic violence may reveal important clues.

Examination of the optic fundi, although a long-standing tradition, has been challenged as to its usefulness in evaluating the hypertensive patient. Even expert observers have difficulty grading degrees of arteriolar vasospasm.[13] On the other hand,

detection of retinal hemorrhages, exudates, papilledema, marked arteriovenous crossing defects, and markedly increased light reflex should alter one's diagnostic and therapeutic strategy. The eyes and facial features may give clues to hyperthyroidism and hypothyroidism, as well as Cushing's syndrome.

Look for gingival hypertrophy. Many patients who receive treatment with dihydropyridine calcium antagonists develop varying degrees of gingival hypertrophy, and this may become problematic.[14] Establishing the negative before initiating therapy is important.

The carotid arteries should be checked for amplitude of pulse and bruits. History and other clues will dictate the thoroughness of the thyroid examination.

Examination of the heart should focus on rate and rhythm, left parasternal heave, displacement of the apex impulse, accentuation of the aortic component of S_2, auscultation for S_4, and auscultation for murmurs, particularly of mitral incompetence. Looking for signs of heart failure is important.

The abdominal examination should include careful auscultation for a bruit of renal artery origin. With the patient supine, listen in the epigastric area and then work toward both flanks. If a systolic bruit is heard, the sensitivity and specificity for renal artery stenosis are poor; however, if the bruit has both systolic and diastolic components and especially if it can be heard over the costovertebral angles with the patient prone, the specificity is much higher.[15] Palpate for enlarged kidneys indicative of polycystic kidney disease. Palpate for an enlarged urinary bladder. A distended bladder may be an important source of sympathetic discharge. Some or all of the BP elevation may be reduced by relieving urinary outflow obstruction.[16]

If coarctation of the aorta is suspected, BP must be measured in the leg and arm. Decreased leg BP may indicate coarctation or other obstructive vascular disease. The radial and femoral arteries should be palpated simultaneously to determine if there is a pulse delay; this is also suggestive of aortic coarctation. These tests should be routine for children with hypertension.

Peripheral pulses should be checked, and peripheral edema should be assessed. Diabetic patients should have a much more thorough examination of the feet including testing for position and vibratory sense.

BASIC LABORATORY EVALUATION

Absent specific clues to secondary hypertension from the history and physical examination, the basic initial laboratory evaluation should be simple.

Urinalysis is important to assess for intrinsic renal disease, as well as damage to the kidney as a target organ. Testing for microalbuminuria, especially in diabetics, has growing impetus as its predictive value for both renal and cardiovascular disease is revealed and the test becomes more readily available.[17]

Serum urea nitrogen and creatinine, especially with an estimate of glomerular filtration rate (eGFR), are important basic tests. Be aware that the formula used in the Modification of Diet in Renal Disease (MDRD) trial may greatly underestimate GFR in normal people.[18] This formula is used by some clinical laboratories to calculate eGFR. The simple Cockcroft-Gault formula ([140-age in years] $\times$ weight in kg/[serum creatinine in mg/dL $\times$ 72]) remains a useful estimator of GFR. The only laboratory test required by this formula is the serum creatinine.

Serum electrolytes may provide important clues to secondary hypertension or other disease entities. Persistent serum potassium levels below 4.0 mmol/L, but still within the normal range, without use of a diuretic or other reason for potassium loss may suggest hyperaldosteronism. This would be further supported by evidence of metabolic alkalosis.

Elevated serum glucose should lead to further testing given the important interaction between hypertension and diabetes. Although not specifically part of the hypertensive work-up, an assessment of serum lipids should be made because of risk factor clustering.

Uric acid has been considered to be a possible independent cardiovascular risk factor.[19] It should be measured before prescribing a thiazide diuretic.

Assays of plasma renin activity and plasma aldosterone levels are not recommended for the initial evaluation of the hypertensive patient. These assays may play a role in the diagnosis of secondary hypertension, as discussed in later chapters.

A baseline electrocardiogram should be part of the initial evaluation of every hypertensive patient. If there is evidence of left ventricular hypertrophy, this should be confirmed with an echocardiogram. An echocardiogram should not be viewed as a routine initial evaluation.

A chest x-ray should be performed only if specifically indicated. It is not part of the initial evaluation of the hypertensive patient.

OVERVIEW OF TREATMENT OF THE HYPERTENSIVE PATIENT

Once the initial evaluation of the patient has been completed, decisions on the choice of therapy should be made. The JNC 7 algorithm (Fig. 30–2) may be a useful guide for most patients. All patients should have the lifestyle modifications that are discussed in the remainder of this chapter initiated and maintained. For those who require pharmacologic treatment, we recommend first identifying any compelling indications (e.g., heart failure, post-myocardial infarction, high coronary disease risk, diabetes, chronic kidney disease, recurrent stroke prevention) because a compelling indication may drive the selection of the antihypertensive medication. If there is no compelling indication, then treatment is based on the stage of hypertension, and this is discussed in following chapters.

If the patient fails to achieve the goal BP despite treatment with full doses of three or more drugs, one of which is a diuretic, he or she is defined as having resistant hypertension. This requires careful assessment and attempt at correction of predisposing factors. The most common cause of resistant hypertension is volume overload. Nonadherence to prescribed regimens or prescription of inadequate doses or inappropriate combinations of medications are also common causes of treatment resistance. Many patients do not take their medications as prescribed or do not take them at all. Assessment and treatment of the patient with resistant hypertension are discussed in Chapter 36.

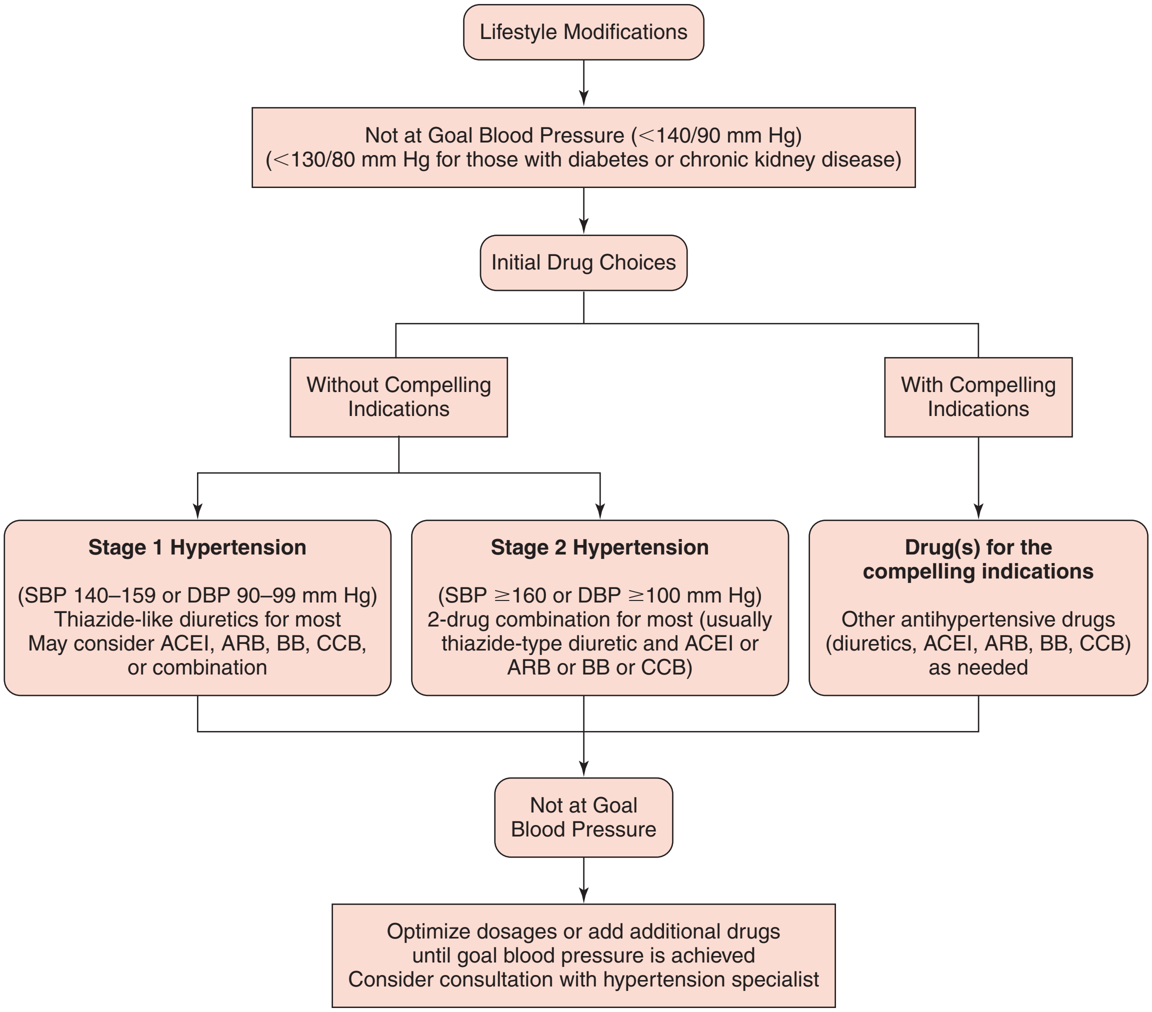

Figure 30–2 Algorithm for the treatment of hypertension. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BB, β-adrenergic receptor blocker; CCB, calcium channel blocker. (Modified from Chobanian AV, Bakris GL, Black HR, et al, for the National High Blood Pressure Coordinating Committee: Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Hypertension 2003;42:1206-52.)

LIFESTYLE MODIFICATIONS IN THE TREATMENT OF HYPERTENSION

Adopting a healthy lifestyle is a critical component in the prevention and management of hypertension. Despite the availability of effective medical therapy for the treatment of hypertension, BP control rates for patients with this chronic disease are only 31% and far below the Healthy People 2010 goal of 50%.[20,21] In addition to resistance to treatment and poor medication adherence, an unhealthy lifestyle is an important contributor to poor control of BP. Evidence from clinical research studies including randomized controlled trials has demonstrated that lifestyle modification, alone or in combination with antihypertensive medication, decreases BP, enhances the efficacy of antihypertensive medication therapy, and decreases cardiovascular risk.[2] With improved BP control and reduced cardiovascular risk resulting from the adoption of a healthy lifestyle by patients with hypertension, many of the complications associated with hypertension can be prevented (i.e., tertiary prevention[22]).

The major recommendations for lifestyle modifications in JNC 7 include maintaining a normal body weight, consuming a diet rich in fruits, vegetables, and low-fat dairy products, reducing dietary sodium intake, engaging in regular physical activity, and limiting consumption of alcohol (Table 30–4).[2,23-30] Potassium supplementation also lowers BP and should be part of the management plan for prevention and treatment of hypertension.[31-35] An Institute of Medicine report recommended 4.7 g (120 mmol)/day as an adequate intake for potassium in adults.[34] This contrasts with an average intake of approximately 2.0 to 3.0 g potassium/day in most recent surveys in the United States. In the same report an adequate intake for sodium was set at 1.5 g (65 mmol)/day in young adults, 1.3 g/day for those between 56 and 70 years, and 1.2 g/day for those 71 years of age and older. An upper intake level for sodium was set at 2.3 g (100 mmol)/day.[34] The latest statement from the American Heart Association regarding dietary approaches to prevent and treat hypertension endorses these recommendations.[35]

Table 30–4 Lifestyle Modifications for the Management of Hypertension*

Category	Recommendation for Modification	Approximate Systolic Blood Pressure Reduction Range
Weight	Maintain normal body weight (BMI 18.5-24.9 kg/m^2)	5-20 mm Hg/10-kg weight loss[23,24]
Physical activity	Engage in regular aerobic physical activity, such as brisk walking (at least 30 minutes per day, most days of the week)	4-9 mm Hg[28,29]
Diet plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat	8-14 mm Hg[25,26]
Dietary sodium	Reduce dietary sodium intake to no more than 100 mmol/day (2.4 g sodium or 6 g sodium chloride)	2-8 mm Hg[25,26,27]
Dietary potassium	Increase dietary potassium intake to 120 mmol (4.7 g)	2-7 mm Hg[31]
Alcohol consumption	Limit consumption to no more than 2 drinks per day (1 oz or 30 mL ethanol [e.g., 24 oz beer, 10 oz wine, or 3 oz 80-proof whiskey] in most men and no more than 1 drink per day [0.5 oz of ethanol] in lighter-weight persons and women)	2-4 mm Hg[30]

*The effects of implementing these modifications are dose and time dependent and could be higher for some individuals.
BMI, body mass index.

Practical Approaches to Encouraging Lifestyle Modifications

The scientific evidence to date indicates that changes in lifestyle are achievable and sustainable over time provided the approaches are practical, address barriers, and are relevant to the patient. Translating scientific evidence for behavior change into clinical practice presents unique challenges in the management of the patient with hypertension, in part because of the asymptomatic characteristic and chronic nature of the condition. In addition, other factors are associated with adherence to recommendations for the management of hypertension. A conceptual framework presented in Figure 30–3 outlines the link between the risk factors for poor adherence, low adherence to prescribed regimens, poor clinical outcomes, and increased cost and use.[36] Not surprisingly, patients value their quality of life, in general, and how they feel, specifically. Emphasizing improvements in quality of life associated with lifestyle modifications will likely improve adherence to recommendations and ultimately clinical outcomes. Simplifying the complexity of the behavior change and minimizing the side effects of the therapeutic regimen will likely lead to greater adherence. These and the other risk factors listed in Figure 30–3 often present as barriers to following therapeutic recommendations. These system-specific and patient-specific barriers are discussed in subsequent sections of this chapter.

Barriers to Lifestyle Modifications

In order to be effective in encouraging lifestyle modifications, physicians and other health care providers must first understand risk factors for and barriers to following the recommendations. Two broad categories of barriers contribute to poor adherence: system-specific barriers (general access, health care, and environmental barriers) and patient-specific barriers. System-specific barriers include inadequate access to the proper foods and exercise facilities due to high cost, low availability, or lack of transportation to grocery stores and community recreational facilities. Poor access to health care facilities and providers for initial evaluation and ongoing management of hypertension, as well as limited physician and other health care provider knowledge of the lifestyle recommendations including practical approaches to adhering to the recommendations, are other system barriers. Environmental factors, such as climate and unsafe neighborhoods, also contribute to poor adherence.

Patient-specific barriers include limited patient knowledge regarding his or her disease and the importance of lifestyle modifications in the management of high blood pressure and lack of motivation to change behaviors. Other patient-specific barriers are illnesses, such as arthritis or pulmonary disease, which may decrease quality of life, result in significant limitations in the ability to engage in a specific exercise regimen, and increase the complexity of treatment. Sometimes, the patient's cultural and religious background does not support changes in dietary choices and increases in physical activity. These barriers, alone or in combination, may trigger patient use of unconventional or alternative therapies and negatively affect patient adherence to lifestyle modifications. A better understanding of these barriers and their relevance to a particular patient is important in counseling a patient regarding practical approaches to behavior change.

Approaches to Increasing the Adoption of Lifestyle Modifications

In overcoming barriers to lifestyle changes, two general strategies for the management of high BP and its complications are

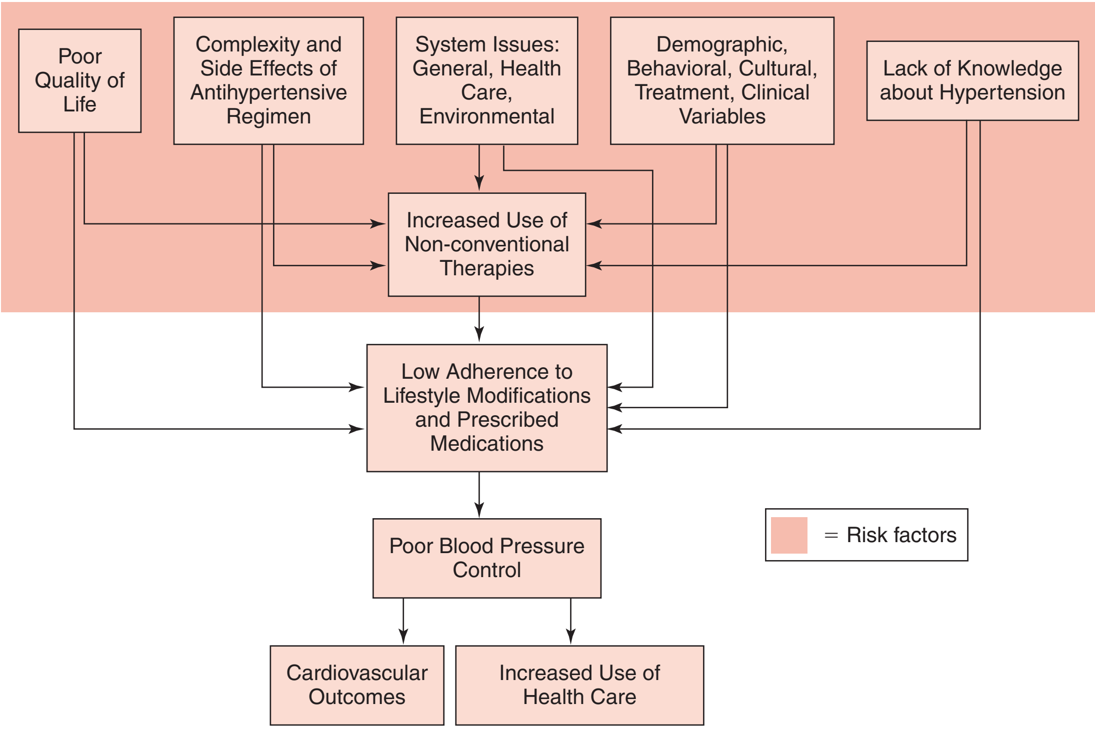

Figure 30–3 Factors associated with patient adherence to antihypertensive therapeutic regimens. (Modified from Krousel-Wood MA, Thomas S, Muntner P, et al: Medication adherence: A key factor in achieving blood pressure control and good clinical outcomes in hypertensive patients. Curr Opin Cardiol 2004;19:357-62.)

helpful: a system-driven, population-based strategy and a patient-driven, targeted strategy directed at those with overt hypertension. The system-driven, population-based approach strives to achieve a downward shift in the distribution of BP in the general population. Some examples of this approach include providing ready access to healthier lifestyle options for the general population by decreasing sodium content, saturated fat, or caloric density in processed foods, enriching foods with minerals such as potassium, and providing safe and convenient opportunities for exercise in schools and communities.[2,32]

The clinical encounter provides an opportunity to implement the targeted patient-driven approach. In this setting, providers have the chance to explore patient-specific barriers to adherence and tailor recommendations to the individual patient. Advice, per se, is not effective. One key to influencing lifestyle modification is assessing patients' readiness to change and matching the interaction to the patients' readiness to adopt healthy lifestyles.

Readiness for Change

Assessing a patient's readiness for change is based, in part, on stages of change introduced by Prochaska and Velicer.[37] Using these stages, patients are classified as "ready" to follow lifestyle recommendations as follows:

Precontemplation Stage	"I won't"
Contemplation Stage	"I might" in 6 months
Preparation Stage	"I will" in 30 days
Action Stage	"I am" in less than 6 months
Maintenance Stage	"I have" for 6 months or more

Drawing from motivational interviewing strategies,[38] the ALLHAT Dissemination Committee has suggested physicians use the acronym "PICM" in approaching patients regarding lifestyle recommendations: ***Permission***: ask the patient's permission to talk about lifestyle changes; ***Interest***: assess the patient's readiness for change—how interested is the patient in adopting lifestyle modifications on a scale of 1 to 10? (with higher score indicating greater interest); ***Confidence***: ask how sure the patient is that he or she can manage the behavior; ***Match:*** match the health care provider's message to the interest and confidence of the patient.[39] In the clinical setting, if a patient states that his or her interest level in adopting lifestyle changes is a 6, the physician should proceed in eliciting change statements, such as "You are a 6, why are you not a 2 or 3? What would it take for you to be a 7 or 8?" If a patient expresses low interest in changing behaviors, the physician should ask the patient, "Would you be willing to listen to me about why I want you to change?" If the patient expresses low confidence in his or her ability to adopt and maintain change, the physician should ask, "Would you be willing to monitor your activity or diet, think about a plan, and visit with me again about this?" In counseling a patient regarding lifestyle modification, it is important to remember that a patient's readiness for change for one behavior (e.g., reducing caloric intake) may not be the same for another behavior (e.g., increasing physical activity). Differences may also exist, depending on the behavior change desired, in patient readiness to change and interest in communicating with health care providers about the change. In Figure 30–4, readiness for change for physical activity and 3 dietary practices is shown for 59 adult minority patients from 1 of 3 community health centers.[40] In this study, readiness to change and

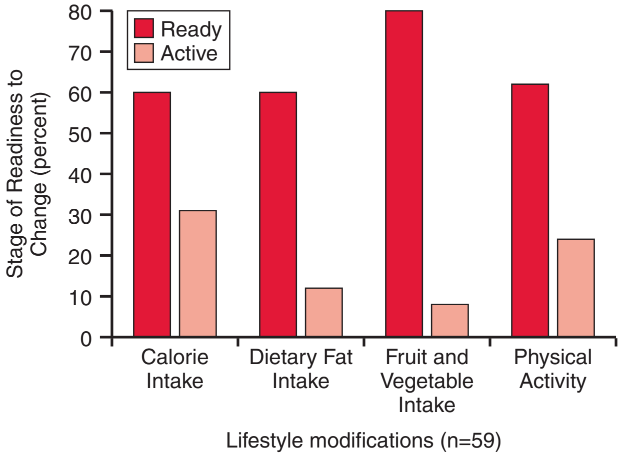

Figure 30–4 Stage of readiness by lifestyle modification. (Modified from Taylor WC, Hepworth JT, Lees E, et al: Readiness to change physical activity and dietary practices and willingness to consult healthcare providers. Health Res Policy Systems 2004;2:2.)

interest in talking to health care providers were separate dimensions. Readiness to change and interest in communicating with health care providers were significantly related for physical activity but not for dietary practices. Patients who were ready for change or actively engaged in physical activity were significantly more interested in discussing physical activity than those classified as not ready to increase physical activity ($P = 0.05$).[40] The goal, nevertheless, is to move patients along a continuum of change; movement toward readiness to change is a key step toward successful adoption of a healthier lifestyle.

Tips for Success in Adopting Healthier Dietary Practices

One way to boost a patient's interest and confidence in adopting healthier dietary practices is to provide simple guidelines for making better choices that can be easily integrated into his or her routine. Understanding the nutritional content of the food he or she eats is an important first step to choosing food that is lower in sodium, fat, and calorie content and higher in minerals, such as potassium and calcium. Reading labels on food products and relating the nutritional content to the lifestyle recommendations before purchasing the products assists adherence. Foods that are lower in sodium and fat are available; however, the patient should realize that the terms *reduced fat* and *fat free* are not synonymous, and neither are the terms *low sodium* and *sodium free* (Tables 30–5 and 30–6). In addition, patients should be aware of the serving size when they are looking for the caloric content of the foods they buy. For example, the calories per serving of most cereals are approximately 110; however, for cereal A the serving size is ¼ cup and for cereal B the serving size is 1 cup. The patient may be surprised that 1 cup of Cereal A for breakfast would result in his or her consuming 440 calories! Choosing snacks like fresh bananas, tomatoes, sweet potatoes, and leafy green vegetables, which are high in potassium, can increase adherence to the potassium supplementation recommendation.

Patients should be encouraged to switch from processed (e.g., canned foods, TV dinners) to unprocessed (e.g., fresh or fresh frozen) foods. Processing of food has a dramatic effect on dietary content of the mineral nutrients. For example, the sodium content of processed canned peas (23.6 mmol/100 g) is much higher than the corresponding content in fresh or fresh-frozen peas (0.1 mmol/100 g). In contrast, the potassium content in fresh or fresh-frozen peas (8.1 mmol/100 g) is much higher than the corresponding content in canned peas (2.5 mmol/100 g). A patient should keep a simple log of the foods and drinks that he or she has consumed over a time period. These logs provide valuable feedback to the patient and provide important information to the health care provider. For example, a patient may bring in a log of foods and drinks consumed over a 2-week period. From review of the information, it may be apparent that the patient drinks six 12-oz soda drinks (not diet drinks) per day. This information might prompt a conversation with the patient regarding the sugar and calorie content of the soda drinks and the benefits of switching to water or other lower-calorie beverages. Some patients may benefit from recording of a more detailed dietary log aimed at identification of the calorie, sodium, and potassium contents of the products.

For patients who are overweight or obese, several recommendations may assist them in their desire to reduce their dietary intake of calories. Patients can limit their consumption of fatty foods by reading labels and choosing fat-free, low-fat, and lower-calorie options. If the patients eat out frequently, modifications in the preparation of foods, such as switching from fried to grilled meats and asking for steamed vegetables in lieu of fried or baked potatoes, can be requested. Food and drinks with a high content of sugar should be avoided. Patients can reduce portion sizes gradually and resist the urge to "supersize" food orders. Fresh fruits and vegetables can be used to replace higher-calorie content snacks, such as chips and cookies. Patients seeking structured diets can adopt meal plans like the DASH diet plan (*http://www.nih.gov/news/pr/apr97/Dash.htm* (accessed September 13, 2006).

Table 30–5 Label Language for Fat

Fat-free	<0.5 g per serving
Low-saturated fat	≤1 g per serving
Low-fat	≤3 g per serving
Reduced-fat	At least 25% less fat than the regular version
Light in fat	One half the fat compared with the regular version

Table 30–6 Label Language for Sodium

Sodium-free	<5 mg per serving
Very-low-sodium	≤35 mg per serving
Low-sodium	≤140 mg per serving
Low-sodium meal	≤140 mg per 3½ oz serving
Light-sodium	At least 50% less sodium per serving than the regular version
Reduced- or less-sodium	At least 25% less sodium per serving than the regular version
Unsalted/no added salt	No salt added during processing

Tips for success in reducing the intake of dietary sodium are also available. Patients should be encouraged to buy fresh or fresh-frozen foods. In addition, patients should read food labels carefully and choose reduced-salt or no-salt-added options. Cured and pickled foods, as well as use of condiments, should be limited. Instead of using salt, patients can season their food with spices. If possible, the patient should avoid or at least limit the use of salt shakers. At restaurants, persons seeking to reduce sodium content should ask for food preparation modifications, such as having the sauce or salad dressing placed on the side of the serving plate.

Tips for Success in Increasing Physical Activity

Engaging in a regular exercise program may be the best way to increase to and maintain physical activity for at least 30 minutes most days (usually 5) of the week. Patients may want to use a home-based exercise videotape regularly for 30 minutes per day on at least 5 days per week, participate in a swimming program for 1½ hours per day on at least 4 days per week at their community recreational facility, plan to walk for 1 hour at least 3 days per week, or play tennis for 2 hours every other day. Patients who choose a plan that has realistic goals, fits into their schedules, and is appropriate for their budgets are more likely to adhere to the program. In addition to enrolling in a formal exercise program, there are many other practical approaches that can be incorporated into a person's daily routine: using the stairs instead of an elevator for going up or down one or two floors, parking further from the entrances of buildings to increase walking, and getting up to change the television channel instead of using the remote control.

General Tips for Adopting Healthier Lifestyles

Other tips for adopting healthier lifestyles include arranging for social support and a periodic review of progress with a knowledgeable counselor. Engaging a family member or friend in the effort to adopt a healthier lifestyle is often of great benefit. Counselors trained in behavior change techniques provide valuable insight into patient-specific strategies for lifestyle modification. As more individuals desire healthy dietary options and practical approaches for increasing physical activity, the demand and ultimately the supply of opportunities for the general population to achieve this goal increase. This creates continuous feedback between system-driven population approaches and patient-driven targeted approaches. Hopefully, as more people adopt healthier lifestyles, the demand and supply of affordable low-fat foods, low-carbohydrate options, and fresh/fresh-frozen fruits and vegetables for the general population will increase.

CONCLUSION

In this chapter we have discussed the initial evaluation and approach to the patient with hypertension. After completing the initial evaluation of the patient, decisions on the choice of therapy should be made. The JNC 7 algorithm may serve as a guide for most patients. For those who require pharmacologic treatment, we recommend first identifying any compelling indications (e.g., heart failure, post–myocardial infarction) that may drive the choice of the antihypertensive medication. If there is no compelling indication, then treatment is based on the stage of hypertension.

All patients should have the lifestyle modifications that are discussed in this chapter initiated and maintained. Lifestyle modifications, such as weight loss, increased physical activity, and dietary changes in individuals, have been shown to improve BP control. Timely adoption of these modifications can reduce complications of this disease and may interrupt the costly cycle of this prevalent chronic disease. As more patients integrate healthier choices into their daily routines, the more likely we will achieve better BP control rates overall, bringing us closer to the Healthy People 2010 goal.

Pharmacologic Treatment of Hypertension

Domenic A. Sica and Todd W. Gehr

CHAPTER CONTENTS

Once the decision is made to begin pharmacologic antihypertensive therapy, several questions arise: Is one drug class more or less appropriate than another in controlling blood pressure (BP) in different types of patients? How long should single-drug therapy continue before a switch to another therapeutic class is made or a second agent is added? Is nonpharmacologic therapy still indicated even when pharmacologic therapy has commenced? Can a patient ever safely discontinue antihypertensive medications and, if so, for how long?

The etiology of long-standing hypertension is generally multifactorial and poorly appreciated in the individual patient. Seldom does one class of drugs succeed in normalizing BP in more than 50% of patients.[1] Furthermore, the initial choice of a medication is often based on nonscientific grounds, anecdotal experience, personal preference, and sometimes intuition. A word-of-mouth approach to therapy sometimes surfaces from successful advertising or promotional efforts, or both, to health care providers and, more recently, patients.

Importantly, a significant proportion of patients who fail to achieve goal BP are suboptimally compliant.[2] Thus the issue of controlling BP is not as simple as choosing the correct first drug or combination of drugs. There is a critical need for a more sophisticated approach to medication-taking behavior on the part of patients with most chronic illnesses. The thoughtful clinician, concerned about optimizing outcomes for patients, brings focus, skills, and perseverance to the challenge of optimizing adherence to a prescription, as well as to the proper diagnosis and evaluation of the hypertensive condition. This chapter addresses many of these issues. Recommendations provided in this chapter should be tailored to a patient's age, gender, race, body habitus, and geographic location.[3]

GENERAL GUIDELINES

Risk Stratification and Treatment

Most current clinical guidelines focus primarily on the management of individual cardiovascular risk factors, such as high BP, hypercholesterolemia, or diabetes. A more appropriate clinical approach to reducing cardiovascular disease (CVD) risk would be based on an all-inclusive assessment of risk profile and accurate stratification of global (absolute) risk in individual patients. Global risk may be logically used as the main determinant of whom to treat, how to treat, and how much to treat. Thus, in some situations, low-risk patients with mildly elevated BP levels would not be recommended for antihypertensive drug treatment, whereas others at high risk but with lower BP would become candidates for treatment.[4] The global risk approach, however, is not consistent with that advanced by the Joint National Committee on Prevention, Evaluation, Diagnosis, and Treatment of Hypertension (JNC-7) and still requires formal testing.[5]

Home Blood Pressure Monitoring

Conventional office BP measurement yields higher BP values than home-based readings, particularly for systolic BP.[6-7] The level of home BP suggested to best correspond to a normal clinic BP of 140/90 mm Hg is approximately 135/85 mm Hg. Home BP monitoring provides a large number of readings and thus adds to the precision of BP determination in a given patient over time.[7-8] Home BP monitoring is useful for the long-term follow-up of patients with white coat hypertension (WCH) and the evaluation of treatment efficacy in patients with sustained hypertension.[7-9] Technical, economic, and behavioral barriers have impeded the widespread use of home monitoring in clinical practice. Two technologic developments, low-cost monitors with memory and systems for telephonic transmission of readings, are likely to overcome these barriers. Such technologic advances are important because many patients will omit or fabricate home readings[10]; thus, devices that have memory or printouts of the readings are recommended.

The number of clinic visits may be reduced with home BP monitoring, making it a potentially cost-effective means for the management of hypertensive patients. Studies have shown that adjustment of antihypertensive treatment based on home BP measurements instead of office BP readings leads to less-intensive drug treatment. Conversely, these studies show that home BP monitoring results in marginally lower costs and poorer BP control, together with no gain in general well-being or left ventricular mass regression.[9] Thus, home BP monitoring requires further validation, and exclusive reliance on self-monitored readings is not broadly recommended.

Comparison among Drugs

Efficacy in Group Trials

The practitioner's selection of a drug to treat hypertension is most often based on the perception of its efficacy in lowering BP and the likelihood of compliance-limiting side effects. In fact, efficacy does not differ meaningfully among the available drug classes.[11-12] Moreover, the recommended starting doses and the sustained release formulations of most drugs preclude BP from being lowered too much or too rapidly, thereby minimizing the risk of hypotension-related side effects. Most oral drugs are designed to lower BP by 10% to 15% in the majority of patients with stage 1 or 2 hypertension and to have similar efficacy. Multidrug comparator trials, such as the Treatment Of Mild Hypertension Study (TOMHS), in which five drugs (chlorthalidone, acebutolol, doxazosin, amlodipine, and enalapril) were compared, showed a BP-lowering response over 4 years that was nearly equal among the drugs tested.[12]

Despite comparable efficacy among classes of antihypertensive agents, individual patient responses may vary considerably, with some of the variability relating to patient-specific determinants, such as race and age. For example, in the Veterans Administration Cooperative Trial, 1292 patients were randomly administered drugs from one of six antihypertensive medication classes (atenolol, captopril, clonidine, diltiazem, prazosin, or hydrochlorothiazide [HCTZ]). The calcium channel blocker (CCB) diltiazem, the angiotensin-converting enzyme (ACE) inhibitor, captopril, and the β-blocker atenolol worked best in blacks, young white males, and older white males, respectively.[11]

The importance of capturing hard endpoint data for individual antihypertensive medications cannot be overemphasized. For example, an analysis of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) showed that despite effective BP reduction by both chlorthalidone and doxazosin, doxazosin use was followed by a two-fold higher CVD event rate, primarily in the form of more frequent episodes of heart failure (HF).[13]

The BP-reducing effect of an antihypertensive medication is important only to the extent that it marks decreases in morbidity and mortality rates. Such hard endpoint data are available for diuretics; ACE inhibitors; CCBs; and, to a lesser degree, β-blockers.[14-15] An overview of placebo-controlled trials of ACE inhibitors showed that with only a modest reduction in BP, these agents decreased the risk of stroke, coronary heart disease, and major CVD events by 20% to 30% among high-risk patients selected on the basis of CVD or diabetes mellitus.[14] A similar overview of placebo-controlled trials with CCBs showed that these agents reduced the risks of stroke and major CVD events by 30% to 40%. It has also been shown that total major CVD events are reduced to a comparable extent in individuals with and without diabetes by regimens based on ACE inhibitors, CCBs, angiotensin receptor blockers (ARBs), and diuretics/β-blockers; thus treatment with any commonly used regimen reduces the risk of total major CVD events, with larger reductions in BP producing larger reductions in risk.[15]

Need for 24-Hour Coverage

The best long-term outcome for hypertensive patients is seen when antihypertensive therapy effectively controls BP throughout a 24-hour cycle of treatment.[16-17] Home BP monitoring rather than office-based readings is necessary to gauge round-the-clock quality of BP control.[16] Drugs that work for 24 hours or longer are particularly attractive choices because they minimize the impact on BP in the 30% of patients who miss a dose of medication at least once weekly.[18] Several long-acting medications, such as the CCB amlodipine, the ACE inhibitor trandolapril, and the ARB candesartan, can maintain continued effect despite a missed medication dose.[19-20]

However, many antihypertensive drugs provide true 24-hour BP coverage only with twice-daily dosing. The failure of a compound to consistently reduce BP over 24 hours can relate to issues of drug half-life, biologic factors dictating whether a patient is a full or partial responder, drug formulation considerations, or a combination of these factors. Importantly, a failure to maintain full effect for 24 hours can be expected to expose the patient to the full brunt of the next day's early morning surge in BP and the attendant risk of an early morning ischemic event.[21]

The medication formulation administered is an important consideration in gaining BP control in the early morning, particularly when nighttime dosing is considered. Nighttime medication dosing should take into consideration two factors: First, does the peak effect of the medication coincide with the natural nocturnal dip in BP, potentially increasing the risk for nocturnal ischemic events?[22-23] Second, is sufficient drug effect still present on awakening to effectively combat the morning surge in BP? Traditional antihypertensive formulations will in most cases cover the morning surge in BP, but only at the expense of an excessive middle-of-the-night drop in BP. This issue can be resolved with new delayed and sustained-release compound technology, which provides peak drug levels to coincide with the morning BP surge, not with the sleep-related fall in BP.[24]

BLOOD PRESSURE GOALS AND THE J-CURVE

Vigorous treatment of BP, down to levels formerly considered harmful, is now suggested, particularly for patients with diabetes or renal disease. This approach has been challenged by studies that concluded that aggressive lowering of diastolic BP can trigger ischemic events rather than provide protection, particularly if critical arterial stenoses are present in the coronary circulation—the "J-curve" hypothesis.[25] Many examples of the J-curve relationship between BP and CVD/non-CVD events reflect reverse causality, where underlying disease (e.g., poor left ventricular function, poor general health, noncompliant arteries) is the basis for both the low BP and the increased risks of both CVD and non-CVD events.[26]

From the Hypertension Optimal Treatment (HOT) study data base, it is reasonable to conclude that for nonischemic hypertensive subjects, lowering diastolic BP to the low 80s mm Hg is both safe and of therapeutic benefit, particularly in diabetic patients. In the HOT study, however, it is unclear whether lowering diastolic BP to below 80 mm Hg was safe or beneficial, or both.[27] In the presence of limited coronary flow reserve, as is seen in coronary artery disease, there is a J-curve relationship between treated diastolic BP and myocardial infarction, but not for stroke.[28-29] Also, a wide pretreatment pulse pressure augurs an increased propensity for CVD

sequelae of hypertension, which can be made more obvious by treatment.[30-31] In such myocardial infarction–prone cases it would be sensible not to bring diastolic BP below the low 80s mm Hg. Practically speaking, if systolic BP is controlled to less than 130 mm Hg, there is marginal benefit, and even the potential for risk, in reducing diastolic BP to less than 80 to 85 mm Hg.

Need to Lower Blood Pressure Gradually

Experts often recommend that BP be brought to goal gradually to avoid sudden and perhaps excessive reductions in cerebral or coronary blood flow. The rate of BP reduction is seldom a problem in the young hypertensive patient, but in the older patient with long-standing hypertension, rapid BP reduction may be poorly tolerated because of diminished cerebral or coronary artery autoregulatory ability.[25,29] If BP drops below the autoregulatory range, symptoms of cerebral hypoperfusion, such as dizziness, fatigue, and forgetfulness, may arise. This is particularly the case in the elderly hypertensive patient, in whom the normal limits of cerebral autoregulation fall around a mean value of 100 to 110 mm Hg. Concern about an "excessive" BP drop in the elderly or the otherwise vulnerable patient should not, however, preclude attempting to reach recommended BP goals within a relatively short time (weeks rather than months) because achieving rapid BP control offers significant benefits to the hypertensive patient who is at high cardiovascular risk.[32]

Choice of Drugs

Many drug options are available for the pharmacologic management of hypertension. The current approach, recommended by JNC 7, suggests that a thiazide-type diuretic be the first medication used in most stage 1 hypertensives but that an ACE inhibitor, an ARB, β-blocker, and CCB are acceptable alternatives.[5] The choice of a starting antihypertensive should be based on the characteristics of the patient—in particular, the presence of concomitant diseases.

The individual characteristics of a patient may influence his or her BP response.[11] An older, overweight black man will likely respond better to diuretic or CCB monotherapy than to a β-blocker or an ACE inhibitor. In general, hypertensive blacks respond better to diuretics or CCBs than to β-blockers, ACE inhibitors, or ARBs. The elderly respond equally well to most drug classes, with the possible exception of β-blockers.[33-35] Women and men respond equally well to most medication classes with the possible exception of CCBs, which produce greater BP reductions in women than men.

The presence of concomitant medical conditions bears on the manner in which hypertension is treated. For example, a hypertensive patient with angina may benefit doubly from either a β-blocker or a CCB. Further, both of these classes may be useful as headache prophylaxis in hypertensive patients with migraines. A logical choice in an elderly male with benign prostatic hyperplasia (BPH) and difficult-to-treat hypertension would be an α-blocker because α-blockers lessen BPH symptomatology and are valuable add-on drugs to multidrug antihypertensive regimens. An ACE inhibitor or ARB would be a suitable choice in a hypertensive patient with heart failure (HF) or proteinuria because these agents reduce the morbidity and mortality rates of HF, as well as urinary protein excretion and the progression of chronic kidney disease (CKD).[36] Conversely, antihypertensive medications may have adverse effects on concomitant conditions (e.g., ACE inhibitors or ARBs in patients with high-grade bilateral renal artery stenosis, high-dose thiazide or loop diuretics in patients with gout).

A stepped-care approach to the treatment of hypertension involves the sequential addition of medications until BP is normalized. The stepped-care approach has heretofore been based mainly on initiating therapy with either a diuretic or a β-blocker. Of late, β-blocker monotherapy has fallen out of favor.[35] ACE inhibitors, ARBs, or CCBs are now viewed as acceptable first-step therapy options. Substitution therapy involves the replacement of one antihypertensive drug class with another and is most appropriate if the drug class first chosen either does not lower BP or is associated with serious or bothersome adverse effects.

A substitution approach to therapy is best applied to stage 1 hypertension because a single drug may often be sufficient for BP control. In stage 2 hypertension, multidrug therapy is more frequently necessary. In this situation, even if the first drug selected is only partially successful in reducing BP, there is no need to substitute another drug. Rather, the stepwise addition of a second or a third medication to the treatment regimen is indicated because the relative ineffectiveness of a first drug can be compensated for by the addition of a suitable second drug. A proper second drug typically is one that has an additive antihypertensive effect to the first drug chosen or reduces the adverse effects of the first drug, or both. To this end, various guidelines—such as JNC 7—now advocate starting two different antihypertensive medications simultaneously if BP is 20/10 mm Hg above goal.[5]

DRUG CLASSES: POSITIONING AND USE

Diuretics: First or Second Line

Thiazide-type diuretics are important primary and adjunctive therapies in the treatment of hypertension. They are useful when administered, even in doses as low as 6.25 mg of HCTZ, in the form of fixed-dose combination therapy.[37] Diuretics are widely promoted for the control of hypertension because they have been shown in numerous controlled clinical trials to decrease hypertension-associated morbidity and mortality rates.[38-39] Diuretics have been recommended as initial treatment in each of the seven reports (1977 to 2003) of the JNC of the National High Blood Pressure Education Program.[5]

The effect of a thiazide diuretic on BP may be divided into three sequential phases: acute, subacute, and chronic, which correspond to periods of 1 to 2 weeks, several weeks, and several months, respectively. In the "acute" response phase, the BP lowering effect of a diuretic is coupled with a reduction in extracellular fluid (ECF) volume and a corresponding fall in cardiac output. The early response (first 2 to 4 days of treatment) to a thiazide-type diuretic, in the setting of a "no-salt-added" diet (100 to 150 mmol/day), results in a net Na^+ loss of 100 to 300 mmol, which translates into a 1 to 2 L decrease in ECF volume, which comes in similar proportions from the intravascular and interstitial compartments. This change in plasma volume can stimulate both the sympathetic nervous and renin-angiotensin-aldosterone (RAA) systems.[40-41]

Later in the course of treatment, thiazide diuretic effects on volume and cardiac output lessen in importance, although BP remains lowered. During the *subacute* phase of the treatment response (first few weeks), plasma volume returns to slightly less than pretreatment levels, despite the continued administration of the diuretic. The *subacute* response phase is a transitional period during which both volume and resistance factors contribute to the BP reduction. The chronic vasodepressor effect of thiazide-type diuretics is more closely related to a persistent reduction in total peripheral resistance than to volume reduction.[42] This process is not so well characterized for loop diuretics. In general, loop diuretics do not reduce BP as well as thiazide-type compounds when given as single-drug therapy, particularly when dosed once a day. Loop diuretics find their greatest use as antihypertensive agents when they can normalize clearly defined, volume-expanded states (Tables 31–1 and 31–2).[43]

The dose-response relationship for BP reduction with a thiazide-type diuretic, such as HCTZ, is flat at doses greater than 25 mg/day.[38,44] Much of the negative biochemical and metabolic experience with diuretics was related to the high doses (100 to 200 mg/day of HCTZ) that were once the therapeutic norm. Metabolically negative side effects, such as hypokalemia, hypomagnesemia, glucose intolerance, and hypercholesterolemia, are uncommon with low-dose diuretic therapy (e.g., 12.5 to 25 mg HCTZ once daily).[39]

The strong evidence that diuretics are effective in preventing target organ damage and CVD outcomes, combined with their excellent tolerability at low doses, supports their use as initial therapy for persons with stage 1 or 2 hypertension and no evidence of target organ damage.[39] Early studies, in which high-dose diuretic therapy was used, showed a lowering of stroke risk but minimal protection from coronary artery disease, perhaps as a consequence of metabolic abnormalities produced by high-dose diuretic therapy. In contrast, low-dose diuretic therapy has been shown to reduce coronary heart disease risk.[45]

In the stage 1 hypertensive, thiazide diuretics lower BP to an extent comparable with most other classes of drugs.[11] Blacks and the elderly typically respond well to diuretics, but not necessarily better than nonblacks or younger patients. Supporting data for the use of diuretic therapy in the elderly are available from the Systolic Hypertension in the Elderly Program (SHEP)[46] and in blacks from the ALLHAT.[47] In SHEP, the diuretic chlorthalidone controlled BP more effectively than did the β-blocker atenolol[46]; likewise, in ALLHAT a chlorthalidone-based treatment regimen effectively controlled BP in hypertensive blacks.[47] Salt-sensitive forms of hypertension, as in the patient with diabetes or renal impairment, or both, may be particularly responsive to diuretic-based regimens. Diuretics are extremely useful adjunctive therapy in situations in which nondiuretic antihypertensive therapy has led to expansion of extracellular volume.

Aldosterone Receptor Antagonists—Second Line

The aldosterone receptor antagonist (ARA) spironolactone contains elements of the progesterone molecule, and its use can be accompanied by progestogenic and antiandrogenic adverse effects, such as painful gynecomastia and other sexual side effects. Eplerenone has a much lower affinity for progesterone and androgen receptors, resulting in a several-fold decrease in progestogenic and antiandrogenic adverse effects.

The onset of action for spironolactone is characteristically slow, with a peak response at 48 hours or more after the first dose. This may relate to a requirement for several days of spironolactone dosing in order for its active metabolites to reach steady-state plasma/tissue levels. Unlike spironolactone, no active metabolites have been identified for eplerenone. The duration of the natriuretic and antikaliuretic effects of spironolactone may differ: The antikaliuretic effect persists for several days after discontinuation of spironolactone, differentiating spironolactone from the shorter-acting ARA eplerenone.[48]

The most extensive antihypertensive treatment experience with ARAs is with spironolactone. Spironolactone has been used with or without a thiazide-type diuretic in the treatment

Table 31–1 Pharmacology of Diuretics

Classes Available
Thiazide diuretics (hydrochlorothiazide)
Thiazide-type (chlorthalidone, indapamide)
Loop diuretics (furosemide, bumetanide, torsemide)
Potassium-sparing diuretics (triamterene, amiloride, spironolactone, eplerenone)

Mode of Action
Early natriuresis and reduction in cardiac output
Long-term decrease in peripheral vascular resistance
Majority of antihypertensive effect at low doses (e.g., ≤25 mg hydrochlorothiazide)
Blockade of aldosterone receptor (spironolactone) and epithelial sodium channel (amiloride and triamterene)

Indications/Considerations in Use
Thiazide-type diuretics are first-line therapy. Loop diuretics are effective antihypertensives when they can specifically correct extracellular fluid volume expansion.
Volume-expanded forms of hypertension not marked by edema.
Salt-sensitive forms of hypertension.
Aldosterone-receptor antagonists are useful in treatment-resistant forms of hypertension.

Contraindications
Prior anaphylactic or Stevens-Johnson–type reactions, or both, to sulfa-type drugs preclude use of sulfa-type diuretics. Less extreme reactions are not an absolute contraindication.

Side Effects
Typically dose dependent
Short-term increase in cholesterol
Increase in new-onset diabetes
Hypokalemia, hypomagnesemia, hyponatremia (mainly with thiazide diuretics)
Hyperkalemia (all potassium-sparing diuretics), gynecomastia (spironolactone)
Hypocalcemia (loop diuretics), hypercalcemia (thiazide diuretics), hyperuricemia
Impotence

Table 31–2 Doses of Diuretics

Drug	Brand Name	Total Dose Range (mg) (frequency/d)	Comment
Chlorthalidone	Hygroton	12.5-50 (1)	More prolonged effect than hydrochlorothiazide.
Hydrochlorothiazide	HydroDIURIL Microzide	12.5-50 (1)	
Indapamide	Lozol	1.25-5.0 (1)	
Metolazone	Mykrox	0.5-1.0 (1)	Improved bioavailability for Mykrox compared with Zaroxolyn; thus the lower dose given. Zaroxolyn remains effective at a GFR < 30 mL/min.
	Zaroxolyn	2.5-10 (1)	
Loop Diuretics			
Bumetanide	Bumex	0.5-4.0 (2-3)	Same as furosemide.
Furosemide	Lasix	40-240 (2-3)	Shorter duration of action; multiple daily dosing to avoid rebound sodium retention. Erratic absorption.
Torsemide	Demadex	5-100 (1-2)	Long duration of action and predictable bioavailability.
Ethacrynic acid	Edecrin	25-100 (2-3)	Only nonsulfonamide diuretic, ototoxicity.
Potassium Sparing			
Amiloride	Midamor	5-10 (1-2)	Hyperkalemia.
Eplerenone	Inspra	50-100 (1-2)	Metabolized by CYP3A4—levels increase with coadministration of verapamil or diltiazem.
Spironolactone	Aldactone	25-100 (1-2)	Dose-dependent gynecomastia, long half-life, hyperkalemia, mg-for-mg more potent than eplerenone.
Triamterene	Dyrenium	25-100 (1-2)	Hyperkalemia.

of essential hypertension and more recently as add-on therapy in the setting of resistant hypertension.[49] Of note, the mg-for-mg BP lowering effect of eplerenone is less than that of spironolactone. The magnitude of the BP reduction with 50-mg of spironolactone twice daily is 1.3 to 2.0 times greater than that seen with eplerenone 50-mg twice daily (or 100-mg once daily).[50]

This add-on effect of spironolactone occurs within weeks, persists for months, and is independent of ethnicity and urinary aldosterone excretion rate. When spironolactone (12.5 to 50 mg/day) was added to a regimen of a diuretic, an ACE inhibitor, or an ARB, a mean decrease in BP of 21 ± 20 mm Hg/10 ± 14 mm Hg and 25 ± 20 mm Hg/12 ± 12 mm Hg was observed at 6 weeks and 6 months of therapy, respectively. The benefit of aldosterone blockade in the general population of patients with resistant hypertension suggests that aldosterone excess may be a more common cause of resistant hypertension than was first believed.[49]

The most common side effect of spironolactone is breast related. Breast symptoms are dose dependent and can include an increase in size (occasionally unilateral); the development of nipple or breast tenderness, or both; the appearance of discrete breast masses; or a combination. Gynecomastia generally corrects on discontinuation of the drug; however, the time required for reversibility can be prolonged, particularly if significant gynecomastia is present. Gynecomastia occurs much less frequently with eplerenone, and eplerenone can be safely substituted for spironolactone in the patient with gynecomastia.[51] Hyperkalemia (>5.5 mEq/L) can occur with ARAs when used in the treatment of resistant hypertension and occurs most typically when ARAs are administered in the setting of either a reduced glomerular filtration rate (GFR) and/or conjoint therapy with an ACE inhibitor or ARB.[48]

β-Blockers: Second or Third Line

The efficacy and side effect profiles of β-blockers are both compound specific and delivery system dependent.[52] β-Blockers have relatively flat dose-response curves for BP reduction and reduce BP without decreasing peripheral vascular resistance.[53] β_1-Cardioselective agents have some advantages, particularly at low doses. One such benefit is a reduced risk of paradoxic pressor effects during major stresses compared with nonselective β-blockade.[54] Nonselective β-blockade may be preferred if certain concomitant illnesses, such as essential tremor or migraine, are present in a hypertensive patient (Tables 31–3 and 31–4).

Over the past decade, national and international guidelines have proposed that β-blockers be used on an equal footing with diuretics for initial therapy of hypertension. This preferred status was based on evidence documenting a reduction in morbidity and mortality rates with β-blocker therapy in hypertension; however, current review of these data find little evidence that β-blocker–based therapy, despite lowering BP, reduces the risk of heart attacks or strokes.[34-35] Moreover, these agents have limited usefulness as monotherapy in a

Table 31–3 Pharmacology of β-Adrenergic-Blocking Drugs

Available Compounds
Noncardioselective (propranolol, nadolol)
Cardioselective (acebutolol, atenolol, betaxolol, bisoprolol, metoprolol)
Intrinsic sympathomimetic activity (acebutolol, pindolol)
Short acting (esmolol)
Combined α- and β-blockers (carvedilol and labetalol)*
Mode of Action
Reduction in cardiac output and heart rate
Little to no change in peripheral vascular resistance
Inhibition of renin release
Direct central nervous system effect
Alteration in catecholamine release or response
Indications/Considerations in Use
Pulse rate-dependent forms of hypertension
Hypertensive persons with symptomatic coronary artery disease
Second-line therapy in congestive heart failure
Essential tremor and headache prophylaxis
Contraindications
Bronchospastic pulmonary disease
Decompensated congestive heart failure
Heart block, sick sinus syndrome
Insulin-dependent diabetes mellitus—cautious use
Side Effects
Bronchospasm
Heart block
Worsening of congestive heart failure
Increased triglyceride and/or decreased high-density lipoprotein levels
Masking of most hypoglycemic symptoms in diabetes mellitus
Depression or nightmares, or both

*Combined α- and β-blockers are also discussed in Table 31–13.

number of patient subsets that include blacks, the elderly, and diabetic patients. Hence, β-blockers should no longer be considered as suitable first-step therapy in the treatment of hypertension.[34-35]

β-Blocker use should be reserved for select circumstances.[55-56] First-step β-blocker therapy is particularly useful for patients with a hyperkinetic form of hypertension, as in individuals with a high cardiac awareness profile or somatic manifestations of anxiety, such as tremor, sweating, and tachycardia.[38] β-Blockers are useful as add-on therapy in hypertensive subjects with tachycardic responses to drugs, such as dihydropyridine CCBs, or vasodilators, such as hydralazine or minoxidil.[57] β-Blockers also have important roles in the treatment of angina pectoris,[58-59] HF with systolic dysfunction,[60] the post–myocardial infarction patient,[61] and diastolic dysfunction (see Chapter 34). When used for secondary prevention in patients after an acute myocardial infarction, the greatest protection has been observed with cardioselective, lipid-soluble agents without intrinsic sympathomimetic activity (ISA). Perioperative hypertension also may be treated with β-blocker therapy.[62]

β-Blocker use for hypertension has been on the decline over the past several years due to the perception that β-blockers are associated with frequent adverse effects. However, these adverse effects are not nearly as troubling as once was believed, particularly if doses are kept within reasonable boundaries. Escalating doses of β-blockers can induce salt and water retention, making diuretics a needed adjunctive form of therapy.[37] Abrupt discontinuation of a β-blocker, particularly when administered in high doses, may be followed by adrenergically mediated withdrawal symptoms.[63] Therefore a stepwise reduction in dose is advised. β-Blockers administered with either verapamil or diltiazem can cause sharp reductions in heart rate; this combination should be used with caution.

Angiotensin-Converting Enzyme Inhibitors: First or Second Line

ACE inhibitors are considered a suitable first-step option in the treatment of hypertension in a diversity of patient types. Enthusiasm for the use of ACE inhibitors extends beyond their effects on BP because they are at best comparable with other drug classes including diuretics, β-blockers, and CCBs for both BP control and most outcome benefits in both diabetic and nondiabetic hypertensives. Response rates with ACE inhibitors range from 40% to 70% in stage 1 or 2 hypertension, with level of sodium intake and ethnicity influencing the overall effect. In the interpretation of clinical trial results with ACE inhibitors, a distinction should be made between the mean reduction in BP (which is typically significant) and the percentage of individuals who are poor, average, or excellent responders (which may vary considerably among studies).[36,64]

The BP-lowering response to ACE inhibition is inconsistently predicted by such markers as ACE gene polymorphism and pretreatment or post-treatment plasma renin activity (PRA) (used as markers of renin-angiotensin axis [RAA] activity), or both. However, when hypertension is marked by significant RAA activation, as in renal artery stenosis, the initial BP response to an ACE inhibitor can be large.[36,64]

ACE inhibitors are generally ineffective as monotherapy in salt-sensitive, low-renin forms of hypertension (e.g., black and diabetic hypertensive persons) unless administered in higher-than-usual doses.[65] However, BP responses to ACE inhibition are so variable that some individuals in these groups experience significant reductions in BP with ACE inhibitor treatment. Further, even those who do not manifest robust BP responses to ACE inhibitors should not be denied the "beyond BP" benefits of this drug class.[66] The low-renin state, characteristic of the elderly hypertensive, differs from other low-renin forms of hypertension in that it reflects senescence-related changes in the RAA axis and not volume expansion. The elderly generally respond well to ACE inhibitors at usual doses,[67] although senescence-related renal failure, which reduces the elimination of most ACE inhibitors, complicates analysis of dose-specific treatment results.[68]

ACE inhibitors show a steep dose-response curve for BP reduction at low doses; thereafter, the dose-response relationship typically flattens. ACE inhibitor use is not accompanied by salt and water retention or increased heart rate. Multiple-dose titrations of an ACE inhibitor are seldom warranted except in HF. In salt-sensitive forms of hypertension, the

Table 31–4 Doses of β-Adrenergic-Blocking Drugs

Drug	Brand Name	Total Dose Range (mg) (frequency/d)	Comment	Fixed-Dose Combination
Acebutolol	Sectral	200-800 (1)	Cardioselective, intrinsic sympathomimetic activity	
Atenolol	Tenormin	25-100 (1)	Cardioselective	Tenoretic
Betaxolol	Kerlone	10-20 (1)	Cardioselective	
Bisoprolol	Zebeta	2.5-20 (1)	Cardioselective, indicated as first-step therapy as combination product	Ziac
Carteolol	Cartrol	2.5-10 (1)		
Carvedilol	Coreg	3.125-25 (1-2)	Combined α- and β-blocker, postural hypotension	
Esmolol	Brevibloc		Short-acting IV form	
Labetalol	Normodyne Trandate	100-400 (2)	Combined α- and β-blocker	
Metoprolol	Lopressor Toprol XL	25-200 (1, 2)	Cardioselective, long-acting preparation available	
Nadolol	Corgard	40-320 (1)		Corzide
Penbutolol	Levatol	10-20 (1)		
Pindolol	Visken	5-15 (2)	Intrinsic sympathomimetic activity	
Propranolol	Inderal Inderal-LA	10-240 (1-2)	Long-acting preparation available	Inderide
Timolol	Blocadren	20-60 (2)		Timolide

addition of a diuretic either as sequential therapy or in the form of fixed-dose combination therapy increases the effectiveness of ACE inhibitors (Tables 31–5 and 31–6).[37]

Results from head-to-head comparison trials support the comparable antihypertensive efficacy and tolerability of the various ACE inhibitors at equivalent doses. However, there are differences among the ACE inhibitors, in time to onset and duration of effect, which may relate to their absorption and tissue distribution characteristics.[36,64] Multiple options exist for orally available ACE inhibitors, but enalaprilat is the lone ACE inhibitor available in an IV form.

ACE inhibitors labeled as “once daily” differ in their capacity to decrease BP for a full 24 hours, as defined by a trough-to-peak ratio >50%, with many patients requiring a second daily ACE inhibitor dose to maintain effect.[19,69] Consequently, the dosing frequency for an ACE inhibitor should take into consideration the highly individualized response patterns to these drugs. Also, ACE inhibitor responses are linked to a patient’s volume state. Thus when intentional volume losses occur (diuretic therapy) or unintended changes in volume occur (sweating/exercise), or both, major decreases in BP can arise.

The rationale for combining a diuretic with an ACE inhibitor is that diuretic-induced sodium depletion activates the RAA system and moves BP to an angiotensin II–dependent mode.[37] Even minimally natriuretic doses (12.5 mg/day) of thiazide-type diuretics reduce BP when given with an ACE inhibitor.[37] A β-blocker can also be given together with an ACE inhibitor, although the incremental effect on BP lowering is minor. β-blockade in this combination blunts the reactive rise in PRA that follows from ACE inhibition. Adding a peripheral α-antagonist, such as doxazosin, to an ACE inhibitor can further reduce BP, albeit with an uncertain mechanistic basis. The BP-lowering effect of an ACE inhibitor is also significantly enhanced with the addition of either a dihydropyridine or a non-dihydropyridine-type CCB.[64,69-70]

ACE inhibitors confer significant benefit to the morbidity and mortality rates in randomized controlled clinical trials in patients with HF[60,71] or progressive renal disease.[72] Thus ACE inhibitors are preferred in the treatment of concomitant illnesses, such as HF, left ventricular hypertrophy (LVH), proteinuric renal failure, and myocardial infarction associated with systolic dysfunction.[60,72,73] ACE inhibitors can restore endothelial function in the patient with endothelial dysfunction and can remodel blood vessels and, in the process, improve vascular compliance.[74] The BP-lowering effect or tissue protection afforded by ACE inhibitor therapy, or both, may be attenuated by the coadministration of aspirin, although the degree of this interaction remains a controversial issue.[75]

Side effects associated with ACE inhibitors include cough, angioedema, and a distinctive form of functional renal insufficiency.[76] Once cough or angioedema has occurred with an ACE inhibitor, there is no advantage to switching to an alternative ACE inhibitor because these are *class effect* phenomena.[77,78] The occurrence of functional renal insufficiency with an ACE inhibitor does not preclude a patient from future ACE inhibitor therapy unless high-grade bilateral renal artery stenosis is present. Although initiation of ACE inhibitor therapy often reduces GFR, these drugs are not intrinsically nephrotoxic (see Chapter 35). No specific level of renal function precludes their use unless clinically relevant hyperkalemia occurs.[79]

Angiotensin Receptor Blockers: First or Second Line

ARBs are suitable first-step options in a diversity of hypertensive phenotypes. As with ACE inhibitors, enthusiasm for the use of ARBs goes beyond their effects on BP because drugs in this class are at best comparable with diuretics, β-blockers,

Table 31–5 Pharmacology of Angiotensin-Converting Enzyme Inhibitors

Available Compounds
Sulfhydryl containing (captopril), phosphinyl containing (fosinopril), and carboxyl containing (all others)
Renally and nonrenally cleared (fosinopril, trandolapril); highly tissue bound (perindopril, quinapril, ramipril, trandolapril)
IV form (enalaprilat)
Information to support the concept of a "preferred" ACE inhibitor based on tissue binding characteristics is inadequate

Mode of Action
Indirect arterial vasodilation by decreasing angiotensin II–related vasoconstriction or vasodilation secondary to an increase in bradykinin, or both
Decreased sympathetic nervous system activity and variably lowered aldosterone concentrations
Decrease in vasoconstrictor substances, such as endothelin or improvement in endothelial dysfunction, or both
Increase in concentrations of the vasodilator peptide angiotensin (1-7)
Absence of a compensatory tachycardia or antinatriuresis with BP reduction

Indications/Considerations in Use
Initial monotherapy of patients with a variety of comorbid conditions accompanying hypertension, such as heart failure or diabetic nephropathy
Enhanced response with addition of a diuretic or a calcium channel blocker
Hypertensive blacks as a group, but not necessarily on an individual patient basis, respond less well
Patients requiring multidrug therapy with otherwise resistant hypertension, such as a diabetic patient or patient with renal failure or unilateral renal artery stenosis
Hypertensive patient with metabolic abnormalities including insulin resistance

Contraindications
Angioedema
Second and third trimesters of pregnancy
Bilateral renal artery stenosis or stenosis in a solitary kidney

Side Effects
First-dose hypotension, particularly if volume contracted
Cough
Angioedema
Functional renal insufficiency—typically requires at least temporary drug stoppage
Small changes in serum creatinine (e.g., a 20% ↑) can occur as a normal response in patients with renal failure; therapy need not be stopped
Increase in serum potassium
Developmental defects in newborns if given in the second or third trimester
Taste disturbances and rash with captopril
Occasional hypoglycemia, particularly with captopril
Anemia secondary to alterations in erythropoietin amount or effect

ACE inhibitors, and calcium channel blockers (CCBs) for BP control and reduction in outcomes. Support for this drug class resides in its ability to prevent new-onset diabetes in at-risk patients[80] and improve renal outcomes beyond what might be expected from BP reduction alone.[81-83] Whether ARB therapy reduces cardiac outcomes in high-risk coronary artery disease patients in a "beyond-the-numbers" fashion is unclear.[84-85]

The pharmacology of the various ARBs including their bioavailability, rate of absorption, volume of distribution, and metabolism (CYP450 or not) has been a matter of considerable discussion. However, for the most part, pharmacologic differences between members of this class are of little practical consequence.[86] All ARBs are eliminated through some combination of renal and hepatic clearance. This distinguishes the ARBs from ACE inhibitors, which are predominantly renally cleared.[87] Duration of receptor occupancy, a surrogate for the BP-lowering effect of drugs in this class, is probably only relevant when low-end doses of ARBs are used. At high-end doses, the impact of drug-specific differences in receptor occupancy or elimination half-life, or both, is reduced.[88]

ARBs are pulse-rate neutral and do not promote salt and water retention or sympathetic nervous system activation. They have a steep dose-response curve for BP reduction at low- to mid-range doses; thereafter, the dose-response relationship is shallow, obviating multiple dose-titration steps. Increasing the dose of an ARB typically does not increase its peak effect; rather, it prolongs the response (Tables 31–7 and 31–8).

Current starting doses of many ARBs (as recommended by package inserts) do not sustain maximal blockade of angiotensin-II effect for a 24-hour dose interval. Thus, it is desirable to start ARB therapy at "higher" doses. However, most health care providers prescribe antihypertensive medications including ARBs at low starting doses and frequently fail to uptitrate appropriately. Head-to-head studies comparing different ARBs at these recommended low-end starting doses can be difficult to interpret when full dose-ranging comparisons have not been undertaken and may unfairly favor one drug in the class over another.[89] Little separates one ARB from another with the exception of losartan, which does not reduce BP as effectively as longer-acting ARBs, such as candesartan, but does have a mild uricosuric effect of uncertain clinical significance.[86] The Food and Drug Administration views the difference between the BP-lowering effects of candesartan and losartan (systolic and diastolic BP 2 to 3 mm Hg lower with 32 mg of candesartan versus 100 mg of losartan) as being sufficient to be cited in the package insert for candesartan.[90]

Response rates with ARBs range from approximately 40% to 70% in stage 1 or 2 hypertension, with sodium intake and ethnicity having some bearing on the overall effect. No reliable predictors of the magnitude of BP reduction in response to an ARB are available. Certain patient groups are recognized as being generally more responsive (high-renin and young hypertensives) or less responsive (low-renin, salt-sensitive, volume-expanded individuals, such as the diabetic and the black hypertensive) to ARB monotherapy. However, the BP response to ARB monotherapy can be highly variable in black and diabetic patients, with some individuals in these groups experiencing significant reductions.[66]

Most ARBs are indicated for once-daily dosing but may occasionally lose efficacy at the end of a dose interval, thereby

Table 31–6 ACE Inhibitors: Dosage Strengths and Treatment Guidelines

Drug	Trade Name	Usual Total Dose and/or Range for Hypertension (Frequency/d)	Usual Total Dose and/or Range for Heart Failure (Frequency/d)	Fixed-Dose Combination*
Benazepril	Lotensin	20-40 (1)	Not FDA approved for heart failure	Lotensin HCT Lotrel
Captopril	Capoten	12.5-100 (2-3)	18.75-150 (3)	Capozide **
Enalapril	Vasotec	5-40 (1-2)	5-40 (2)	Vaseretic
Fosinopril	Monopril	10-40 (1)	10-40 (1)	Monopril-HCT
Lisinopril	Prinivil, Zestril	2.5-40 (1)	5-20 (1)	Prinzide, Zestoretic
Moexipril	Univasc	7.5-30 (1)	Not FDA approved for heart failure	Uniretic
Perindopril	Aceon	2-16 (1)	Not FDA approved for heart failure	
Quinapril	Accupril	5-80 (1)	10-40 (1-2)	Accuretic
Ramipril	Altace	2.5-20 (1)	10 (2)	
Trandolapril	Mavik	1-8 (1)	1-4 (1)	Tarka

*These fixed-dose combinations typically contain a thiazide-like diuretic except for Lotrel, which contains the calcium channel blocker amlodipine, and Tarka, which contains the calcium channel blocker verapamil.
**Capozide is indicated for first-step treatment of hypertension.
FDA = Food and Drug Administration.

necessitating twice-daily dosing. The effectiveness of an ARB can be improved with the addition of a diuretic given either as sequential therapy or as fixed-dose combination therapy. On the basis of experience with ACE inhibitors, it can be expected that addition of a β-blocker to an ARB would have a minimal additional effect on BP unless a significant decrease in pulse-rate occurs with the β-blockade. Alternatively, adding a peripheral α-antagonist, a CCB, or an aldosterone receptor antagonist to an ARB (with or without a diuretic) is likely to lead to a significant additional reduction in BP.[89] ACE inhibitors and ARBs can be administered together, although only a modest additional BP reduction can be expected.[91] In the patient with CHF or proteinuria, additional benefits including a reduction in proteinuria and an improvement in CHF symptomatology are derived from such combination therapy.[92-93]

ARBs have been studied in a number of randomized controlled clinical trials in patients with HF and progressive renal disease.[81,92] These trials have documented BP-independent benefits of ARBs for patients with LVH, HF, and proteinuric renal disease. Of note, in these trials, ARBs have been combined with diuretics and most of the patients have been on combination therapy including 2 to 4 antihypertensive agents. Whether ARBs prevent acute vascular events, such as myocardial infarction, is less clear.[94]

Side effects are uncommon with ARBs. Cough does not occur with ARBs, and angioedema is rare.[95] The occurrence of functional renal insufficiency with an ACE inhibitor does not preclude future therapy with an ARB, unless high-grade bilateral renal artery stenosis exists. ARBs may be used safely in patients with CKD. Hyperkalemia appears to be less common with ARBs than with ACE inhibitors in these patients.[96]

Calcium Channel Blockers: First or Second Line

Calcium channel blockers (CCBs) encompass a heterogeneous group of compounds, with distinctive structures and pharmacologic characteristics. CCBs fall into two major classes: dihydropyridines and nondihydropyridines, a subclass that includes verapamil and diltiazem. Dihydropyridine-type CCBs are generally potent vasodilators, which can prompt activation of the sympathetic nervous system. This does not occur with the non-dihydropyridine CCBs verapamil and diltiazem. Second-generation dihydropyridine CCBs, such as amlodipine or felodipine, are vascular selective, with little, if any, effect on cardiac contractility. Diltiazem and verapamil have modest negative inotropic effects and can inhibit atrioventricular nodal function.[97]

The availability of sustained-release delivery systems for CCBs has simplified the use of these drugs, in part because side effects decrease as the intensity of exposure to drug is lessened. For example, short-acting dihydropyridine CCBs reduce BP abruptly, thereby activating the sympathetic nervous system and potentially inciting coronary ischemia. This process does not occur with long-acting dihydropyridine CCBs, which lower BP gradually and smoothly. The long-term impact of low-grade sympathetic nervous system activation, as occurs with dihydropyridine CCBs, seems not to carry a readily identifiable CVD risk.[13,98-99]

CCBs can have a fairly steep dose-response curve for BP reduction. The amount by which BP is reduced with a CCB is a function of the pretherapy BP; thus the higher the BP at the start of therapy, the greater the drop in BP. The BP reduction achieved as a dihydropyridine CCB is titrated upward in dose will be influenced by the degree to which pulse rate is increased. If a CCB is considered for use in a patient with a pulse rate–related form of hypertension, verapamil or diltiazem is preferred. CCBs have a mild natriuretic effect, which may explain why they have more of an effect on BP reduction in patients on a high-sodium diet.[100] CCBs alter the activity of the RAAS axis: they increase plasma renin activity without a commensurate rise in plasma aldosterone so that the ratio of plasma aldosterone to plasma renin activity falls.[100-101] Activation of the RAAS may offset some of the direct BP-lowering effect of CCBs.

All patient groups are to some degree responsive to CCB monotherapy; however, there are no reliable predictors of

Table 31–7 Pharmacology of Angiotensin Receptor Blockers

Available Compounds
Losartan, candesartan, eprosartan, irbesartan, olmesartan, telmisartan, valsartan

Mode of Action
Indirect arterial vasodilation by blockade at the AT_1-receptor
Possible contribution from AT_2-receptor stimulation
Decreased sympathetic nervous system activity and possibly lowered aldosterone concentration
Decrease in vasoconstrictor substances, such as endothelin or improvement in endothelial dysfunction, or both
Absence of a compensatory tachycardia or antinatriuresis with BP reduction

Indications/Considerations in Use
Patients requiring multidrug therapy with otherwise resistant hypertension, such as a diabetic patient or a patient with renal failure
Hypertensive blacks respond less well as a group to monotherapy
Response is improved noticeably by the addition of a diuretic
Hypertensive patient with metabolic abnormalities including insulin resistance or hypercholesterolemia, or both
ACE inhibitor–responsive patients having developed a cough
Add-on therapy to an ACE inhibitor in patients with proteinuria or heart failure

Contraindications
Angioedema
Second and third trimesters of pregnancy
Bilateral renal artery stenosis or stenosis in a solitary kidney
Baseline increased serum creatinine levels are not a contraindication to use

Side Effects
First-dose hypotension, particularly if volume contracted
Angioedema (rarely)
Functional renal insufficiency—typically requires at least temporary drug stoppage
Small changes in serum creatinine (e.g., a 20% ↑) can occur as a normal response in patients with renal failure; therapy need not be stopped
Increase in serum potassium—less so than with an ACE inhibitor
Developmental defects in newborns if given in the second or third trimester
Anemia secondary to alterations in erythropoietin amount or effect (less so than with an ACE inhibitor)

the magnitude of the BP reduction to a CCB. Low-renin, salt-sensitive, volume-expanded diabetic and black hypertensive patients are more often responsive to a CCB than to an ACE inhibitor or a β-blocker. Age is a relative determinant of response to a CCB. Elderly patients are more sensitive to CCBs as a function of age-related alterations in pharmacokinetics (Table 31–9). This may explain, in part, the usefulness of drugs in this class for isolated systolic hypertension. CCBs differ from ACE inhibitors and ARBs in that their BP-lowering effect is not enhanced with sodium restriction. Although gender has not been viewed as an important factor in the response to antihypertensive agents, oral verapamil is not as well cleared in women and plasma concentrations (and effect) are higher than in men at comparable doses.[102]

First-step CCB therapy is of particular use when concomitant conditions, such as coronary artery disease with angina, intermittent claudication, migraine headaches, and Raynaud's phenomenon, are present.[103] In the presence of HF with systolic dysfunction, if a CCB is required, a dihydropyridine CCB is preferred because diltiazem, and more particularly verapamil, have negative inotropic effects.[104] Rate-lowering CCBs, such as verapamil or diltiazem, are preferred if LVH, diastolic dysfunction, or supraventricular tachyarrhythmias are present. Dihydropyridine CCBs should not be used as monotherapy in hypertensive patients with CKD and proteinuria.[105] Verapamil or diltiazem is preferred for the proteinuric CKD patient.[106] The extent to which the detrimental renal effects of dihydropyridine CCBs are reduced when combined with either an ACE inhibitor or an ARB remains to be determined.

CCBs are useful as second-step therapy. Dihydropyridine CCBs can be effectively combined with a β-blocker, an ACE inhibitor, or a peripheral α-antagonist, such as doxazosin or terazosin.[57,70,107-108] Nondihydropyridine CCBs can also be combined with an ACE inhibitor or a peripheral α-antagonist, but their use with a β-blocker is not recommended.[109-110] The combination of a diuretic with a CCB produces an additive response at most. Fixed-dose combination products containing a CCB and an ACE inhibitor are available (e.g., benazepril and amlodipine, felodipine and enalapril, or trandolapril and verapamil) (Table 31–10).[37]

Analysis of data from nine randomized trials comparing different treatment approaches in 62,605 hypertensive patients found that CCBs afforded CV protection compared with that seen with diuretics and β-blockers.[111] In addition, a meta-analysis by the Blood Pressure Lowering Treatment Trialists' Collaboration observed that a CCB-based treatment regimen lowered the rate of stroke by 7% compared with diuretic-β-blocker–based regimens and by 12% compared with ACE inhibitor–based regimens.[14] The positive effect of CCB therapy on reducing stroke occurrence is further supported by the findings of a meta-regression analysis by Verdecchia et al[112]; CCBs, however, have been shown to be less beneficial than diuretics, β-blockers, or ACE inhibitors in prevention of HF.[14]

CCB use can be associated with a variety of troubling side effects, such as polyuria, gastroesophageal reflux, and gingival hyperplasia.[113] Peripheral edema, however, is the side effect that has the greatest impact on the continued use of these drugs. Peripheral edema is due to a disproportionate change in arteriolar resistance, whereby precapillary hydrostatic pressures increase, favoring a fluid shift into the interstitial compartment. CCB-related edema is more common in women and relates to upright posture, age, and choice and dose of the CCB. It can be slow to resolve without intervention.[114]

Strategies for treating CCB-related edema include switching CCB classes; reducing dosage; and adding a venodilator, such as a nitrate, an ACE inhibitor, or an ARB, to the treatment

Table 31–8 Doses of Angiotensin Receptor Blockers

Drug	Brand Name	Total Dose Range (mg) (frequency/d)*	Comment	Fixed-Dose Combination
Candesartan	Atacand	8-32 (1)	Indicated in heart failure	Atacand/HCT
Eprosartan	Teveten	400-800 (1-2)		Teveten-HCT
Irbesartan	Avapro	75-300 (1)	Indicated in type 2 diabetic nephropathy	Avalide
Losartan	Cozaar	25-100 (1-2)	Uricosuric, indicated in type 2 diabetic nephropathy and to reduce the risk of stroke in patients with hypertension and left ventricular hypertrophy	Hyzaar
Olmesartan	Benicar	20-40 (1)		Benicar HCT
Telmisartan	Micardis	20-80 (1)		Micardis HCT
Valsartan	Diovan	80-320 (1)	Indicated in heart failure and post-MI	Diovan HCT

*Higher top-end doses are occasionally employed when the full antiproteinuric effect of an ARB is sought.

Table 31–9 Pharmacology of Calcium Channel Blockers

Available Compounds
Phenylalkylamines (verapamil)
Benzothiazepines (diltiazem)
Dihydropyridines (amlodipine, felodipine, isradipine, nifedipine)

Mode of Action
Decrease cellular calcium entry via the L-type channel with a reduction in total peripheral resistance
Negative inotropic and chronotropic effects (nondihydropyridines)
Interference with angiotensin II, α_1, and α_2-adrenergic agonist–mediated vasoconstriction
Natriuresis

Indications/Considerations in Use
Sodium-sensitive and sodium-resistant forms of hypertension
Concomitant diastolic dysfunction (nondihydropyridines) or variant angina
Concurrent cerebral vascular disease
Cyclosporine therapy; verapamil and diltiazem decrease its metabolism and thereby the amount necessary to maintain therapeutic drug levels
Grapefruit juice increases the absolute bioavailability of felodipine, nisoldipine, and nicardipine

Contraindications
Heart block and congestive heart failure (nondihydropyridines); cautious use of verapamil or diltiazem with β-blockers

Side Effects
Tachycardia (dihydropyridines); bradycardia, heart block (nondihydropyridines).
Acute myocardial infarction (short-acting dihydropyridines); heart failure (nondihydropyridines)
Headache, peripheral edema without weight gain (dihydropyridines and nondihydropyridines)
Gingival hyperplasia (dihydropyridines and nondihydropyridines)
Gastroesophageal reflux (dihydropyridines and nondihydropyridines)
Constipation (verapamil)

regimen. ACE inhibitors have been best studied in this regard. Diuretics may reduce the edema somewhat, but at the expense of further reducing plasma volume. Traditional measures, such as limiting the amount of time that a patient is upright and use of graduated compression stockings, are useful adjunctive therapies. When all else fails, CCB therapy can be discontinued and an alternative antihypertensive therapy given.[114]

Most side effects of CCBs are class specific, with the exceptions of constipation and atrioventricular block, which occur more commonly with verapamil. A final consideration relates to drug interactions. The bioavailability of a number of CCBs is increased when they are taken with grapefruit juice.[115] Verapamil and diltiazem can slow the metabolism of cyclosporine. This may prove advantageous from a cost point of view because it may result in the use of lower doses of cyclosporine.[116]

α-Adrenergic-Receptor Blockers: Third Line

α_1-Adrenergic-blocking drugs (α_1-blockers) effectively reduce BP in a manner comparable with other major drug classes. α_1-Blockers have evolved from short-acting compounds, such as prazosin, to longer-acting compounds, such as doxazosin, which has simplified their use (Table 31–11). These compounds are most effective when patients are in the upright position, reducing systolic and diastolic BPs by 8% to 10%.[117]

α_1-Blockers incrementally reduce BP when combined with most drug classes and are the only antihypertensive drug class to improve plasma lipid profiles and reduce insulin resistance.[118-119] In the difficult-to-treat hypertensive, these compounds reduce BP significantly, when used as adjunctive therapy to ACE inhibitors or CCBs. Dose escalation of an α_1-blocker can trigger renal Na^+ retention, and the ensuing volume expansion can attenuate its BP-lowering effect. Thus α_1-blockers should be given with a diuretic unless doses are kept very low.[120-121] First-dose hypotension or syncope is less common with doxazosin or terazosin than with shorter-acting α_1-blockers. However, orthostatic hypotension can occur with these compounds, particularly in volume-contracted patients. Dizziness, headache, and drowsiness are other common side effects of α_1-blockers.[120]

A modest decline in the use of doxazosin and other α_1-adrenergic blocking drugs occurred coincident with the early termination of the doxazosin treatment arm in the

Table 31–10 Doses of Calcium Channel Blockers

Drug	Brand Name	Total Dose Range (mg) (frequency/d)	Comment	Fixed-Dose Combination
Dihydropyridines				
Amlodipine	Norvasc	2.5-10 (1-2)	Very long acting	Amlodipine and benazepril (Lotrel)
Felodipine	Plendil	2.5-20 (1)	Plasma levels increased with grapefruit juice intake	Felodipine and enalapril (Lexxel)
Isradipine	DynaCirc, DynaCirc SR	2.5-5 (1-2)	Dose-dependent increase in heart rate—similar to all drugs in this class	
Nicardipine	Cardene SR	30-60 (2)	Plasma levels increased with grapefruit juice intake	
Nifedipine	Procardia XL, Adalat CC	30-120 (1-2)		
Nimodipine		60 (4-6)	Indicated for subarachnoid bleed	
Nisoldipine	Sular	10-40 (1)		
Nondihydropyridines				
Diltiazem	Cardizem, Cardizem CD or SR, Tiazac	120-360 (1)	Immediate-release form requires multiple daily doses Inhibits cytochrome 3A4	
Verapamil	Calan, Calan SR, Isoptin, Covera-HS,* Verelan PM*	120-360 (1)	Immediate release forms given three times daily	Verapamil and trandolapril (Tarka)

*Nocturnal dosing indicated.

ALLHAT.[13,122] However, α_1-blockers remain important elements of the treatment plan for symptomatic benign prostatic hyperplasia (BPH), typically improving both symptom score and urinary flow in men with BPH. It should not be presumed, however, that patients receiving α-adrenergic blocking drugs for lower urinary tract symptoms are being optimally treated for their hypertension, as has been put forward by the American Urologic Association.[123] Uroselective α-adrenergic blocking drugs have been developed to treat individuals with BPH and for the most part do not lower BP.[124] This highly selective form of BPH therapy typically avoids the vasodepressor risk of α_1-adrenergic blockade in normotensive patients.

Central α-Agonists: Second or Third Line

Central α-agonists have had a lengthy history, starting with α-methyldopa, which has seen its use limited because of bothersome side effects. Clonidine is the most commonly prescribed member of this class (Table 31–12). A small dose of clonidine (0.1 to 0.2 mg twice daily) augments the BP-lowering effect of most other agents and can be reliably used as add-on therapy. Dose titration of clonidine beyond 0.4 mg daily is commonly followed by troubling side effects, such as sluggishness and dry mouth. These side effects can also occur at lower doses (see Table 31–12).[125] Escalating doses of clonidine often bring on salt and water retention; thus, when clonidine or a similar compound is administered, a diuretic becomes useful adjunctive therapy.[126]

Clonidine is available in a transdermal delivery system, which offers distinct therapeutic advantages but is limited in its use by issues of cost and skin irritation (see Table 31–12). Transdermal clonidine is particularly useful in the management of the labile hypertensive patient who requires multiple medications, the hospitalized patient who cannot take medications by mouth, and the patient prone to early morning surges in BP. At equivalent doses, transdermal clonidine is more likely than oral clonidine to precipitate salt and water retention.[127]

Clonidine has become a mainstay of therapy for hypertensive urgencies because of its ease of use and relative safety.[128] Its hourly administration, in doses of 0.1 to 0.2 mg, successfully reduces BP in many patients with hypertensive urgencies. Rebound hypertension occurs in some patients receiving oral clonidine if the drug is suddenly terminated. Particularly vulnerable are patients with excessive adrenergic tone and those receiving high doses of clonidine or concomitant β-blocker therapy that is continued while discontinuing clonidine. Rebound hypertension can be avoided by frequent dosing of oral clonidine (three or four times daily) or by use of a transdermal delivery system. Clonidine overdose produces paradoxical hypertension when the depressor effects of central α_2-adrenergic receptor stimulation are exceeded by the pressor effects of peripheral α_2-adrenergic receptor stimulation, resulting in a predominantly vasoconstrictor response.[129]

Combined α- and β-Adrenergic Receptor Blockers: Second or Third Line

Drugs in this class are nonselective β-blockers without sympathomimetic activity. These compounds reduce peripheral resistance even as their β-blocking effect exceeds their potential

Table 31–11 Pharmacology of α-Adrenergic Receptor Blockers

Available Compounds
Prazosin, terazosin, doxazosin

Mode of Action
Direct arterial vasodilation with minimal effect on the renin-angiotensin-aldosterone axis
Dose-dependent pseudotolerance for BP effect linked to sympathetic nervous system activation or fluid retention, or both

Indications/Considerations in Use
Multidrug requiring patient with otherwise resistant hypertension, such as a diabetic or chronic kidney disease patient
Hypertensive patient with metabolic abnormalities, including insulin resistance and hypercholesterolemia
Hypertensive patients with benign prostatic hyperplasia

Dosing Considerations
Prazosin: Effectiveness relates to the degree of sympathetic activation, which is, in turn, dependent on whether an immediate or sustained-release formulation is being used.
Terazosin: Most BP lowering occurs at the low- to mid-dose range, such as 5-10 mg. Some patients require higher doses. More effective in the upright position.
Doxazosin: Most BP lowering occurs at the low- to mid-dose range, such as 4-8 mg. Some patients require higher doses. More effective in the upright position.

Contraindications
The presence of heart failure dictates careful use

Side Effects
Fluid retention or tachycardia, or both (dose-dependent)
Lethargy, fatigue, dizziness, headache, orthostatic hypotension, first-dose hypotension
Urinary incontinence in women

Table 31–12 Pharmacology of Central α-Agonists

Available Compounds
Alpha-methyldopa, clonidine, guanfacine, guanabenz

Mode of Action
Decreased sympathetic nervous system activity and lowered plasma renin activity by central adrenergic receptor stimulation
Modest reduction in heart rate

Indications/Considerations in Use
Patients requiring multidrug therapy with otherwise resistant hypertension, such as diabetic and renal failure patients.
Primary therapy for patients with sympathetically driven forms of hypertension.
Perioperative forms of hypertension. An anesthesia- and analgesia-sparing property of these drugs may prove beneficial.
Adjunct therapy in systolic forms of heart failure.

Dosing Considerations
Clonidine: Oral clonidine is best given two to three times daily. It is a short-acting compound so that patients with excessive sympathetic activity can have a short-lived response to it. A 1- to 2-day delay in the onset of action after initial patch application with transdermal clonidine exists, making it inappropriate for the management of hypertensive emergencies.
Guanfacine: The initial response to guanfacine is delayed compared with clonidine, but its longer duration of action allows it to be effectively dosed in a range of 1-3 mg given once or twice daily in a split-dose.

Contraindications
None

Side Effects
Fluid retention and bradycardia—dose dependent
Sedation and dry mouth
Skin irritation with transdermal clonidine delivery systems
Autoimmune hemolytic anemia, fever, liver dysfunction (α-methyldopa)
Rebound hypertension with clonidine, particularly if it is stopped and β-blocker therapy is continued or substituted
Large overdoses can paradoxically increase BP

for α-blockade (Table 31–13).[130] Their pharmacodynamic profile is a result of different receptor selectivity of their component stereoisomers, rather than combined α/β-blocking activity in a single chemical entity. Their use has generally been reserved for the complicated hypertensive patient when an antihypertensive effect beyond β-blockade is desired.[131] Sodium retention can occur with higher doses of labetalol.[132] Labetalol, either orally or intravenously, has been used to treat hypertensive emergencies, particularly when associated with cocaine use or in the postoperative setting (see Table 31–13).[133] Carvedilol has been studied more extensively than labetalol from an outcomes perspective. It has been shown to reduce urinary protein excretion more than metoprolol in hypertensive diabetic patients.[134] Carvedilol does not adversely affect glycemic control to the same degree as a traditional β-blocker, such as metoprolol,[134] and is effective in the patient with HF and systolic dysfunction.[135] Carvedilol has added benefit for the HF patient treated with ACE inhibitor or spironolactone therapy.[136]

Direct Vasodilators: Third Line

Hydralazine is seldom used in the management of hypertension, having been supplanted by safer and more convenient and effective agents. Hydralazine must be given in multiple daily doses. The third-line status for hydralazine in hypertension therapy, in part, relates to the lack of outcomes studies to support its use. Its use is generally confined to the setting of

Table 31–13 Pharmacology of Combined α- and β-Adrenergic Blockers

Available Compounds
Labetalol, carvedilol

Mode of Action
Nonselective β-blockers, α-blocking activity
Reduction in total peripheral resistance and heart rate

Indications/Considerations in Use
May be more effective in hypertensive blacks
Patients with chronic kidney disease
Patients with heart failure (caution: large doses can precipitate heart failure)
Hypertensive emergencies
Perioperative management of pheochromocytoma
Patients with aortic dissection
Rebound hypertension with clonidine
Cocaine-related hypertensive crisis

Dosing Considerations
Labetalol: 200-1200 mg/d administered twice daily. Given parenterally as intermittent bolus therapy (10-20 mg IV every 5-10 min) or a continuous infusion (0.5-2.0 mg/min). Dose and dose frequency can be adjusted according to clinical circumstances.
Carvedilol: 12.5-25 mg twice daily for hypertension; 25-50 mg twice daily for angina

Contraindications
Same as with β-blockers
Cautious use in patients with liver disease

Side Effects
Bronchospasm
Heart block
Heart failure
Transaminase elevation (labetalol)
Postural hypotension, fatigue, gastrointestinal symptoms, scalp tingling

pregnancy-induced hypertension and HF in the patient who is intolerant of ACE inhibitors.[137-138]

Minoxidil is a potent vasodilator that is generally reserved for refractory hypertensive patients. Early use of minoxidil can simplify the process of establishing BP control in the hypertensive patient, requiring several antihypertensive medications for BP control. Minoxidil is generally given together with a diuretic and a β-blocker to combat its tachycardic and salt-and-water retaining effects. These counter-regulatory responses can effectively negate its BP-lowering effect.[139] Hypertrichosis is common with minoxidil and can be disfiguring, particularly in women. Hair growth begins within 3 to 6 weeks of starting therapy, occurring over the temples and eyebrows initially, spreading to areas between the eyebrows and hairline or sideburn regions, to finally involve the trunk, extremities, and scalp. Hypertrichosis usually disappears within a few weeks of discontinuing minoxidil, though in some cases the process is prolonged (Table 31–14).

Table 31–14 Pharmacology of Direct Vasodilators

Available Compounds
Hydralazine, minoxidil

Mode of Action
Direct arterial vasodilation with minimal venodilation
Reflex activation of sympathetic nervous and renin-angiotensin-aldosterone systems

Indications/Considerations in Use
Patients requiring multidrug therapy with resistant hypertension and refractory to other agents, particularly patients with chronic kidney disease
Minoxidil loading over 24-36 hr can quickly establish BP control in hypertensive emergencies

Dosing Considerations
Hydralazine: Total dose of 75-300 mg given two to four times daily. The incidence of systemic lupus erythematosus is higher in patients receiving large doses.
Minoxidil: Total dose of 2.5-40 mg given once to three times daily. Usually requires coadministration of a diuretic (loop diuretic and metolazone combination may be warranted), a β-blocker, and an ACE inhibitor. The LVH seen with minoxidil is best treated with an ACE inhibitor.

Contraindications
Pericardial effusion (minoxidil)
Dissecting aortic aneurysm

Side Effects
Fluid retention
Tachycardia
Lupus-like syndrome (hydralazine)
Pericardial effusion (minoxidil)
Hypertrichosis (minoxidil)

SPECIAL CONSIDERATIONS

Women

Hypertensive complications are less common in women than men, except in the older age groups. Early trial results suggested greater efficacy of antihypertensive drug treatment in the prevention of CVD-related complications and death in men than in women; however, more recent trials, such as ALLHAT, which included 19,865 women among its 42,448 high-risk hypertensive participants, showed no gender difference between treatments (amlodipine/chlorthalidone and lisinopril/chlorthalidone) in the primary coronary outcome measure or in all-cause mortality.[140]

Women respond to most therapies similarly to men and the thresholds and goals of antihypertensive therapy, and choices of antihypertensive drugs are generally the same for both genders.[141-142] Of note, data collected in the Women's Health Initiative Observational Study indicate an increased CVD risk for women being treated with CCBs as monotherapy

or in combination with diuretics.[143] However, as in all observational studies, there is uncertainty as to the ability to control fully for confounding by indication.[143] Moreover, these findings differ from those in a large meta-analysis of randomized controlled trials,[14] as well as in important individual clinical trials,[144-145] which demonstrated no differences between the effects of regimens based on CCBs, ACE inhibitors, ARBs, or diuretics/β-blockers on CVD mortality.[15]

Some special considerations may influence treatment choices in women. Thiazide-type diuretics are useful in women, particularly in older women, in that they decrease urinary calcium excretion and thus decrease fracture rate.[146] β-Blockers tend to be less effective than in men. Women more commonly experience side effects with all antihypertensive medications and are more liable to certain compound-specific side effects[147] (e.g., diuretic-induced hyponatremia,[148] ACE inhibitor-related cough,[149] CCB-induced vasodilatory edema,[150] and minoxidil-induced hirsutism).[139] Further, ACE inhibitors and ARBs should be used cautiously in women planning to become pregnant because of the high risk of serious fetal developmental defects if exposed to these medications during the second and third trimester.

Blacks and Other Ethnic Groups

Blacks have a higher prevalence of hypertension and more significant target-organ disease including end-stage renal disease, LVH, and nonischemic HF.[152-155] Intrauterine growth retardation and excessive early childhood weight gain appear to forecast future hypertension and possibly the development of CKD in blacks.[156] The distinct pathophysiology of hypertension in blacks may affect the response to antihypertensive therapy (Tables 31–15 and 31–16). In particular, aldosterone-induced volume expansion and a nondipping nocturnal BP pattern are increasingly recognized as important contributors to the progression of hypertension and related target organ damage in blacks.[157-158]

The treatment of hypertension in blacks is complex, with socioeconomic and behavioral issues, as well as health care beliefs, typically influencing the success or failure of a particular regimen.[159] When these factors are coupled with the high rates of obesity and smoking in blacks, the treatment of hypertension becomes exceedingly complicated.[160-161] Given equal access to health care resources, however, blacks often respond to antihypertensive treatment comparably with whites.[160] Moreover, the majority of whites and blacks have similar responses to most commonly used antihypertensive drugs (Fig. 31–1). Therefore, clinical decisions to use a specific drug should be made on an individualized and not a group basis.[66]

Despite the overall similarity of responses to antihypertensive treatment in blacks and whites, there are some differences

Table 31–15 Special Considerations Relative to Target Organ Disease in Hypertensive Blacks

- Cerebrovascular accidents and, in particular, intracerebral hemorrhage are more common in blacks than in whites.
- The incidence of end-stage renal disease is several-fold higher in blacks than in whites and the profibrotic growth factor transforming growth factor-β_1 (TGF-β_1) is hyperexpressed in black patients with hypertension and those undergoing hemodialysis.
- LVH is more prevalent in blacks than in whites, which may in part explain the higher rate of sudden cardiac death in blacks. Exercise favorably affects LVH in hypertensive blacks.
- There is a disproportionate rate of coronary heart disease deaths in blacks, particularly in black women, compared with whites, possibly related to a greater clustering of known coronary artery disease risk factors.
- Hypertension is a major predisposing factor for the development of heart failure in black patients.
- Obesity, particularly in black women, may contribute to the high rates of hypertension and target organ injury in blacks.
- Nocturnal “nondipping” BP patterns and nighttime BP elevations are more common in blacks than in whites.
- Endothelin levels are generally increased and nitric oxide bioavailability reduced in hypertensive blacks compared with hypertensive whites.

LVH, left ventricular hypertrophy.

Table 31–16 Treatment Considerations in Hypertensive Blacks

- Hypertension is more common and more severe in blacks than in whites, and there is a persistent high rate of undetected, untreated, and uncontrolled hypertension in blacks.
- Target organ damage is more likely to present in blacks for any given level of BP.
- Intrauterine growth retardation in black infants, as well as excessive weight gain in adolescence, are determinants of high BP.
- The hypertensive black is likely to be younger than his or her white counterpart, therefore presenting potential age-related problems with medication compliance.
- Response to a variety of drugs or combinations of drugs may be different from other racial/ethnic groups. Blacks have a higher incidence of cough and angioedema with an ACE inhibitor.
- Socioeconomic considerations include lack of access to physicians, medications, and other health care resources. For example, in 1993, whites had a significantly higher rate of visits to physicians than did blacks (3.0 and 1.8 visits per person per year, respectively).*
- Low socioeconomic status, low levels of formal education, and exposure to violence lessen the success of antihypertensive therapy.†
- Uncontrolled severe hypertensives are more likely to be current smokers, and smoking, as a marker of poor health behavior, is associated with reduced compliance with medications.

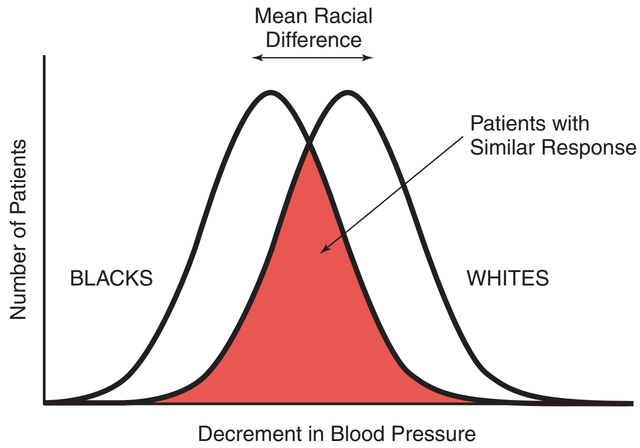

Figure 31–1 Decrement in blood pressure among whites and blacks after administration of antihypertensive drug. Red area represents whites and blacks who have similar responses. (Modified from Sehgal AR: Overlap between whites and blacks in response to antihypertensive drugs. Hypertension 2004;43:566-72.)

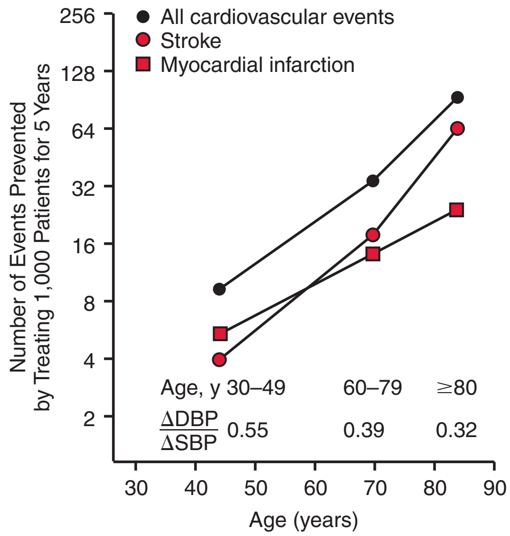

Figure 31–2 Absolute benefits in the prevention of fatal and nonfatal cardiovascular events, stroke, and myocardial infarction in three age groups. Symbols represent the number of events that can be prevented by treating 1000 patients for 5 years. ΔDBP/ΔSBP refers to the mean ratio of DBP-to-SBP lowering; y, years. (Modified from Wang JG, Staessen JA, Franklin SS, et al: Systolic and diastolic blood pressure lowering as determinants of cardiovascular outcome. Hypertension 45:907-913, 2005.)

that may influence treatment choices. Blacks as a group respond somewhat less well than whites to monotherapy with β-blockers and ACE inhibitors, perhaps because they tend to have a salt-sensitive, low-renin form of hypertension.[162] Higher-than-conventional doses of an ACE inhibitor may improve the BP response in these patients, however.[65] Blacks and whites generally respond equally well to diuretics, CCBs, and peripheral α-blockers. To achieve adequate BP control, a diuretic is required more often in blacks than in whites. The addition of a fixed dose of isosorbide dinitrate plus hydralazine to standard therapy for HF including neurohormonal blockers is efficacious and increases survival among black patients with advanced HF.[163] Because hydralazine and isosorbide dinitrate in tandem increase nitric oxide bioavailability, the presumption has been that such changes explain the observed positive outcomes in these studies.

Elderly Patients

The elderly (aged 65 years and older) represent a growing proportion of the U.S. population, and hypertension is the single-most important remedial risk factor for CVD in this group. Both systolic and diastolic BP increase with age, although there is a disproportionate increase in systolic BP, which continues to rise until the eighth or ninth decade, whereas diastolic BP tends to stabilize by the age of 60 and decline thereafter. Systolic hypertension in the elderly involves increases in arterial stiffness and early wave reflections, both of which cause a predominant or selective increase in systolic BP.[164] This disproportionate rise in systolic BP produces a widened pulse pressure and isolated systolic hypertension (ISH). The Framingham Heart Study, among others, has clearly shown that ISH is a major risk factor for cardiovascular death in elderly persons.[165] Moreover, clinical trials have repeatedly shown the benefits of BP control for prevention of stroke and dementia of both the multi-infarct and Alzheimer subtypes.[166] However, the best choice of individual antihypertensive agents and combinations of agents in the elderly hypertensive remains controversial.

Anatomic and humoral changes that occur with aging dictate that special attention be paid to the clinical assessment and treatment of hypertension in the elderly. Clinical assessment of ISH is often confounded by a widened auscultatory gap, which may lead to underestimation of systolic BP. Therefore it is important to inflate the cuff to at least 250 mm Hg when measuring BP in elderly persons. Elderly persons are prone to the development of *pseudohypertension,* a phenomenon related to calcified, noncompressible arteries, in which cuff BP can significantly overestimate true intra-arterial BP. This finding can be diagnosed by manually inflating the BP cuff above systolic BP, whereupon brachial or radial artery pulses should be obliterated. If these arteries remain palpable, a positive Osler's sign, the patient likely has a component of pseudohypertension. As an example of this, 7.2% (243 of 3387) of SHEP patients were determined to be Osler maneuver positive.[167] In the elderly, it is also important to test for orthostatic hypotension both before and during therapy. Failure to detect this condition may result in potentially life-threatening consequences.

The once-common notion that ISH is a physiologic consequence of aging that preserves organ perfusion and does not require treatment has been dispelled by results of randomized controlled trials (Fig. 31–2).[46,168-170] For example, the SHEP and Syst-EUR trials have clearly documented the benefits of BP control in elderly patients.[46,169] Reducing BP in elderly hypertensive persons has obvious survival benefits, and treatment of ISH in older patients with SBP of at least 160 mm Hg is supported by strong evidence. The evidence to support treatment of ISH patients to a goal of 140 mm Hg or those with baseline SBP of 140 to 159 mm Hg is less strong. These treatment decisions should be more sensitive to patient preferences and tolerance of therapy.[171]

The process of initiating treatment remains a challenge and is not without the risk of significant neurologic and constitutional side effects. It is appropriate to initiate treatment with lower doses of antihypertensive agents and to bring BP down slowly, monitoring for orthostatic hypotension, impaired cognition, and electrolyte abnormalities. Diuretics decrease cerebrovascular and CVD events and can be used as first-line therapy in the elderly.[46,172] β-Blockers may be less effective in elderly patients and have not been shown to reduce all-cause mortality rates.[33-35] Central α-agonists and peripheral α-antagonists often result in troubling side effects, such as dry mouth and orthostatic hypotension, and therefore should be used with particular care in elderly patients. CCBs, ACE inhibitors, and ARBs can be used, and the latter two classes often can be successfully combined with a diuretic. Low-dose combination therapy is well suited for this population and offers the advantages of reducing the risk of dose-dependent side effects and decreasing the number of pills that need to be taken.[37,173]

Step-Down Therapy

An effort to decrease the number or dosage of antihypertensive medications, or both, should be considered after hypertension has been effectively controlled for at least 1 year.[174] This should be done in a deliberate, slow, and progressive manner. The Trial of Nonpharmacologic Interventions in the Elderly (TONE) demonstrated that dietary Na^+ restriction (reducing intake by 40 mmol) or weight 1oss (≈3.5-kg), or both, in older patients without evidence of CVD and with BP < 150/90 mm Hg permitted the safe discontinuation of antihypertensive medication.[175] However, continued surveillance on the part of the physician is necessary for these patients because BP not uncommonly rises again to hypertensive levels, sometimes months or years after medication discontinuation, particularly when previously successful lifestyle modifications are not sustained.[175]

CHOICE OF DRUGS: FIRST, SECOND, AND BEYOND

A number of algorithms have been put together for the treatment of hypertension. Such algorithms at best offer simple guidelines for treatment. Treatment guidelines are most helpful when a population-based approach to therapy is sought. They are of lesser usefulness when the clinician is called on to choose a starting medication for the individual

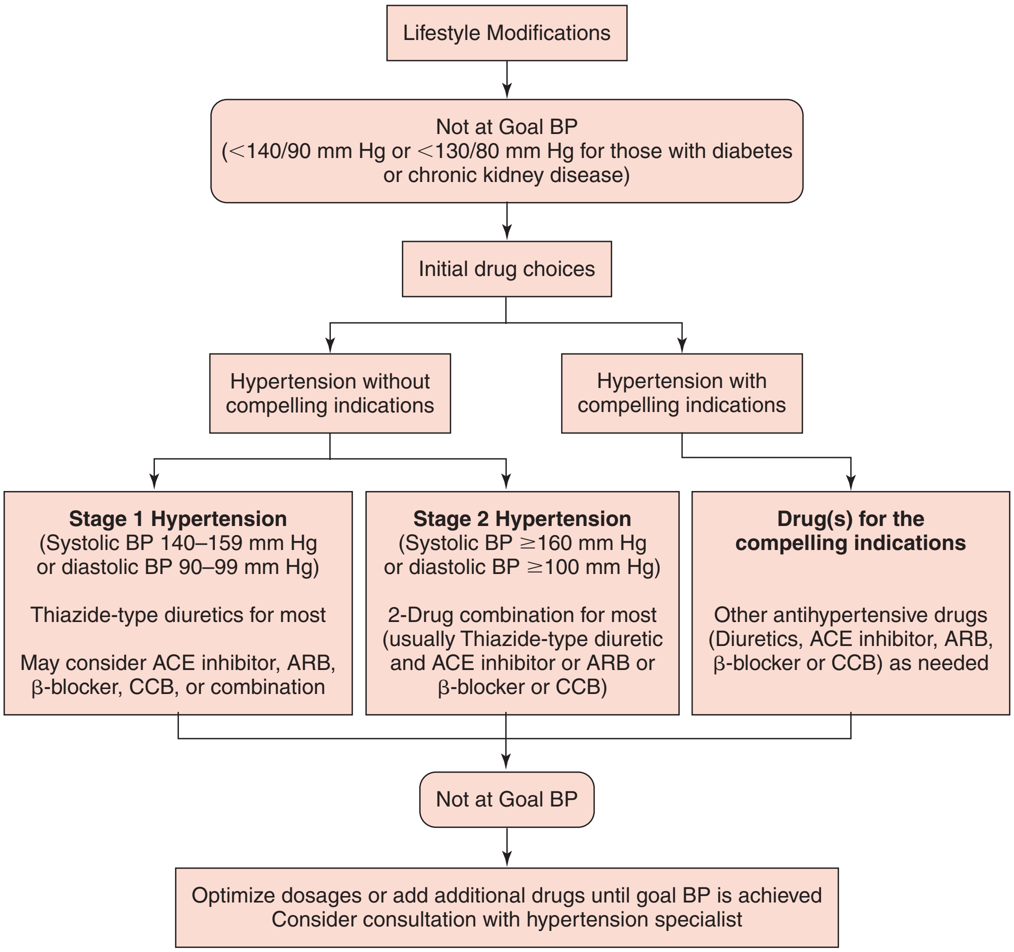

Figure 31–3 Hypertension treatment algorithm. (Modified from Chobanian AV, Bakris GL, Black HR, et al, for the NHLBI Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: The JNC 7 Report. JAMA 2003;289:2560-72.)

patient. The individual patient should receive customized therapy whenever possible. Clinical trial results indicate that many hypertensive patients require multidrug therapy to achieve goal BP, particularly if systolic BP values < 130 mm Hg are being sought.[5] A practical approach to achieving BP control is to rely on low-dose combinations of antihypertensive medications given either as fixed-dose combinations or one drug sequentially added to the other.[176] This approach, advanced by JNC-7, takes advantage of the well-established additive or synergistic effects of various combinations of drugs (Fig. 31–3).[5]

Secondary Hypertension: Endocrine Causes

William F. Young, Jr.

CHAPTER CONTENTS

Hypertension may be the initial presentation of many endocrine disorders (Table 32–1). Although endocrine causes of hypertension are uncommon, an accurate diagnosis provides clinicians with a unique treatment opportunity, that is, to render a surgical cure or to achieve a dramatic response with pharmacologic therapy.[1] The therapeutic approaches to endocrine disorders—ranging from the classic adrenal causes of hypertension (e.g., pheochromocytoma and primary aldosteronism) to pituitary-dependent hypertension (e.g., Cushing's syndrome and acromegaly)—are reviewed in this chapter.

PHEOCHROMOCYTOMA

Catecholamine-producing tumors that arise from chromaffin cells of the adrenal medulla and the sympathetic ganglia are termed *pheochromocytomas* and *catecholamine-secreting paragangliomas* (or *extra-adrenal pheochromocytomas*), respectively. Because clinical presentations of these disorders and the therapeutic approaches to them are similar, the term *pheochromocytoma* is used to refer to both adrenal pheochromocytomas and catecholamine-secreting paragangliomas.

Presentation

Although catecholamine-secreting tumors are rare (annual incidence of 2 to 8 cases per 1 million people),[1a] it is important to suspect, confirm, localize, and resect these tumors because (1) the associated hypertension is curable with surgical removal of the tumor; (2) the risk of a lethal paroxysm exists; (3) at least 10% of the tumors are malignant; and (4) 10% to 20% are familial, and detection of this tumor in the proband may result in early diagnosis in other family members. These tumors occur with equal frequency in men and women, primarily in the third, fourth, and fifth decades. Patients harboring catecholamine-secreting tumors may be asymptomatic and present with an incidentally discovered adrenal mass on computerized imaging.[2] However, symptoms are usually present and due to the pharmacologic effects of excessive levels of catecholamines or cosecreted peptide hormones (Table 32–2).[3] The resultant hypertension may be sustained or paroxysmal. Episodic symptoms may occur in spells, or paroxysms, that can be extremely variable in presentation.

Syndromic Pheochromocytoma

Approximately 10% to 20% of patients with catecholamine-secreting tumors have associated germline mutations (inherited mutations present in all cells of the body) in genes known to cause genetic disease.[4,5] The familial neurocristopathic syndromes associated with adrenal pheochromocytoma include multiple endocrine neoplasia (MEN) type 2A (pheochromocytoma, medullary thyroid carcinoma, and hyperparathyroidism) and type 2B (MEN 2B) (pheochromocytoma, medullary thyroid carcinoma, mucosal neuromas, thickened corneal nerves, intestinal ganglioneuromatosis, and marfanoid body habitus); neurofibromatosis type 1 (NF1); von Hippel-Lindau disease (VHL) (pheochromocytoma, retinal angiomas, cerebellar hemangioblastoma, renal and pancreatic cysts, and renal cell carcinoma); familial pheochromocytoma (specific mutations yet to be identified); and familial paraganglioma. Another syndrome associated with catecholamine-secreting tumors that does not appear to be inherited is the Carney triad (gastric leiomyosarcoma, pulmonary chondroma, and extra-adrenal pheochromocytoma).[6]

Familial paraganglioma is an autosomal dominant disorder characterized by paragangliomas that are located most often in the head and neck, but they also have been found in the thorax, abdomen, adrenal medulla, pelvis, and urinary bladder. The occurrence of catecholamine hypersecretion in familial paraganglioma depends on tumor location; approximately 5% of head and neck paragangliomas and 50% of abdominal paragangliomas are hormone-producing tumors.[7] Familial paraganglioma is caused by mutations in the succinate dehydrogenase (SDH; succinate-ubiquinone oxidoreductase) subunit genes *SDHB*, *SDHC*, *SDHD*, which comprise portions of mitochondrial complex II.[8,9] *SDHB* mutations have been associated with increased risk of malignant paraganglioma.[9,10]

Diagnosis

The diagnostic approach to catecholamine-producing tumors is divided into two series of studies (Fig. 32–1). First, the diagnosis of a catecholamine-producing tumor must be suspected and then confirmed biochemically by increased concentrations of fractionated catecholamines and metanephrines in the urine or plasma. The 24-hour urinary excretion rates of

catecholamines (norepinephrine, epinephrine, and dopamine) and fractionated metanephrines are the tests of choice to screen for catecholamine-secreting tumors (see Fig. 32–1).[11] Measurement of the concentrations of plasma fractionated metanephrines is also useful in screening for pheochromocytoma.[11,12]

The next step is to localize the catecholamine-producing tumor to guide the surgical approach. Computer-assisted adrenal and abdominal imaging (magnetic resonance imaging [MRI] or computed tomography [CT]) is the first localization test. About 98% of these tumors are in the abdomen, with approximately 90% of them in the adrenal glands.[13] If the findings on abdominal imaging are negative, scintigraphic localization with [^{123}I]metaiodobenzylguanidine (^{123}I-MIBG) is indicated. Thorough discussions of the diagnostic investigation of catecholamine-producing tumors may be found elsewhere.[14]

Principles of Treatment

The treatment of choice for pheochromocytoma is surgical resection. Most of the tumors are benign and can be excised totally. However, preoperatively, the chronic and acute effects of excess circulating catecholamines should be reversed.

Preoperative Management

Combined α- and β-adrenergic blockade is required preoperatively to control blood pressure and to prevent intraoperative hypertensive crises. α-Adrenergic blockade should be started 7 to 10 days preoperatively to allow expansion of the contracted blood volume. A liberal salt diet is advised during the preoperative period. After adequate α-adrenergic blockade has been achieved, β-adrenergic blockade is initiated, usually about 3 days preoperatively. Echocardiography performed preoperatively may be helpful in detecting catecholamine cardiomyopathy.

α-Adrenergic Blockade

Phenoxybenzamine is an irreversible, long-acting, α-adrenergic blocking agent (Table 32–3). The effects of daily administration are cumulative for nearly a week, and approximately 25% of an oral dose is absorbed. Phenoxybenzamine is available in 10-mg capsules. The initial dosage is 10 mg orally one to two times a day, and the dosage is increased by 10 to 20 mg every 2 to 3 days as needed to control the blood pressure and spells. The average dosage is 20 to 100 mg/day. The target blood pressure is less than 120/80 mm Hg seated, with systolic blood pressure greater than 90 mm Hg standing. These target blood

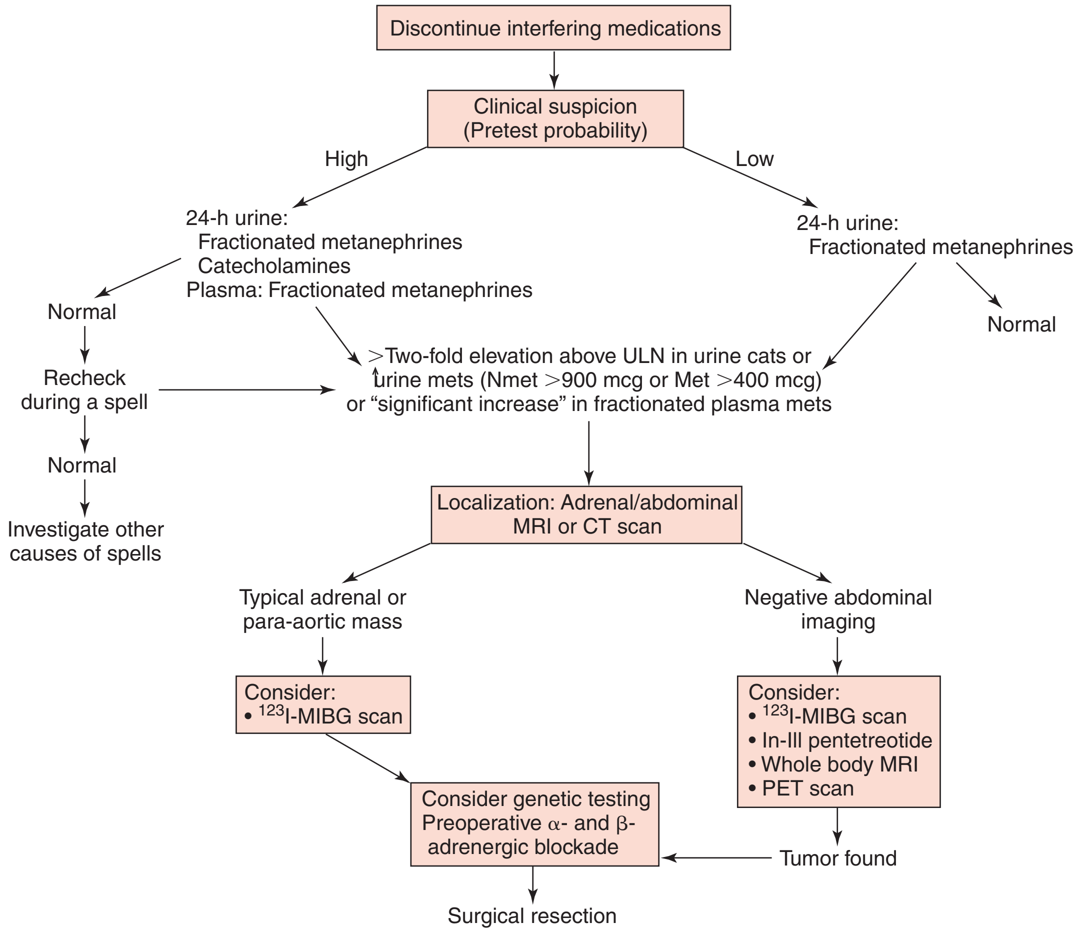

Figure 32–1 Evaluation and treatment of catecholamine-producing tumors. Clinical suspicion is triggered by the following: paroxysmal symptoms (especially hypertension); hypertension that is intermittent, unusually labile, or resistant to treatment; family history of pheochromocytoma or associated conditions; or incidentally discovered adrenal mass. See text for details. CT, computed tomography; ^{123}I-MIBG, ^{123}I-metaiodobenzylguanidine; MRI, magnetic resonance imaging. (Modified from Young WF Jr: Pheochromocytoma: 1926-1993. Trends Endocrinol Metab 1993;4:122-7.)

pressure readings may be modified on the basis of age and comorbid disease. Side effects include postural hypotension, tachycardia, miosis, nasal congestion, inhibition of ejaculation, diarrhea, and fatigue. Prazosin, terazosin, and doxazosin are selective α_1-adrenergic blocking agents. Because these agents have a more favorable side effect profile, they may be preferable to phenoxybenzamine when long-term pharmacologic treatment is indicated (e.g., for mild metabolically active metastatic pheochromocytoma). However, phenoxybenzamine is the drug preferred for preoperative preparation because it provides α-adrenergic blockade of long duration. Effective α-adrenergic blockade permits expansion of blood volume, which is usually severely decreased because of excessive adrenergic vasoconstriction.

β-Adrenergic Blockade

A β-adrenergic antagonist should be administered only after α-adrenergic blockade is effective because β-adrenergic blockade alone may increase the severity of the hypertension through unopposed α-adrenergic stimulation. Preoperative β-adrenergic blockade is indicated to control the tachycardia associated with both the high concentrations of circulating catecholamines and the α-adrenergic blockade. Caution is indicated if the patient has asthma or congestive heart failure. A chronic excess level of catecholamines can produce myocardiopathy, and β-adrenergic blockade can result in acute pulmonary edema. Noncardioselective β-adrenergic blockers, such as propranolol and nadolol, or cardioselective β-adrenergic blockers, such as atenolol and metoprolol, may be used. Mechanisms of action, routes of metabolism, dosages, and side effects of β-adrenergic blockers are discussed in Chapter 5. When initiating treatment with a β-adrenergic blocker, the drug should be started at a low dose. For example, propranolol is usually started at a dose of 10 mg orally every 6 hours at least 4 to 7 days after the initiation of α-adrenergic blockade. The dose is increased as needed to control the tachycardia.

Labetalol exhibits both selective α_1-adrenergic and nonselective β-adrenergic blocking activities in a ratio of approximately 1:3 (see Table 32–3). Paradoxical hypertensive responses in patients with pheochromocytoma treated with labetalol have been reported, presumably because of incomplete α-adrenergic blockade. Therefore, the safety of labetalol as primary therapy is controversial.

Table 32–3 Orally Administered Drugs Used to Treat Pheochromocytoma

Drug	Dosage, mg/d* Initial—Maximum	Side Effects
α-Adrenergic blocking agents		
Phenoxybenzamine	20†-100†	Postural hypotension, tachycardia, miosis, nasal congestion, diarrhea, inhibition of ejaculation, fatigue
Prazosin	1-20‡	First-dose effect, dizziness, drowsiness, headache, fatigue, palpitations, nausea
Terazosin	1-20†	First-dose effect, asthenia, blurred vision, dizziness, nasal congestion, nausea, peripheral edema, palpitations, somnolence
Doxazosin	1-20	First-dose effect, orthostasis, peripheral edema, fatigue, somnolence
Combined α- and β-adrenergic blocking agent		
Labetalol	200†-1200†	Dizziness, fatigue, nausea, nasal congestion, impotence
Calcium Channel Blockers		
Nicardipine sustained release	60-120†	Edema, dizziness, headache, flushing, nausea, dyspepsia
Catecholamine Synthesis Inhibitor		
α-Methyl—*p*-L-tyrosine (metyrosine)	1000‡-4000‡	Sedation, diarrhea, anxiety, nightmares, crystalluria, galactorrhea, extrapyramidal symptoms

*Given once daily unless otherwise indicated.
†Given in two doses daily.
‡Given in three or four doses daily.

Catecholamine Synthesis Inhibitor

Rarely, α- and β-adrenergic blocking agents may be ineffective or poorly tolerated, and an alternative medical approach is necessary. α-Methyl-*p*-L-tyrosine (metyrosine) inhibits the synthesis of catecholamines by blocking the enzyme tyrosine hydroxylase. Metyrosine is absorbed rapidly from the gastrointestinal tract, and most of it is excreted unchanged in the urine. Metyrosine is available as 250-mg capsules (see Table 32–3). The initial dosage is 250 mg orally four times a day. The dosage may be increased by 500 mg/day, every 1 or 2 days, to a maximum of 4 g/d (1 g four times per day) as needed for blood pressure control. Side effects include sedation, somnolence, depression, diarrhea, anxiety, nightmares, crystalluria and urolithiasis, galactorrhea, and extrapyramidal manifestations. Therefore, this agent should be used only after other agents have been ineffective. The extrapyramidal effects of phenothiazines or haloperidol may be potentiated, and their concomitant use with metyrosine should be avoided. High fluid intake to avoid crystalluria is suggested for any patient taking more than 2 g daily. Metyrosine is especially useful for patients who, for cardiopulmonary reasons, cannot be treated with combined α- and β-adrenergic blockade.

Calcium Channel Blockers

Calcium channel blockers, which block norepinephrine-mediated calcium transport into vascular smooth muscle, have been used successfully at several medical centers to preoperatively prepare patients with pheochromocytoma.[15-17] Nicardipine is the most commonly used calcium channel blocker in this setting. Nicardipine is given orally to control blood pressure preoperatively and is given as an intravenous infusion intraoperatively. When calcium channel blockers are used as the primary mode of antihypertensive therapy, they appear to be just as effective as α- and β-adrenergic blockade.

Acute Hypertensive Crises

Acute hypertensive crises may occur before or during surgery and should be treated with nitroprusside, phentolamine, or nicardipine administered intravenously (Table 32–4) (see Chapter 5). Phentolamine is a short-acting, nonselective α-adrenergic blocker available in lyophilized form in 5-mg vials. An initial test dose of 1 mg is administered and, if necessary, followed by repeat 5-mg boluses or continuous infusion. The response to phentolamine is maximal in 2 to 3 minutes after a bolus injection and lasts 10 to 15 minutes. Nicardipine infusion is initiated at 5.0 mg/hr, and the infusion rate may be increased by 2.5 mg/hr every 15 minutes up to a maximum of 15.0 mg/hr. The use of nitroprusside is discussed later.

Anesthesia and Surgery

Resection of a catecholamine-secreting tumor is a high-risk surgical procedure, and an experienced surgeon/anesthesiologist team is required. The last oral doses of α- and β-adrenergic blockers can be administered orally early in the morning on the day of the operation. Fentanyl, ketamine, and morphine should be avoided because they can potentially stimulate catecholamine release from a pheochromocytoma.[18] Also, parasympathetic nervous system blockade with atropine should be avoided because of the associated tachycardia. Anesthesia may be induced with intravenous injection of propofol, etomidate, or barbiturates in combination with synthetic opioids.[18] Most anesthetic gases can be used, but halothane and desflurane should be avoided. Cardiovascular and hemodynamic variables must be monitored closely. Continuous measurement of intra-arterial pressure and heart rhythm is required. If the patient has congestive heart failure or decreased cardiac

Table 32–4 Intravenously Administered Drugs Used to Treat Pheochromocytoma

Agent	Dosage Range
For Hypertension	
Phentolamine	1 mg IV test dose, then 2- to 5-mg IV boluses as needed or continuous infusion.
Nitroprusside	Infusion rates of 2 mcg/kg/min are suggested as safe, whereas rates greater than 4 mcg/kg/min may lead to cyanide toxicity within 3 hr. Doses exceeding 10 mcg/kg/min are rarely required, and the maximal dose should not exceed 800 mcg/min.
Nicardipine	Initiate therapy at 5.0 mg/hr, and the infusion rate may be increased by 2.5 mg/hr every 15 min up to a maximum of 15.0 mg/hr.
For Cardiac Arrhythmia	
Lidocaine	Initiate therapy with a bolus of 1 to 1.5 mg/kg (75 to 100 mg); additional boluses of 0.5 to 0.75 mg/kg (25-50 mg) can be given every 5 to 10 minutes if needed up to a maximum of 3 mg/kg. Loading is followed by a maintenance infusion of 2 to 4 mg/min (30 to 50 mcg/kg/min) adjusted for effects and settings of altered metabolism (e.g., heart failure, liver congestion) and as guided by blood level monitoring.
Esmolol	An initial loading dose of 0.5 mg/kg is infused over a minute duration followed by a maintenance infusion of 0.05 mg/kg/min for the next 4 min. Depending on the desired ventricular response, the maintenance infusion may then be continued at 0.05 mg/kg/min or increased stepwise (e.g., by 0.1 mg/kg/min increments to a maximum of 0.2 mg/kg/min) with each step being maintained for 4 or more min.

IV, intravenous.

reserve, monitoring of pulmonary capillary wedge pressure is indicated. Surgical survival rates are 98% to 100%.[19] The preoperative and perioperative treatment approaches outlined here are the same for adults and children.[20,21]

In the past, an anterior midline abdominal surgical approach was generally used for resecting adrenal pheochromocytoma. However, the laparoscopic approach to the adrenal gland is currently the procedure of choice for patients with solitary intra-adrenal pheochromocytomas that are less than 8 to 10 cm in diameter.[22] The average length of hospitalization for patients who undergo laparoscopic adrenalectomy for pheochromocytoma is 1.7 to 2.3 days.[23,24] If the pheochromocytoma is in the adrenal gland, the entire gland should be removed. Laparoscopic adrenalectomy for pheochromocytoma should be converted to open adrenalectomy for difficult dissection, invasion, adhesions, or surgeon inexperience.[25] If the tumor is malignant, as much of the tumor should be removed as possible. If a bilateral adrenalectomy is planned preoperatively, the patient should receive glucocorticoid stress coverage while awaiting transfer to the operating room. Glucocorticoid coverage should be initiated in the operating room if unexpected bilateral adrenalectomy is necessary. Cortical-sparing bilateral adrenalectomies have been used to treat patients with MEN 2 and VHL disease.[26] However, with MEN 2 patients, there is a concern of leaving residual adrenal medullary tissue behind and thus increasing the risk of recurrent pheochromocytoma. An anterior midline abdominal surgical approach is indicated for abdominal paragangliomas. Paragangliomas of the neck, chest, and urinary bladder require specialized approaches.

Hypotension may occur after surgical resection of the pheochromocytoma, and it should be treated with fluids and small, intermittent doses of intravenous pressor agents. Postoperative hypotension is less frequent in patients who have had adequate preoperative α-adrenergic blockade. If both adrenal glands were manipulated during surgery, adrenocortical insufficiency should be considered a potential cause of postoperative hypotension. Because hypoglycemia can occur in the immediate postoperative period, blood glucose levels should be monitored and fluid given intravenously should contain 5% dextrose.

Blood pressure is usually normal by the time of hospital discharge, but some patients remain hypertensive for up to 4 to 8 weeks postoperatively. Long-standing, persistent hypertension does occur and may be related to inadvertent ligation of a polar renal artery, resetting of baroreceptors, hemodynamic changes, structural changes of the blood vessels, altered sensitivity of the vessels to pressor substances, functional or structural renal changes, or coincident primary hypertension.

Long-Term Postoperative Follow-up

Approximately 1 to 2 weeks after surgery, catecholamines and metanephrines should be measured by collecting a 24-hour urine specimen. If the levels are normal, the resection of the pheochromocytoma should be considered complete. The survival rate after removal of a benign pheochromocytoma is nearly that of age- and sex-matched normal controls. Increased levels of catecholamines and metanephrines detected postoperatively are consistent with residual tumor, either a second primary lesion or occult metastases. If bilateral adrenalectomy was performed, lifelong glucocorticoid and mineralocorticoid replacement therapy is prescribed. Twenty-four hour urinary excretion of catecholamines and fractionated metanephrines or fractionated plasma metanephrines should be checked annually for life. Annual biochemical testing assesses for metastatic disease, tumor recurrence in the adrenal bed, or delayed appearance of multiple primary tumors. Recurrence rates are highest for patients with familial disease, right-sided adrenal pheochromocytoma, or paraganglioma.[27] Follow-up CT or MRI is not necessary unless the metanephrines or catecholamine levels, or both, become elevated or the original tumor was associated with minimal catecholamine excess.

Genetic testing should be considered for patients with one or more of the following: a family history of pheochromocy-

toma, paraganglioma, or any sign that suggests a genetic cause (e.g., retinal angiomas, axillary freckling, café-au-lait spots, cerebellar tumor, medullary thyroid carcinoma (MTC), hyperparathyroidism).[28] In addition, all first-degree relatives of a patient with pheochromocytoma or paraganglioma should have biochemical testing (e.g., 24-hr urine for fractionated metanephrines and catecholamines). If mutation testing in a patient is positive, first-degree relatives should have stepwise (e.g., parents first) germline screening.

Malignant Pheochromocytoma

Distinguishing between benign and malignant catecholamine-secreting tumors on the basis of clinical, biochemical, or histopathologic characteristics is difficult.[29] Malignancy is rare in patients with a familial adrenal syndrome but common in those with familial paraganglioma caused by mutations in *SDHB*. Although the mean 5-year survival rate for patients with malignant pheochromocytoma is less than 50%, the prognosis is variable: Approximately 50% of patients have an indolent form of the disease, with a life expectancy of more than 20 years, and the other 50% have rapidly progressive disease, with death occurring within 1 to 3 years. Metastatic sites include local tissue, liver, bone, lung, and lymph nodes. Metastatic lesions should be resected if possible. Skeletal metastatic lesions that are painful or threaten structural function can be treated with external radiotherapy or cryoablation therapy. External radiotherapy can also be used to treat unresectable soft tissue lesions.

Local tumor irradiation with therapeutic doses of ^{131}I-MIBG has produced partial and temporary responses in approximately one third of patients.[30-33] Thrombotic therapy for large, unresectable liver metastases and radiofrequency ablation for small liver metastases are options to be considered. In selected cases, long-acting octreotide has been beneficial. If the tumor is considered aggressive and the patient's quality of life is affected, combination chemotherapy may be considered.[34] Management of a patient who has malignant pheochromocytoma can be frustrating because curative options are limited. Clearly, innovative prospective protocols are necessary to seek new treatment options for this neoplasm.[29]

Pheochromocytoma in Pregnancy

Pheochromocytoma in pregnancy can cause the death of both the fetus and the mother.[35] The treatment of hypertensive crises is the same as that for nonpregnant patients except that nitroprusside should be avoided in the pregnant patient. Although some controversy exists about the most appropriate management, pheochromocytomas should be removed immediately if diagnosed during the first two trimesters of pregnancy. The preoperative preparation is the same as that for nonpregnant patients. If medical therapy is chosen or if the patient is in the third trimester, cesarean section and removal of the pheochromocytoma in the same operation are indicated. Spontaneous labor and delivery should be avoided.

PRIMARY ALDOSTERONISM

Hypertension, hypokalemia, suppressed plasma renin activity (PRA), and increased aldosterone excretion characterize the syndrome of primary aldosteronism, which was first described in 1955.[36] Bilateral idiopathic hyperaldosteronism (IHA) and aldosterone-producing adenoma (APA) are the most common subtypes of primary aldosteronism (Table 32–5). A much less common form, unilateral hyperplasia or primary adrenal hyperplasia, is caused by zona glomerulosa hyperplasia of predominantly one adrenal gland. Two forms of familial hyperaldosteronism (FH) have been described: FH type I and FH type II. FH type I, or glucocorticoid-remediable aldosteronism (GRA), is autosomal dominant in inheritance and associated with varying degrees of hyperaldosteronism, high levels of hybrid steroids (e.g., 18-hydroxycortisol and 18-oxocortisol), and suppressability with exogenous glucocorticoids. FH type II refers to the familial occurrence of APA or IHA, or both.

Table 32–5 Subtypes of Primary Aldosteronism

Aldosterone-producing adenoma (APA)
Idiopathic hyperaldosteronism (IHA)
Primary adrenal hyperplasia (PAH) (unilateral adrenal hyperplasia)
Aldosterone-producing adrenocortical carcinoma
Ectopic aldosterone-producing (e.g., ovarian tumor)

FH type 2 (APA or IHA, or both)

Modified from Young WF Jr, Hogan MJ: Renin-independent hypermineralocorticoidism. Trends Endocrinol Metab 1994;5:97-106.

Diagnosis

Screening

In the past, clinicians would not consider the diagnosis of primary aldosteronism unless the patient presented with spontaneous hypokalemia, and then the diagnostic evaluation would require discontinuing antihypertensive medications for 2 weeks. The "spontaneous hypokalemia/no antihypertensive drug" diagnostic approach resulted in predicted primary aldosteronism prevalence rates of <0.5% of hypertensive patients.[37,38] However, it is now recognized that most patients with primary aldosteronism are not hypokalemic and present with asymptomatic hypertension, which may be mild or severe.[39] When hypokalemia does occur, it may be associated with nocturia, polyuria, muscle cramps, or palpitations. Screening can be completed with a simple morning (8 to 10 A.M.) blood test (plasma aldosterone concentration [PAC]–to–plasma renin activity [PRA] ratio) in a seated ambulant patient.[40] The patient may take any antihypertensive drugs except aldosterone-receptor blockers and high-dose amiloride (spironolactone and eplerenone should be discontinued 4 to 6 weeks before testing for primary aldosteronism). Hypokalemia is associated with false-negative ratios, and any potassium deficit should be corrected before testing. Although there is some uncertainty about test characteristics and lack of standardization, the PAC-PRA ratio is widely accepted as the screening test of choice for primary aldosteronism.

The use of the PAC-PRA ratio as a screening test followed by aldosterone suppression confirmatory testing has resulted in much higher prevalence estimates (5%-13% of all hypertensives) for primary aldosteronism.[39] The prevalence of primary

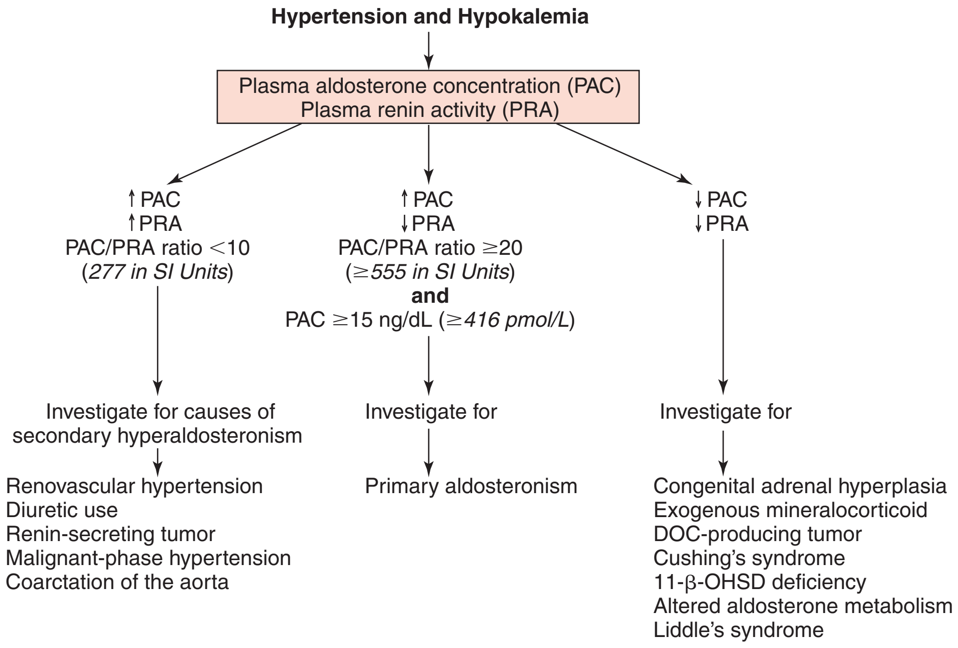

Figure 32–2 Use of the plasma aldosterone concentration (PAC)–to–plasma renin activity (PRA) ratio to differentiate among different causes of hypertension and hypokalemia. DOC, deoxycorticosterone; OHSD, hydroxysteroid dehydrogenase. (Modified from Young WF Jr, Hogan MJ: Renin-independent hypermineralocorticoidism. Trends Endocrinol Metab 1994;5:97-106.)

aldosteronism approaches 20% in patients with resistant hypertension.[41] Patients with hypertension and hypokalemia, regardless of presumed cause (e.g., diuretic treatment), and most patients with treatment-resistant hypertension should undergo screening for primary aldosteronism with a PAC-PRA ratio (cutoff is laboratory dependent) (Fig. 32–2).[42] A high PAC-PRA ratio is a positive screening test result, a finding that warrants confirmatory testing.

Confirming the Diagnosis

Confirmatory testing is completed with sodium suppression testing [oral sodium loading, saline suppression test, or fludrocortisone (Florinef) suppression testing].[43] At the Mayo Clinic, we prefer the high-sodium diet for 3 to 4 days with 24-hour urine collection (days 3 to 4) for aldosterone, sodium, and creatinine.[43] When the 24-hour urinary sodium is >200 mEq (confirming adequate sodium loading), patients with primary aldosteronism demonstrate autonomous aldosterone production with urinary aldosterone levels >12 mcg/24-hour. During the oral sodium loading, it is important to monitor serum electrolytes and blood pressure daily and increase potassium supplementation and antihypertensive medications as indicated.

Subtype Evaluation

Unilateral adrenalectomy in patients with APA or PAH results in normalization of hypokalemia in all; hypertension is improved in all and is cured in approximately 30% to 60% of these patients. In IHA, unilateral or bilateral adrenalectomy seldom corrects the hypertension. IHA and GRA should be treated medically. Therefore for those patients who want to pursue a surgical cure, accurate distinction among the subtypes of primary aldosteronism is a critical step (Fig. 32–3). The subtype evaluation may require one or more tests, the first of which is imaging the adrenal glands with computed tomography (CT) (see Fig. 32–3). When a solitary hypodense (Hounsfield unit score <10 HU) unilateral macroadenoma (>1 cm) and normal contralateral adrenal morphology are found on CT in a young patient (<40 years) with primary aldosteronism, unilateral adrenalectomy is a reasonable therapeutic option. However, in many cases, CT may show normal-appearing adrenals, minimal unilateral adrenal limb thickening, unilateral microadenomas (≤1 cm), or bilateral macroadenomas. We have found in 203 patients, who were evaluated with both CT and adrenal vein sampling, that CT accurately distinguished APA from IHA in only 53% of patients.[44] Small APAs may be labeled incorrectly as "IHA" on the basis of CT findings of bilateral nodularity or normal-appearing adrenals. Also, apparent adrenal microadenomas may represent areas of hyperplasia, and unilateral adrenalectomy would be inappropriate. In addition, nonfunctioning unilateral adrenal macroadenomas are not uncommon, especially in older patients (>40 years).

Patients with APAs have more severe hypertension, more frequent hypokalemia, higher plasma (>25 ng/dL; >694 pmol/L) and urinary (>30 mcg/24 hour; >83 nmol/d) levels of aldosterone, and are younger (<50 years) than those with IHA. Patients fitting these descriptors are considered to have a "high probability of APA" (see Fig. 32–3). However, these factors are not absolute predictors of unilateral versus bilateral adrenal disease. Adrenal venous sampling (AVS) is a difficult procedure because the right adrenal vein is both small and difficult to cannulate; the success rate depends on the proficiency of the angiographer.[43,44] A practical approach is the selective use of AVS as outlined in Figure 32–3.

Principles of Treatment

The treatment goal is to prevent the morbidity and mortality associated with hypertension, hypokalemia, and cardiovascular damage. The cause of the primary aldosteronism helps to determine the appropriate treatment. Normalization of blood pressure should not be the only goal in managing the patient with primary aldosteronism. In addition to the kidney and colon, mineralocorticoid receptors are present in the heart, brain, and blood vessels. Excessive secretion of aldos-

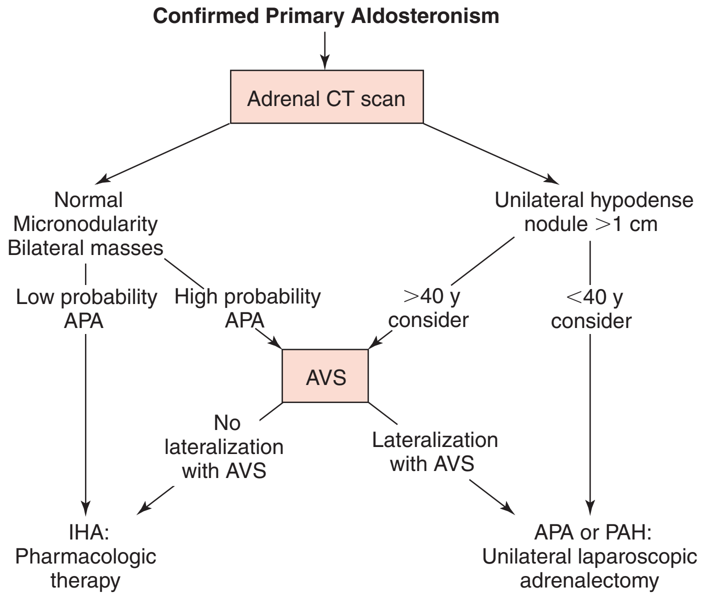

Figure 32–3 Subtype evaluation of primary aldosteronism. See text for details. APA, aldosterone-producing adenoma; AVS, adrenal venous sampling; CT, computed tomography; GRA, glucocorticoid-remediable aldosteronism; IHA, idiopathic hyperaldosteronism; PAH, primary adrenal hyperplasia. (Modified from Young WF Jr, Hogan MJ: Renin-independent hypermineralocorticoidism. Trends Endocrinol Metab 1994;5:97-106.)

terone is associated with increased risk of cardiovascular disease and morbidity. This issue was addressed in a retrospective study that compared 124 patients with primary aldosteronism with 465 patients with apparent essential hypertension who were matched for age, gender, and blood pressure (mean 175/107 mm Hg).[45] The patients with primary aldosteronism had significantly higher rates of stroke (12.9% versus 3.4% in those with essential hypertension), nonfatal myocardial infarction (4.0% versus 0.6%), and atrial fibrillation (7.3% versus 0.6%). The rate of cardiovascular complications appeared to be similar in those with an adrenal adenoma and adrenal hyperplasia.[45] In addition, aldosterone excess can induce adverse cardiovascular effects independently of blood pressure.[46] Therefore, normalization of circulating aldosterone or aldosterone-receptor blockade should be part of the management plan for all patients with primary aldosteronism.

Surgical Treatment of Aldosterone-Producing Adenoma and Unilateral Hyperplasia

Unilateral laparoscopic adrenalectomy is an excellent treatment option for patients with APA or unilateral hyperplasia. Blood pressure control improves in nearly 100% of patients postoperatively, and average long-term cure rates of hypertension after unilateral adrenalectomy for APA range from 30% to 60%.[47] Persistent hypertension following adrenalectomy is correlated directly with having more than one first-degree relative with hypertension, use of more than two antihypertensive agents preoperatively, older age, increased serum creatinine, and duration of hypertension and is most likely due to coexistent primary hypertension.[47]

Laparoscopic adrenalectomy is the preferred surgical approach and is associated with shorter hospital stays and less long-term morbidity than the conventional open approach. To decrease the surgical risk, hypokalemia should be corrected with spironolactone preoperatively; treatment with this drug should be discontinued postoperatively. PAC should be measured 1 to 2 days after the operation to confirm a biochemical cure. For the first few weeks postoperatively, serum potassium levels should be monitored weekly and a generous sodium diet should be followed to avoid the hyperkalemia of hypoaldosteronism that may occur because of the chronic suppression of the renin-angiotensin-aldosterone axis. Typically, the hypertension resolves in 1 to 3 months postoperatively. Adrenalectomy for APA has been found to be significantly less expensive than long-term medical therapy.[48]

Pharmacologic Treatment

IHA and GRA should be treated medically.[49] In addition, APA patients may be treated medically if the medical treatment includes mineralocorticoid receptor blockade. A sodium-restricted diet (<100 mEq sodium/d), maintenance of ideal body weight, tobacco avoidance, and regular aerobic exercise contribute significantly to the success of pharmacologic treatment. No placebo-controlled randomized trials have evaluated the relative efficacy of drugs in the treatment of primary aldosteronism.[49] Spironolactone has been the drug of choice to treat primary aldosteronism for more than three decades. Spironolactone is available as 25-, 50-, and 100-mg tablets. The dosage is 12.5 to 25 mg/d initially and increased to 400 mg/d, if necessary, to achieve normokalemia without the aid of oral potassium chloride supplementation. Hypokalemia responds promptly, but hypertension may take as long as 4 to 8 weeks to be corrected. After several months of therapy, the dosage of spironolactone often can be decreased to as little as 25 to 50 mg/d; dosage titration is based on a goal serum potassium level in the high-normal range. Serum potassium and creatinine should be monitored frequently during the first 4 to 6 weeks of therapy (especially in patients with renal insufficiency or diabetes mellitus). Spironolactone increases the half-life of digoxin, and the dosage may need to be adjusted when treatment with spironolactone is started. Concomitant therapy with high-dose salicylates should be avoided because they interfere with the tubular secretion of an active metabolite and decrease the effectiveness of spironolactone. Spironolactone is not selective for the mineralocorticoid receptor, and antagonism at the testosterone receptor and agonism at the progesterone receptor may result in painful gynecomastia, impotence, and menstrual irregularity.[50]

Eplerenone is a newer steroid-based antimineralocorticoid that acts as a competitive and selective mineralocorticoid

receptor antagonist. It was approved by the FDA for the treatment of uncomplicated essential hypertension in late 2003. The 9,11-epoxide group in eplerenone results in a significant reduction of the molecule's progestational and antiandrogenic actions compared with spironolactone; eplerenone has 0.1% of the binding affinity to androgen receptors and <1% of the binding affinity to progesterone receptors compared with spironolactone. Treatment trials comparing the efficacy of eplerenone with spironolactone for the treatment of primary aldosteronism have not been published. Eplerenone will likely be the superior drug if it is shown to be as effective as spironolactone for the treatment of mineralocorticoid-dependent hypertension and if it lacks the limiting antiandrogen side effects of spironolactone.

Patients with IHA frequently require a second antihypertensive agent to achieve good blood pressure control. Hypervolemia is a major reason for resistance to drug therapy, and low doses of a thiazide (e.g., 12.5 to 50 mg of hydrochlorothiazide daily) or a related sulfonamide diuretic are effective in combination with the mineralocorticoid-receptor antagonist. Because these agents often lead to further hypokalemia, serum potassium levels should be monitored.

Pharmacologic Treatment of Glucocorticoid-Remediable Aldosteronism

Before initiating treatment, GRA should be confirmed with genetic testing. Genetic testing should be considered in patients with a family history of primary aldosteronism, onset of primary aldosteronism at a young age (e.g., <20 years old), or a family history of stroke at a young age. In the GRA patient, chronic treatment with physiologic doses of a glucocorticoid normalizes blood pressure and corrects hypokalemia. However, treatment with spironolactone in these patients is just as effective and avoids the potential disruption of the hypothalamic-pituitary-adrenal axis and risk of iatrogenic side effects. A role for glucocorticoid therapy or mineralocorticoid receptor blockade may exist even in normotensive GRA patients.[46]

OTHER FORMS OF MINERALOCORTICOID EXCESS

The spectrum of effects of excess mineralocorticoid in patients with low PRA includes hyperdeoxycorticosteronism, Cushing's syndrome, and apparent mineralocorticoid excess (see Table 32–1). These diagnoses should be considered when PAC and PRA are low in patients with hypertension and hypokalemia (see Fig. 32–2).

Hyperdeoxycorticosteronism

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is caused by enzymatic defects in adrenal steroidogenesis that result in deficient secretion of cortisol. The lack of inhibitory feedback by cortisol on the hypothalamus and pituitary produces an ACTH-driven build-up of cortisol precursors proximal to the enzymatic deficiency. A deficiency of both 11-β-hydroxylase and 17-α-hydroxylase causes hypertension and hypokalemia because of hypersecretion of the mineralocorticoid 11-deoxycorticosterone (DOC). The mineralocorticoid effect of increased circulating levels of DOC also decreases PRA and aldosterone secretion. These defects are autosomal recessive in inheritance and typically are diagnosed in childhood. However, partial enzymatic defects have been shown to cause hypertension in adults.[51]

11-β-Hydroxylase Deficiency

Approximately 5% of all cases of CAH are due to 11-β-hydroxylase deficiency; the prevalence in whites is 1 in 100,000.[52] In addition to high levels of DOC and 11-deoxycortisol, the substrate mass effect results in increased levels of adrenal androgens. Females present in childhood with hypertension, hypokalemia, and virilization, and pseudoprecocious puberty appears in males. Approximately two thirds of patients have mild to moderate hypertension.[53] Markedly increased levels of DOC, 11-deoxycortisol, and adrenal androgens confirm the diagnosis. Glucocorticoid replacement normalizes the steroid abnormalities and hypertension. Glucocorticoid replacement options in adults include dexamethasone (0.5 to 0.75 mg daily), prednisone (5 mg in the morning and 2.5 mg in the evening), or hydrocortisone (20 mg in the morning and 10 mg in the evening). For screening, family members should have the cosyntropin stimulation test for cortisol and 11-deoxycortisol.[52]

17-α-Hydroxylase Deficiency

The 17-α-hydroxylase deficiency form of CAH is rare (only 120 cases have been reported).[54] The deficiency results in decreased production of cortisol and sex hormones. Genetic 46,XY males present with either pseudohermaphroditism or as phenotypic females, and 46,XX females present with primary amenorrhea. Therefore, a person with this form of CAH may not come to medical attention until puberty. The biochemical findings include low concentrations of plasma adrenal androgens, plasma 17-α-hydroxyprogesterone, aldosterone, and cortisol and increased plasma concentrations of DOC, corticosterone, and 18-hydroxycorticosterone, which suppress PRA. As with 11-β-hydroxylase deficiency, glucocorticoid replacement corrects the steroid abnormalities and hypertension. Sex steroids also need to be replaced. For screening, family members should have the cosyntropin stimulation test for cortisol and 17-hydroxypregnenolone.[54]

Deoxycorticosterone-Producing Tumor

DOC-producing adrenal tumors are usually large and malignant.[55,56] Some of them secrete androgens and estrogens in addition to DOC, which may cause virilization in women and feminization in men. A high level of plasma DOC or urinary tetrahydrodeoxycorticosterone and a large adrenal tumor seen on CT confirm the diagnosis. Optimal treatment is complete surgical resection.

Primary Cortisol Resistance

Increased cortisol secretion and plasma cortisol concentrations without evidence of Cushing's syndrome are found in patients with primary cortisol resistance, a rare familial syndrome.[57] The syndrome is characterized by hypokalemic alkalosis, hypertension, increased plasma concentrations of DOC, and increased adrenal androgen secretion, which are probably caused by several defects in glucocorticoid receptors and the steroid-receptor complex. The treatment for the mineralocor-

ticoid-dependent hypertension is blockade of the mineralocorticoid receptor with spironolactone or suppression of ACTH secretion with dexamethasone at the dosages outlined in the preceding sections on primary aldosteronism and CAH, respectively.[58]

Apparent Mineralocorticoid Excess Syndromes

Cortisol can be a potent mineralocorticoid. The microsomal enzyme 11-β-hydroxysteroid dehydrogenase (11-β-OHSD; EC 1.1.1.146) is responsible for the renal metabolism of cortisol to the metabolically inactive cortisone. Deficiency of this enzyme results in a high intrarenal concentration of cortisol, as well as hypertension, hypokalemia, suppressed PRA, and low aldosterone levels.[59,60] An increased ratio of urinary cortisol to cortisone confirms the diagnosis.

Two types of defects have been described in the renal metabolism of cortisol. Type 1 apparent mineralocorticoid excess (AME) syndrome refers to deficiency in the 11-β-OHSD enzyme. Type 2 AME is due to a deficiency in the ring A reduction metabolic pathway.[60] Treatment includes blockade of the mineralocorticoid receptor with spironolactone or suppression of endogenous cortisol secretion with dexamethasone. The congenital forms are rare autosomal recessive disorders.[59] The acquired forms are more common and include licorice-induced hypertension and Cushing's syndrome.

CUSHING'S SYNDROME

Hypertension occurs in 75% to 80% of patients with Cushing's syndrome.[61] The mechanisms of hypertension include increased production of DOC, increased vascular reactivity to catecholamines, and cortisol inactivation overload with stimulation of the mineralocorticoid receptor. Deficient cortisol ring A reduction caused by overload of metabolizing enzymes results in a functional type 2 AME in patients with severe hypercortisolism.[62] Cushing's syndrome is a symptom complex that results from prolonged exposure to supraphysiologic concentrations of glucocorticoids. The source of excess glucocorticoids may be exogenous (iatrogenic) or endogenous. Endogenous Cushing's syndrome is caused by (1) hypersecretion of corticotropin (ACTH), referred to as *ACTH-dependent Cushing's syndrome,* or (2) primary adrenal hypersecretion of glucocorticoids, referred to as *ACTH-independent Cushing's syndrome*. The overall treatment program for patients with Cushing's syndrome includes the resolution of hypercortisolism; the concomitant treatment of the complications of the syndrome (e.g., hypertension, osteoporosis, and diabetes mellitus); and, after definitive treatment, the management of glucocorticoid withdrawal and hypothalamic-pituitary-adrenal (HPA) axis recovery.

Presentation

Typical signs and symptoms of Cushing's syndrome include weight gain with central obesity; facial rounding and plethora; dorsocervical fat pads; easy bruising; fine "cigarette paper" skin; poor wound healing; purple striae; proximal muscle weakness; emotional and cognitive changes (e.g., irritability, crying, depression, restlessness); hypertension; osteoporosis; opportunistic and fungal infections (e.g., mucocutaneous candidiasis, tinea versicolor, pityriasis); altered reproductive function; and hirsutism.

Diagnosis

Accurate diagnosis of Cushing's syndrome and the subtype is essential to direct the appropriate treatment program. Because of the known manifestations of the disorder, hypercortisolism must be suspected and then confirmed with measurements of the serum and 24-hour urine concentrations of cortisol and midnight salivary cortisol. Autonomous hypercortisolism is confirmed with the low-dose dexamethasone suppression test (dexamethasone 0.5 mg orally every 6 hours for 48 hours); a 24-hour urinary cortisol excretion of 20 mcg or greater confirms the diagnosis. The plasma ACTH concentration classifies the subtype of hypercortisolism as either ACTH dependent ("normal" to high levels of ACTH) or ACTH independent (undetectable ACTH).

MRI of the pituitary gland should be performed in patients with ACTH-dependent Cushing's syndrome. If a pituitary tumor is not found with computerized imaging, further evaluation is indicated with imaging of the lungs and inferior petrosal sinus sampling for ACTH with ovine corticotropin-releasing hormone stimulation.

In patients with ACTH-independent hypercortisolism, the high-dose dexamethasone suppression test shows no suppression in urinary cortisol excretion. In these patients, computerized imaging of the adrenal glands usually indicates the type of adrenal disease.

Principles of Treatment

For patients with pituitary-dependent disease, selective pituitary adenomectomy by transsphenoidal surgery is the treatment of choice. The long-term surgical cure rate for ACTH-secreting microadenomas is approximately 90%. If pituitary adenomectomy is not curative, bilateral adrenalectomy and pituitary irradiation are adjunctive treatment options. For patients with primary adrenocortical disease or ectopic ACTH production, surgical extirpation of an adrenal adenoma or carcinoma or the source of ectopic ACTH production is the treatment of choice. For patients with ACTH-independent bilateral macronodular or micronodular hyperplasia, bilateral adrenalectomy is the preferred treatment. Pharmacologic therapy is reserved for patients not cured with these surgical approaches.

The hypertension associated with Cushing's syndrome should be treated until a surgical cure is obtained. Spironolactone, at dosages used to treat primary aldosteronism, is effective in reversing the hypokalemia. Second-step agents (e.g., thiazide diuretics) may be added for optimal control of blood pressure. The hypertension associated with the hypercortisolism usually resolves over several weeks after the surgical cure, and antihypertensive agents can be tapered and withdrawn.

THYROID AND PARATHYROID DISEASE

Dysfunction of the thyroid and parathyroid glands may be the sole cause of hypertension or contribute significantly to underlying primary hypertension.

Thyroid Dysfunction

Presentation and Diagnosis

Hyperthyroidism is the clinical syndrome that occurs when excessive amounts of circulating thyroid hormones interact with thyroid hormone receptors on peripheral tissues. This results in increased metabolic activity and increased sensitivity to circulating catecholamines. Thyrotoxic patients usually have high cardiac output and increased systolic blood pressure.[63]

Hypothyroidism is the syndrome resulting from deficiency of thyroid hormones, which causes many metabolic processes to slow down. The frequency of hypertension, usually diastolic, is increased threefold in hypothyroid patients.[63]

The clinical suspicion of thyroid gland dysfunction is confirmed with laboratory tests. Increased blood levels of thyroid hormones (thyroxine and triiodothyronine) and low serum levels of thyroid-stimulating hormone (TSH) are the hallmarks of hyperthyroidism. The diagnosis of hypothyroidism is based on low serum levels of thyroid hormone and increased serum levels of TSH.

Principles of Treatment

The initial management of patients with hypertension who have hyperthyroidism includes a β-adrenergic blocker (e.g., atenolol) to treat hypertension, tachycardia, and tremor. The definitive treatment of hyperthyroidism is cause specific. For example, patients with autoimmune hyperthyroidism (Graves' disease) should have thyroid gland ablation with ^{131}I. For patients with hyperthyroidism caused by multinodular goiter (Plummer's disease), ^{131}I is usually not curative and subtotal thyroidectomy is the treatment of choice. Finally, if the hyperthyroidism is associated with acute thyroid inflammation (e.g., subacute thyroiditis), only temporary treatment (≈3 months) with a β-adrenergic inhibitor may be necessary.

Treatment of thyroid hormone deficiency decreases blood pressure in most patients with hypertension.[64] Synthetic levothyroxine is the treatment of choice for hypothyroidism. The initial dosage of levothyroxine is based on body weight (1.6 mcg/kg/d). The daily dosage requirement may be lower in older patients (e.g., <1.0 mcg/kg/d). In patients older than 50 years or those with cardiac disease, the initial dosage of levothyroxine should be lower (e.g., a total of 25 to 50 mcg/d) and increased every 2 weeks by 25 mcg until the target dosage is achieved. Clinical and biochemical reevaluations should be completed at 2-month intervals until the serum TSH concentration has normalized.

Primary Hyperparathyroidism

Presentation and Diagnosis

Hypercalcemia is associated with an increased frequency of hypertension. The most common cause of hypercalcemia is primary hyperparathyroidism. The frequency of hypertension in patients with primary hyperparathyroidism varies from 10% to 60%.[65] In most cases the disease is caused by a benign, solitary, parathyroid adenoma. However, when associated with the MEN syndromes, hyperparathyroidism is usually due to hyperplasia of all four parathyroid glands.

Most patients with primary hyperparathyroidism are asymptomatic, and the focus of the presentation may be the side effects of chronic hypercalcemia: polyuria and polydipsia, constipation, osteoporosis, renal lithiasis, peptic ulcer disease, and hypertension.

The hallmarks of primary hyperparathyroidism are hypercalcemia, hypophosphatemia, and an increased serum concentration of parathyroid hormone. In patients with hypercalcemia, measurement of the serum concentration of parathyroid hormone is the most specific way to diagnose primary hyperparathyroidism. If the serum concentration of parathyroid hormone is not increased, the clinical data should be reviewed and nonparathyroid causes of hypercalcemia should be investigated (e.g., pheochromocytoma, hyperthyroidism, cancer, multiple myeloma, vitamin D intoxication, sarcoidosis).

Principles of Treatment

The treatment of hyperparathyroidism is surgical. This involves neck exploration; identification of all four parathyroid glands; and, in sporadic cases, removal of the single adenoma or, in the case of MEN, subtotal (3.5 glands) resection of the hyperplastic glands.

ACROMEGALY

Presentation and Diagnosis

Chronic growth hormone (GH) excess from a GH-producing pituitary tumor results in the clinical syndrome of acromegaly. The effects of chronic excess of GH include acral and soft tissue overgrowth; progressive dental malocclusion; degenerative arthritis related to chondral and synovial tissue overgrowth within joints; low-pitched sonorous voice; excessive sweating and oily skin; perineural hypertrophy leading to nerve entrapment (e.g., carpal tunnel syndrome); cardiac dysfunction; and hypertension. Hypertension occurs in 20% to 40% of the patients.[66-68]

A patient with acromegaly has a characteristic appearance that includes coarsening of facial features, prognathism, frontal bossing, spadelike hands, and wide feet. Often, the patient has a history of progressive increase in shoe, glove, ring, or hat size. These changes may occur slowly and may go unrecognized by the patient, family, and physician.

The diagnosis of acromegaly depends on two criteria: a GH level that is not suppressed to less than 1 mcg/L after an oral glucose load (75 to 100 g) and an increased serum concentration of insulin-like growth factor I. The laboratory assessment of acromegaly is supplemented with MRI of the pituitary.

Principles of Treatment

Treatment is indicated for all patients who have signs and symptoms of acromegaly and biochemical confirmation of the syndrome. The goals of treatment are to prevent the long-term consequences of GH excess, remove the pituitary neoplasm, and preserve normal pituitary tissue and function. Pituitary surgery is the treatment of choice; if necessary, it is supplemented with medical therapy or irradiation, or both.[69,70] The hypertension of acromegaly is most effectively

treated by curing the excess of GH. If a surgical cure is not possible, the hypertension usually responds well to diuretic therapy.

Chapter 33

Secondary Hypertension: Renal Vascular Causes

Gary L. Schwartz

CHAPTER CONTENTS

DEFINITIONS

From a pathologic standpoint, *renovascular hypertension* can simply be defined as elevated blood pressure due to renal hypoperfusion. From the clinical standpoint, it is always a diagnosis confirmed in retrospect. That is, one observes a favorable blood pressure response after successful intervention in a hypertensive patient with suggestive clinical features and a renal artery stenosis suspected of being severe enough to cause hypertension. If blood pressure fails to improve, a patient with essential hypertension and renovascular disease, not renovascular hypertension, is identified. Sorting out renovascular hypertension from essential hypertension with renovascular disease is challenging.

Arteriographic evidence of mild renovascular disease (50% lumen narrowing) was observed in 10.9% of normotensive potential renal transplant donors.[1] However, the prevalence of renovascular disease as a cause of hypertension in the general population is unknown. Estimates are generally in the range of 0.2% to 4%.[2] The presence of significant renovascular disease increases with age. In a population-based study of individuals older than age 65, the prevalence of potentially significant stenosis (>60% lumen narrowing) was 6.8% by duplex ultrasound (more common in men [9.1%] than in women [5.5%]).[3]

Ischemic nephropathy or *azotemic renovascular disease* is a loss of renal function manifested by a reduction in glomerular filtration rate (GFR) or a quantitative loss of renal parenchyma as a consequence of renal artery stenosis affecting the entire functioning renal mass (bilateral renal artery stenosis or stenosis in the renal artery of a solitary functioning kidney).[4] This subset of renovascular disease has unique clinical presentations that occur in the presence or absence of concomitant hypertension.

PATHOPHYSIOLOGY

Renovascular hypertension arises when a lesion impairs blood flow to renal tissue sufficiently to stimulate the renin-angiotensin-aldosterone cascade (Fig. 33–1). Vascular wall stretch receptors sense a reduction in renal perfusion pressure and stimulate juxtaglomerular cells of afferent arterioles to increase renin synthesis and release into the circulation.[5] Renin, a proteolytic enzyme, acts on circulating angiotensinogen formed in the liver to produce the decapeptide, angiotensin I. Angiotensin I is further acted on by the angiotensin-converting enzyme found on endothelial cells throughout the vasculature (especially in the lungs) to produce the octapeptide, angiotensin II. Angiotensin II causes vasoconstriction by a direct effect on vascular smooth muscle cells and by stimulation of the sympathetic nervous system both centrally and peripherally through facilitation of norepinephrine release from sympathetic neurons and catecholamine release from the adrenal medulla.[6] In addition, angiotensin II increases intravascular fluid volume directly by increasing reabsorption of sodium in the proximal renal tubules and indirectly by stimulating aldosterone release from the zona glomerulosa of the adrenal glands, release of antidiuretic hormone from the posterior pituitary gland, and thirst. Thus, hypertension is the consequence of both increased vascular volume and peripheral vascular resistance. Long-term effects of increased angiotensin II include vascular smooth muscle and cardiac hypertrophy.

In unilateral disease the contralateral normal kidney is exposed to increased perfusion pressure, which suppresses its release of renin and increases its excretion of sodium (pressure naturesis). To a limited extent, this dampens the pressor effect of the involved kidney but also produces a chronic stimulus for ongoing renin release. Eventually, chronic exposure to

Figure 33–1 Physiologic and pathologic consequences of renal artery stenosis. SNS, sympathetic nervous system. (Courtesy of the Mayo Clinic.)

increased systemic arterial pressure causes nephrosclerosis in the uninvolved kidney. This may be a cause of persistent hypertension following successful repair of a long-standing renal artery stenosis.

In bilateral disease, initial stimulation of the renin-angiotensin-aldosterone cascade causes an increase in vascular volume. In the absence of an uninvolved kidney, volume expansion persists and may be the dominant mechanism of hypertension. Renin secretion is often suppressed by persistent volume expansion. If vascular volume is lowered, for example by diuretic therapy, the hypertension can be converted back to a renin-dependent form.

ETIOLOGY AND NATURAL HISTORY

Any disorder that impairs perfusion to a kidney enough to stimulate the renin-angiotensin-aldosterone axis can cause renovascular hypertension. Potential causes are listed in Table 33–1. The vast majority of cases are due to atherosclerosis or fibromuscular dysplasia of the main renal arteries or their branches.

Fibromuscular dysplasia is most common in women between the ages of 15 and 50 years.[7] It is a noninflammatory, dysplastic process of the arterial wall leading to renal artery stenosis and impaired renal perfusion. Its cause is unknown, and it is not associated with other cardiovascular risk factors. Fibromuscular dysplasia is bilateral in 35% of cases. It is classified into intimal, medial, and adventitial subtypes on the basis of the layer of the arterial wall that is affected. Medial fibroplasia is the most common subtype and has a characteristic "string-of-beads" appearance on angiography. The beads are typically larger than the diameter of the normal renal segments. Perimedial fibroplasia can present as a focal stenosis or as a "string-of-beads." However, in contrast to medial fibroplasia, the beads are smaller than the normal renal segments. Intimal fibroplasia accounts for <10% of cases and may present as a focal stenosis or as a long, smooth narrowing resembling the lesions seen in large-vessel vasculitis. Adventitial hyperplasia is rare and may present with localized areas of stenosis. Fibromuscular dysplasia typically affects the mid and distal main renal artery segments, often extending into branches. Intimal and adventitial subtypes are more often associated with the complications of dissection and thrombosis. Medial fibroplasia progresses in about 30% of cases but rarely leads to occlusion. Fibromuscular dysplasia accounts for approximately 10% of cases of renovascular hypertension.[8]

Table 33–1 Potential Causes of Renovascular Hypertension

Atherosclerosis
Fibromuscular disease
Renal artery aneurysm
Atheroemboli
Vasculitis:
Takayasu's disease
Polyarteritis nodosa
Arteriovenous malformation
Aortic dissection
Renal artery dissection
Neurofibromatosis-associated renal artery disease
Renal artery trauma
Radiation-induced renal artery stenosis
Surgical ligation of the renal artery
Large intrarenal cysts
Renal artery thrombosis
Subcapsular or perirenal hematoma
Tumor compression
Retroperitoneal fibrosis
Ureteral obstruction
William's syndrome

Atherosclerotic renovascular disease is most common in persons aged 50 years or older who have cardiovascular disease risk factors or manifest atherosclerosis in other vascular beds. Atherosclerotic renovascular disease is bilateral in 30% of cases and has a progression rate of 35% to 50% over a 3- to 5-year period. Progression to occlusion occurs in 3% to 16% over this interval with a greater likelihood in more severely affected vessels at baseline.[8] Atherosclerotic renal vascular disease accounts for a small but increasing proportion of older persons reaching end-stage renal disease.[9-10] It usually affects the proximal renal artery near or at the orifice where it often represents extension of an aortic atherosclerotic plaque across the renal artery orifice.

CLINICAL SYNDROMES

The two major syndromes associated with renovascular disease are renovascular hypertension and ischemic or azotemic nephropathy (Fig. 33–2). Some patients may have manifestations of both syndromes, whereas others may lack signs or

Figure 33–2 Clinical syndromes associated with renovascular disease. RAAS, renin-angiotensin-aldosterone system; GFR, glomerular filtration rate. (Courtesy of the Mayo Clinic.)

symptoms of either. Unilateral disease is sufficient to cause the syndrome of renovascular hypertension, whereas ischemic nephropathy usually requires bilateral renal artery stenosis or significant stenosis of the renal artery to a solitary functioning kidney. An unknown number of persons with renal artery stenosis do not develop either hypertension or significant abnormalities of renal function. In some but not all cases, this is because the degree of arterial narrowing is insufficient to stimulate the renin-angiotensin-aldosterone axis. Studies suggest that luminal narrowing of >70% to 80% is necessary to stimulate renin secretion.[11] No evidence from prospective studies indicates that revascularization of renal artery stenosis in the absence of associated hypertension or renal dysfunction is of benefit.

Complicating the ability to identify patients with the syndromes of renovascular hypertension or ischemic nephropathy is the recognition that essential hypertension and chronic kidney disease commonly coexist with atherosclerotic renovascular disease. Chronic hypertension interacts with other cardiovascular risk factors to cause generalized atherosclerosis. Increasing evidence suggests that the atherosclerotic process has direct adverse effects on the intrarenal microcirculation leading to renal injury and progressive dysfunction. Aortic atherosclerotic plaques located near the origins of the renal arteries may slowly enlarge over many years and eventually extend across one or both renal artery lumens, causing some degree of stenosis. Older patients with a longstanding history of hypertension present with difficult-to-control blood pressure with or without renal dysfunction and are discovered to have renovascular disease on further evaluation. The majority of these patients will not benefit from revascularization either for blood pressure control or preservation of renal function.

RENOVASCULAR HYPERTENSION

Clinical Clues

Clinical clues suggesting renovascular hypertension are noted in Table 33–2. Essential hypertension usually has its onset in the fourth or fifth decade of life. The onset of hypertension in childhood or young adulthood should always raise suspicion of secondary hypertension. In girls or young women, fibromuscular dysplasia should be considered. The sudden onset or sudden worsening of preexisting hypertension beyond the age of 50 years, especially in a patient who smokes or has other cardiovascular risk factors or who has known coronary, carotid, or aorto-iliac atherosclerosis, should raise suspicion of renovascular hypertension either alone or superimposed on a background of essential hypertension.

Table 33–2 Clinical Clues Suggesting Renovascular Hypertension

History
Onset in childhood, young adulthood or after 50 years of age
Absence of family history of HTN
Short duration (sudden onset)
Recent worsening of preexisting HTN
Symptoms of coronary, cerebral, or peripheral vascular disease
Tobacco use
Diabetes
Accelerated or malignant HTN
Refractory HTN
Examination
Grade III or IV retinopathy
Signs of coronary, cerebral, or peripheral vascular disease (diminished pulses, bruits)
Epigastric abdominal bruit
Laboratory
Hypokalemia
Elevated creatinine
Proteinuria
Dyslipidemia (elevated total/LDL cholesterol, low HDL cholesterol)
Elevated fasting glucose
Small kidney on imaging study

HDL, high-density lipoprotein; HTN, hypertension; LDL, low-density lipoprotein.

Atherosclerosis is a systemic disease. The presence of disease in one vascular bed increases the likelihood of disease in other vascular beds. For example, significant atherosclerotic renovascular disease has been identified in 7% to 39% of patients evaluated for coronary artery disease.[12-17] In these studies, multivariate analyses demonstrated that older age, higher systolic blood pressure, a history of cerebrovascular or peripheral vascular disease, and reduced renal function were independent predictors of the coexistence of renovascular disease. In addition, renovascular disease has been noted in 36% of patients evaluated for peripheral vascular disease and 10% of patients at autopsy who had clinical evidence of stroke.[18,19]

Up to one third of patients who present with the syndrome of accelerated (retinal hemorrhages) or malignant (papilledema) hypertension have an underlying renovascular etiology. Renovascular disease is present in up to 17% of patients with type 2 diabetes mellitus[20] and in 20% of patients with resistant hypertension.[21]

The most specific finding on physical examination is the presence of an epigastric abdominal bruit. Bruits that are high pitched, continuous, or have both systolic and diastolic components suggest significant vascular stenosis. Whereas specificity is high, the sensitivity of an abdominal bruit is low; thus the absence of a bruit on examination is not sufficient to exclude the diagnosis.[22]

Laboratory findings include hypokalemia, a consequence of secondary aldosteronism. An elevated serum creatinine and a urinalysis showing proteinuria are common. Polycythemia due to excess erythropoietin production in response to renal ischemia is a rare finding. A small kidney noted on any imaging study raises suspicion for renovascular disease.

ISCHEMIC NEPHROPATHY

Clinical Clues

Clinical clues suggesting ischemic nephropathy are noted in Table 33–3.[23] Patients with ischemic nephropathy often have hypertension and evidence of extrarenal atherosclerosis.

In the setting of critical bilateral renal artery stenosis or critical stenosis of the renal artery to a solitary kidney, maintenance of transglomerular hydrostatic pressure for filtration depends on angiotensin II–mediated constriction of the efferent arterioles. Specific agents that block angiotensin II generation (angiotensin converting enzyme inhibitors [ACEIs]) or action (angiotensin receptor blockers [ARBs]) result in dilation of efferent artioles associated with an acute and occasionally progressive reduction in GFR.[24] Importantly, in chronic hypertension accompanied by nephrosclerosis, a sudden decrease in blood pressure with any therapy is often associated with a small rise in serum creatinine. This is the consequence of hypertension-related structural changes in the small arteries of the kidney that results in a shift of the renal autoregulatory range of glomerular filtration to a higher minimum blood pressure level. Changes affecting the afferent renal arterioles including endothelial dysfunction with impaired vasodilatation, hyaline arteriosclerosis, and myointimal hyperplasia render them less able to dilate in response to a sudden and significant decrease in blood pressure. This effect on renal function may be greater with drugs that promote dilation of the efferent arterioles. In contrast to changes in renal function due to ischemic nephropathy, increases in serum creatinine are small and usually stabilize or decline with long-term blood pressure control.

Table 33–3 Clinical Clues Suggesting Ischemic Nephropathy

Acute increase in serum creatinine by >20% or progressive increase on repeat testing in response to treatment with an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker
Acute (flash) pulmonary edema or symptomatic congestive heart failure not explained by cardiac etiologies
Unexplained subacute decline in renal function
Progressive decline in renal function in the presence of known unilateral renal artery disease
Unexplained renal dysfunction or end-stage renal disease

Persons in whom ischemic nephropathy should be considered often demonstrate severe (more than 20%) acute increases in serum creatinine in response to ACEI or ARB therapy or progressive rises in creatinine that do not plateau on serial testing.[24,25] In these situations, the ACEI or ARB should be discontinued and evaluation for ischemic nephropathy considered. The differential diagnosis of acute renal failure complicating ACEI or ARB therapy includes use of these drugs in settings of decreased effective blood volume (concomitant use of high-dose diuretics, severe heart failure), or renal vasoconstriction (concomitant use of nonsteroidal anti-inflammatory drugs, cyclosporine, or tacrolimus).

A spectacular presentation of ischemic nephropathy is the sudden onset of dyspnea from accumulation of fluid in the alveolar spaces of the lungs referred to as “flash pulmonary edema.”[26] Patients usually present in acute respiratory distress of sudden onset and are observed to have significantly elevated blood pressure. Blood pressure reduction with judicious use of diuretics and other medications as needed results in prompt symptomatic relief. Causative factors include underlying hypertensive heart disease with diastolic dysfunction and extracellular volume expansion from renal dysfunction and secondary aldosteronism.[27,28] Acute episodes are often precipitated by labile increases in blood pressure that are common in this disorder. The differential diagnosis of flash pulmonary edema includes cardiac etiologies (acute myocardial infarction, acute aortic or mitral insufficiency) and noncardiac causes (pulmonary embolism and pneumonia). Ischemic nephropathy should also be considered in hypertensive patients who present with congestive heart failure but who do not have ischemic or valvular heart disease.[28]

Ischemic nephropathy should also be considered in all older patients who develop a progressive rise in serum creatinine, especially if there is evidence of extrarenal atherosclerosis and the urinary sediment does not suggest glomerulonephritis.[29] It may be reasonable to consider this disorder in patients with risk factors who present with end-stage renal disease of uncertain cause before initiation of renal replacement therapy. Finally, because atherosclerotic renal vascular disease is a progressive disorder, a rising serum creatinine in a patient with a prior diagnosis of unilateral atherosclerotic renal vascular disease should prompt an evaluation for ischemic nephropathy even if blood pressure is controlled.

The differential diagnosis of a rising creatinine in an older patient with chronic hypertension and extrarenal atherosclerosis includes cholesterol embolization (atheroembolic renal disease), drug-induced interstitial nephritis, and obstructive nephropathy. Although atheroembolic renal disease is often a complication of angiography, vascular surgery, or anticoagulation, it occurs spontaneously in up to 20% of cases.[30] Its association with the development of significant and labile hypertension and a rising serum creatinine frequently raises the suspicion of renovascular disease and ischemic nephropathy. Differentiating atheroembolic renal disease from ischemic nephropathy is important because angiography or vascular interventions can precipitate further cholesterol embolization with dire consequences. Physical findings associated with systemic atheroembolic disease include livedo reticularis and the “blue toe” syndrome. Livedo reticularis consists of a blue-red mottling of the skin in a netlike pattern often visible over the lower extremities and buttocks arising from obstruction of small vessels in the deep dermis. Blue toe syndrome appears as

small, cyanotic, painful lesions on the feet or toes that may ulcerate and often are bilateral. Occasionally, cholesterol emboli are visible on retinal examination. Laboratory findings include anemia, leukocytosis, thrombocytopenia, elevation of the erythrocyte sedimentation rate, serum C-reactive protein, and eosinophilia of the blood and urine.

DIAGNOSTIC EVALUATION

Once renovascular hypertension or ischemic nephropathy is suspected, several noninvasive tests are available to evaluate the status of the renal arteries (Table 33–4). Ideally, screening tests should have sufficient sensitivity and specificity to limit use of invasive angiography (the reference standard for establishing the diagnosis) to those patients with the highest likelihood of having the disorder and benefiting from intervention. Screening tests that approach this requirement are duplex renal ultrasonography, CT angiography, and contrast-enhanced MRA. Screening tests that fail this requirement are intravenous urography, the captopril test, and plasma measurements of peripheral or renal vein renin activity.

INTRAVENOUS UROGRAPHY

This is one of the earliest tests routinely used to screen for renovascular disease. Criteria for a positive test include a difference in length of the kidneys of ≥1.5 cm, delayed appearance of contrast in the caliceal system of the involved kidney, and increased concentration of contrast in the involved kidney on late films. This test is no longer recommended because of poor test characteristics, the limitations of test interpretation and risk of contrast in the presence of azotemia, and the availability of newer and more accurate tests.[31]

PLASMA RENIN ACTIVITY, RENAL VEIN RENIN, AND THE CAPTOPRIL TEST

Although hypertension due to unilateral renal artery stenosis is renin dependent, an elevated plasma renin activity (PRA) is a nonspecific finding that is often observed in essential hypertension.[31] Moreover, PRA is highly variable in patients with renovascular hypertension and low values are frequently observed. Angiotensin II–mediated elevation of blood pressure and salt and water retention returns initially elevated PRA toward normal. In addition, variation in dietary salt intake and many medications influence PRA. All of these factors need to be controlled in order to interpret PRA properly, which makes measuring the PRA level impractical as a screening test. Additionally, in ischemic nephropathy, hypertension is usually volume dependent and associated with low PRA.

Renal vein sampling of PRA is subject to the same limitations just noted and is invasive. However, it may have a limited role in identifying patients with a nonfunctioning kidney due to renal artery occlusion who would benefit from nephrectomy.[32]

The captopril test is carried out by measuring PRA at baseline and repeating the measure 60 minutes after the oral administration of captopril. A significant captopril-induced rise in PRA is consistent with a stimulated renin-axis and increased likelihood of renovascular hypertension. Unfortunately, the effect of captopril on PRA neither significantly increases its sensitivity as a screening test nor eliminates the multiple issues just reviewed that adversely influence its value as a screening test.

CAPTOPRIL RENAL SCINTIGRAPHY

Radionuclide imaging techniques provide information about renal size, perfusion, and excretory function. The test is

Table 33–4 Screening Tests for Renovascular Hypertension

	Test Characteristics		
Test	Sensitivity	Specificity	Comments
Captopril scintigraphy[33, 40]	74% 64-94%	59% 44-98%	Poor sensitivity in presence of renal insufficiency (serum creatinine >1.5 mg/dL), bilateral disease, or disease to a solitary kidney
Duplex renal ultrasound[40]	76% 17-100%	75% 67-98%	Renal insufficiency does not interfere with test performance; does not use contrast; screens for aortic aneurysm and obstructive uropathy; allows estimation of small vessel disease in kidney (resistance index); better than MR angiography for identification of fibromuscular disease
MR angiography[50]	78% 70-87%	88% 86-91%	Renal insufficiency does not interfere with test performance; contrast is non-nephrotoxic; provides images of the aorta, kidneys, and adrenal glands; better than ultrasound for identification of accessory renal arteries and identification of atherosclerotic lesions in obese patients; claustrophobia limits use in some patients
CT angiography[50]	77% 67-86%	94% 92-95%	Provides images of the aorta, kidneys, and adrenal glands; large contrast load limits use in settings of renal insufficiency or contrast allergy: limitations in obese subjects; better than ultrasound for identification of accessory renal arteries; excellent test for identification of renal artery aneurysms and dissection

performed 60 minutes after the oral ingestion of a 50-mg dose of captopril. Radionuclide agents used are radiolabeled pentetic acid (diethylenetriamine pentaacetic acid [DTPA]), a marker of glomerular filtration, or mertiatide (mercaptoacetultriglycine [MAG_3]), a marker of renal blood flow. Renal measurements used to assess for renal artery stenosis include time to maximal radionuclide activity, peak activity, time course of cortical elimination of radionuclide, and estimated single kidney GFR. The rationale for use of captopril is the recognition that in the presence of a critical renal artery stenosis, transcapillary pressure for glomerular filtration depends on angiotensin II–mediated efferent arteriolar constriction. By inducing efferent arteriolar vasodilation, captopril causes an acute decline in GFR and renal blood flow in the affected kidney that is detected by comparing the rates of uptake and excretion of the radionuclide by the individual kidneys. Initial studies performed in highly selected samples in research settings suggested high sensitivity and specificity; however, when studied in clinical practice settings, sensitivity and specificity were similar to those of intravenous urography.[33] Thus, its role in screening for renovascular hypertension is being called into question.

RENAL DUPLEX ULTRASONOGRAPHY

Renal duplex ultrasonography combines B-mode ultrasound with Doppler examination. It is a useful screening test because it provides information about the location and severity of stenosis; provides an estimate of renal size; screens for obstructive uropathy and aortic aneurysm; is safe to perform in the setting of renal insufficiency; is not affected by renal dysfunction; does not require comparisons between the kidneys for interpretation; provides a measure of small vessel disease in the kidneys; and is relatively inexpensive to perform.[31,34] In addition, duplex ultrasonography is the noninvasive test of choice for the follow-up of renal artery stenosis after stent placement. MRA is affected by scatter or artifact produced by the stent. CT angiography can be used but requires contrast and is more expensive than duplex ultrasonography.[35] Diagnosis of renal artery stenosis relies on identification of increases in blood flow velocity at the site of the stenosis. A stenosis of >60% is associated with a peak systolic velocity >200 cm/sec and a renal-to-aortic peak systolic velocity ratio of >3.5.

Measurement of flow velocity in the renal segmental arteries allows calculation of the "resistance index" ([1 – (end-diastolic velocity ÷ maximal systolic velocity]) × 100). Elevation in this measure reflects structural alterations in the small renal arteries associated with nephrosclerosis and identifies patients at increased risk of progressive renal disease.[36] A resistance index >80 may identify patients with renal artery stenosis in whom interventions to relieve the stenosis are less likely to result in blood pressure reduction, improvement in renal function, or long-term kidney survival.[37] However, this may not be highly reliable as an index of poor response to treatment because of a study that showed improvements in blood pressure and renal function in stented patients in whom the resistance index was higher than 80.[38]

Duplex ultrasonography requires significant operator skill, it may miss accessory renal arteries (sensitivity ≈67%) or stenosis in the distal main renal artery or branches, and it is technically unsatisfactory in 4% to 13% of cases due to obesity or the presence of excessive bowel gas.[31]

COMPUTED TOMOGRAPHIC ANGIOGRAPHY

CT angiography provides images of the renal arteries and aorta. This study also provides an estimate of renal size and imaging of renal and adrenal morphology.[39] CT angiography consists of an initial noncontrast CT image of the abdomen followed by CT angiography. Axial images are obtained during a breath hold timed to coincide with the arterial phase of a bolus infusion of contrast into a peripheral vein. The acquired data are then reformatted using several different software programs to obtain 2- and 3-D reconstructed images. Operator experience, equipment, and variation in the reformatting technique used can influence test performance. Overall sensitivity and specificity are higher than for duplex ultrasound.[40] However, a relatively large amount of contrast is required (120 to 150 mL), limiting its use in the setting of renal insufficiency or contrast allergy; it uses ionizing radiation; and it is more expensive than duplex ultrasonography. Similar to duplex ultrasonography, this study is less useful in obese patients due to limitations of table movement for image acquisition. Patients must be able to suspend respiration during image acquisition because respiratory artifact can significantly degrade image quality. Atherosclerotic disease is identified more readily than fibromuscular disease. CT angiography is a good test to identify renal artery dissection and aneurysms and is better than duplex ultrasound for identification of accessory renal arteries.

CONTRAST-ENHANCED MAGNETIC RESONANCE ANGIOGRAPHY

Similar to CT angiography, contrast-enhanced MR angiography provides images of the renal arteries, aorta, kidneys, and adrenal glands.[41] The test begins with routine T1- and T2-weighted images for evaluation of the abdominal organs including the kidneys and adrenal glands. Subsequently, data are acquired during a breath hold timed to coincide with the arterial phase of a bolus infusion of gadolinium from an antecubital vein. Similar to CT angiography, software programs are then used to construct 3-D multiplane reformations. Although MR angiography itself is operator independent, considerable expertise is required for processing and interpretation of the images. In addition, patients must be able to suspend breathing during data acquisition because respiration can induce significant artifact. Unlike CT angiography, this test can be performed safely in the setting of renal insufficiency or contrast allergy. Contrast-enhanced MR angiography is better than duplex ultrasonography in identifying accessory renal arteries and does not require exposure to ionizing radiation. Overall, sensitivity and specificity are similar to those of CT angiography.[40] Contrast-enhanced MR angiography is superior to duplex ultrasonography for the identification of atherosclerotic lesions, especially in obese subjects.[42,43] However, it is more expensive and has reduced sensitivity for the identification of fibromuscular dysplasia, which is better identified by duplex ultrasonography. In up to

one third of patients the severity of the stenosis may be overestimated.[44] Not all patients can be examined with MR imaging. Claustrophobia is a limitation that often can be overcome with the use of sedatives. Patients with metallic implants, such as mechanical heart valves and cerebral aneurysm clips, or electrically activated implants, such as pacemakers, cannot be studied.

CONTRAST ANGIOGRAPHY

Contrast angiography remains the reference standard. Percutaneous intervention with or without stenting can be carried out at the time of diagnostic angiography if an amenable lesion is identified. A major advantage of contrast angiography is superior spatial resolution allowing for clear visualization of all portions of the renal artery including branches and identification of accessory renal arteries. However, a limitation of angiography is the restricted number of planes of projection that may cause underestimation of the severity of eccentric stenoses and make it difficult to identify the origins of the renal arteries in the presence of a tortuous aorta. In addition, risks of contrast angiography include access site complications of hematoma, pseudoaneurysm, and arterial venous fistula, contrast-induced allergy and acute renal failure, and atheroemboli.

Contrast-induced acute renal failure is associated with increased morbidity and mortality. It is uncommon in patients with normal renal function. Risk factors in the setting of impaired renal function include high doses of ionic, hyperosmolar contrast agents; diabetes; congestive heart failure; volume depletion; and concomitant use of potentially nephrotoxic drugs.[45,46] A number of methods have been studied to reduce the risk of contrast-induced acute renal failure. Hydration with 0.9% saline is helpful. In addition, use of smaller doses of nonionic, low osmolar agents is beneficial. Hydration with a sodium bicarbonate solution has also been shown to be promising.[49] Finally, the use of noniodinated contrast agents, such as CO_2 and gadolinium, should be considered in the setting of significant renal dysfunction (GFR <30 mL/min or serum creatinine >2.0 mg/dL).

APPROACH TO THE DIAGNOSTIC EVALUATION

Figure 33–3 depicts an approach to the diagnostic evaluation for identification of renovascular disease. A number of caveats regarding screening tests for renovascular disease should be kept in mind.

First, estimates of the test characteristics of the available noninvasive screening tests vary widely (see Table 33–4). This may be due to several factors including variation in expertise of test performance and interpretation, publication bias, and sample selection. A meta-analysis of diagnostic tests for renal artery stenosis demonstrated superior diagnostic accuracy of duplex ultrasonography, CT angiography, and contrast-enhanced MRA over captopril scintigraphy.[43] Thus, these three tests should be considered as the preferred noninvasive screening tests for identification of renal artery stenosis. Overall, diagnostic accuracy of CT angiography and contrast-enhanced MRA appears to be superior to duplex ultrasonography; however, cost, local availability and expertise, and patient-specific factors are important considerations for specific test selection.

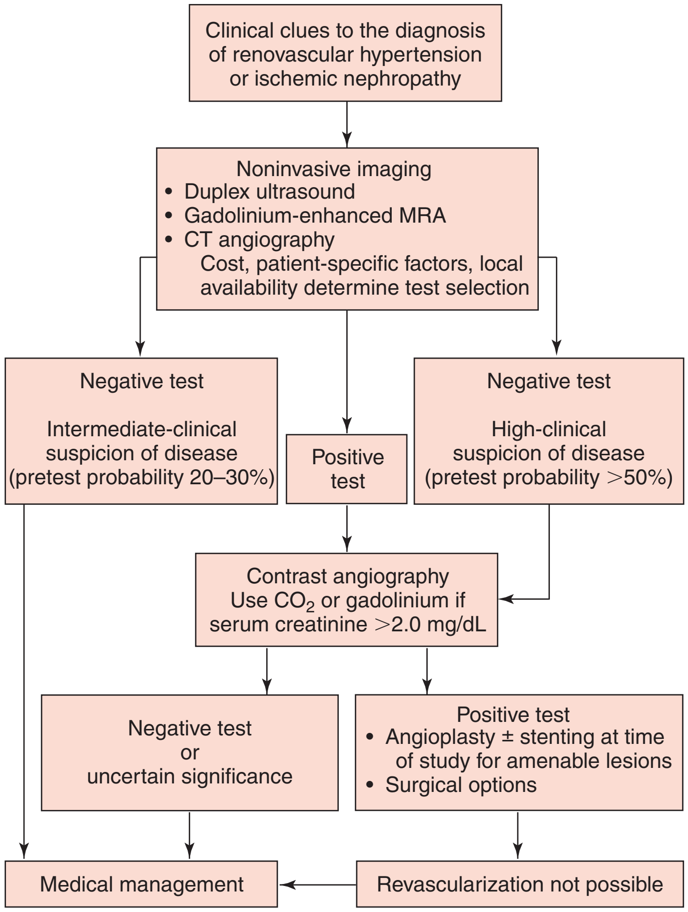

Figure 33–3 Diagnostic approach for renovascular hypertension. CT, computed tomography; MRA, magnetic resonance angiography.

Second, the noninvasive tests are better for identification of atherosclerotic disease than for fibromuscular dysplasia. Overall, duplex ultrasound is probably the best choice to screen for fibromuscular disease. In patients with a high probability of fibromuscular disease, contrast angiography should be considered if the results of noninvasive screening are ambiguous.

Third, a multicenter, prospective comparative study of CT angiography and contrast-enhanced MRA demonstrated that both studies had sensitivities below 90% for detection of significant atherosclerotic renal artery disease.[50] Thus, given our current understanding of the diagnostic accuracy of noninvasive tests, their primary value appears to be in the evaluation of patients with an intermediate pretest probability of disease (20% to 30%). This is the most commonly encountered circumstance in clinical practice. In this setting a technically satisfactory noninvasive screening test that is negative reduces the post-test probability of disease to <5%, a probability that does not justify further evaluation (see Chapter 1). On the other hand, if the pretest probability is >50%, a negative screening test still results in a significant residual (post-test) probability of disease, often >20%, a level that may justify further evaluation. Thus, in the setting of a high pretest

probability of disease, contrast angiography should be considered either as the initial test in patients at low risk of complications from the study or as a subsequent study if the results of noninvasive screening tests are ambiguous. Clinical prediction rules to estimate the pretest probability of renovascular disease are available.[51,52]

MANAGEMENT OF RENOVASCULAR DISEASE

The major treatment goals are to reduce morbidity and mortality by lowering blood pressure and improving or stabilizing renal function. Treatment options include several revascularization procedures consisting of various surgical options or angioplasty with or without endovascular stenting or conservative medical management. Because "cure" of hypertension is often not achieved, most patients with renovascular disease and hypertension require lifelong medical management regardless of the use of revascularization therapies. In addition to blood pressure control, medical management includes identification and treatment of all modifiable cardiovascular risk factors because the most common causes of morbidity and mortality in hypertensive patients with renovascular disease are coronary artery disease and stroke.

MEDICAL THERAPY

Because renovascular disease is a potentially curable form of hypertension, the first consideration should be for revascularization. However, there are several settings in which medical therapy without concomitant revascularization is a reasonable option (Table 33–5). Medical therapy is appropriate if the hemodynamic significance of a renal artery lesion is questionable, if it is not amenable to revascularization because of its location (lesions in segmental arteries or involving branch points), or if the patient declines interventional therapy. Many older patients with long-standing hypertension and chronic, stable renal insufficiency are discovered to have renovascular disease. As noted earlier, the majority of these patients have essential hypertension and should be treated medically. Medical therapy is also preferred if the renal artery lesion is hemodynamically significant but there is evidence of advanced ischemic injury to the affected kidney manifest by renal atrophy (cortical thinning, renal length <8 cm) or a high resistance index by ultrasonography (>80).[37] In addition, medical therapy is the appropriate option for most patients with a significant elevation of serum creatinine and associated markers of parenchymal renal disease because the risk of renal failure associated with invasive therapies is high and the favorable outcomes of lower blood pressure and improved renal function are rarely observed. This would include patients with unilateral disease and a serum creatinine >2.5 mg/dL or patients with bilateral disease and a serum creatinine >3.0 mg/dL, especially in the presence of markers of parenchymal renal disease (cortical atrophy, small kidneys, high resistance index). Lastly, the medical option may be chosen if atherosclerotic renovascular disease is present in a patient who is at high risk for surgery and who has a severely diseased aorta with ulcerative plaques, for which the risk of atheroembolism from catheter based intervention is increased.

Table 33–5 Indications for Medical Treatment of Renovascular Hypertension

Uncertain hemodynamic significance of the renal artery lesion
Renal artery stenosis not amenable to revascularization
Patient declines revascularization
Chronic stable hypertension and renal dysfunction
Evidence of advanced ischemic injury to the stenotic kidney
Advanced renal insufficiency
Unilateral renal artery stenosis with a serum creatinine >2.5 mg/dL
Bilateral renal artery stenosis with a serum creatinine >3.0 mg/dL
Renal artery stenosis and a severely diseased aorta

The goal of drug therapy should be to lower office blood pressure to <140/90 mm Hg. In the presence of concomitant diabetes mellitus or chronic kidney disease, a lower goal of <130/80 mm Hg should be achieved.[53] Pharmacologic treatment should be focused on blocking angiotensin II production or the angiotensin II receptor, or both, and the postreceptor effects of angiotensin II, as well as lowering blood pressure to goal. Importantly, most patients with renovascular disease have resistant hypertension and require antihypertensive drugs in addition to those that block the renin-angiotensin-aldosterone system (RAAS). Angiotensin converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) should be considered as initial drugs of choice. The availability and widespread use of these drugs are largely responsible for improved blood pressure control rates in patients with renovascular disease.[54] Because these drugs only partially inhibit the production of angiotensin II or interaction of angiotensin II with its receptor, titration to maximum-tolerated doses is often beneficial. Moreover, dual blockade of the renin-angiotensin cascade by using combination therapy with both an ACEI and an ARB can be more effective than either agent used alone. This option can be considered in cases of resistant hypertension if other strategies have failed.[55] When these classes of drugs are used, serum creatinine and potassium should be measured within 1 week of initiation of therapy and with subsequent dose increases.

Angiotensin II stimulates production and release of aldosterone from the zona glomerulosa of the adrenal glands leading to salt and water retention, which contributes to blood pressure elevation in patients with renovascular disease. Moreover, reduction in aldosterone levels observed acutely with ACEI or ARB therapy often becomes less evident with chronic therapy.[56] This phenomenon of "aldosterone escape" may be due to an increase in angiotensin II formation from alternative non-ACE pathways interacting with a reactive increase in the number of angiotensin II receptors. In addition, hyperkalemia from ACEI or ARB therapy stimulates aldosterone production. Thus, diuretic therapy is highly effective in combination with ACEI or ARB therapy for blood pressure control in the majority of patients with renovascular hypertension. In cases of resistant hypertension, the use of specific mineralocorticol receptor antagonists can also be considered, especially if aldosterone is observed to be elevated; however, if these agents are used in combination with an ACEI or ARB, potassium must be carefully monitored.

Multiple other antihypertensive drugs are potentially useful. Renovascular hypertension is characterized hemodynamically by increased peripheral vascular resistance; thus direct vasodilators are useful. These include the calcium channel blockers, hydralazine, and minoxidil. When used alone, hydralazine and minoxidil cause reactive fluid retention and sympathetic nervous system stimulation, so they should be used only in combination with a diuretic and an adrenergic inhibitor. β-Blockers are also useful in part because of their ability to inhibit sympathetically mediated renin release. Finally, because angiotensin II stimulates sympathetic nervous system activity, sympatholytic drugs, such as clonidine or guanfacine, can be considered. However, because of their side-effect profiles, these drugs are generally used selectively in patients who are not controlled with standard therapies.

In all patients with renovascular hypertension and especially in those with atherosclerotic disease, medical management should also include therapies to inhibit progression of atherosclerosis. Treatments include smoking cessation strategies, platelet inhibition, and the use of pharmacologic therapies for lipid control. Therapy with statins may retard progression or even induce regression of atherosclerotic renal vascular lesions.[57]

Blood pressure reduction without revascularization can aggravate ischemic injury to an affected kidney. In addition, progression of a lesion to occlusion or renal artery thrombosis with irreversible loss of the affected kidney can occur. These adverse outcomes are rare with fibromuscular disease and primarily occur in atherosclerosis. In unilateral disease, these adverse events are not always associated with a rise in serum creatinine. In bilateral disease or in unilateral disease in the presence of nephrosclerosis, a small rise in creatinine with acute blood pressure reduction is common, especially following initiation of therapy with an ACEI or ARB.[24] In some cases this is due to the acute loss of angiotensin II–dependent efferent arteriolar vasoconstriction, which is needed to maintain adequate transcapillary glomerular pressure for filtration. In other cases, it is simply due to reduction in systemic blood pressure below the level of autoregulation of glomerular filtration in kidneys harboring changes of nephrosclerosis from chronic hypertension. With continued therapy, creatinine stabilizes and may decline. However, in 2% to 6% of cases, a large increase in creatinine may occur acutely following initiation of treatment with an ACEI, ARB, or diuretic.[58] This change can be quickly reversed by reducing or discontinuing diuretic, ACEI, or ARB therapy. Following recovery of renal function, revascularization should be considered in patients with bilateral disease.

Overall, the development of progressive renal failure is uncommon in most patients with atherosclerotic disease managed medically.[59-61] Nevertheless, this potential adverse outcome should be discussed with the patient at the onset of medical therapy. Serial measures of renal function and size are important components of follow-up care. A rising serum creatinine should trigger a diagnostic evaluation that includes evaluation for progressive renal artery occlusive disease and the possible need for revascularization.

REVASCULARIZATION

Although it is uncertain whether revascularization strategies are superior to medical treatment in most patients with renovascular disease and hypertension or renal dysfunction, it is reasonable to consider some subgroups for interventional therapy (Table 33–6). In general, patients with recent onset hypertension (<5 years' duration) or those with chronic hypertension who experience an unambiguous acute increase in blood pressure are more likely to have a favorable outcome from revascularization than are patients with chronic stable hypertension.[8] In addition, patients who have a good blood pressure response to an ACEI or ARB are likely to have a similar response to successful revascularization, although the opposite is not always true. In younger patients, who are at lower risk of complications, elimination of or reduction in the need for antihypertensive medications is an appropriate indication for choosing revascularization. This group includes most patients with fibromuscular dysplasia and some patients with atherosclerotic renal disease. Whether revascularization results in lower rates of morbidity, mortality, or end-stage renal disease than medical management and good blood pressure control in the long term remains uncertain.

Generally, patients with refractory hypertension have benefited from revascularization with lower blood pressure and a reduced medication requirement.[62] Refractory hypertension is defined as blood pressure above goal despite the use of full doses of three antihypertensive drugs including a diuretic. Some patients have refractory hypertension because of intolerance to medication or poor compliance with long-term treatment. They should also be considered for revascularization.

In current practice, preservation of renal function is a more common indication for revascularization than blood pressure control. This indication occurs almost exclusively in patients with atherosclerotic renal artery disease. They are usually older and have evidence of systemic atherosclerosis. Identifying patients who are most likely to experience improvement or stabilization of renal function from revascularization

Table 33–6 Indications for Renal Revascularization

Fibromuscular dysplasia
Atherosclerosis:
Younger patients (<70 yr old) with recent onset or worsening of hypertension
Refractory hypertension
Full doses of 3 drugs, including a diuretic appropriate for level of renal function
Hypertension-dependent renal function
Compelling indication for ACEI or ARB therapy + ACEI or ARB-induced acute renal failure
Flash pulmonary edema
Refractory congestive heart failure with bilateral renal artery stenosis
Recent and progressive decline in renal function:
Critical stenoses that are bilateral or stenosis in a solitary functioning kidney
Renal size >8 cm, resistance index <80, serum creatinine <3.0 mg/dL
Other causes of renal dysfunction excluded (obstruction, interstitial nephritis, atheroembolic renal disease, glomerular disease)

ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker.

is challenging. For patients with a recent and progressive rise in creatinine that is unexplained and who have markers of "salvageable" kidneys based on adequate renal size, cortical thickness and normal resistance indices are most likely to benefit from revascularization procedures. Studies to date have shown that revascularization procedures in patients with renal insufficiency are associated with improved renal function in approximately 25% of cases and no acute change but long-term stabilization of renal function in approximately 50%. Of concern is the observation that in approximately 25% of patients, renal function continues to deteriorate, sometimes in an accelerated fashion, following a revascularization procedure.[63] The factors that cause acute deterioration in renal function are not well understood but include renal atheroembolization and contrast toxicity. Given the potential for worsening of renal function with intervention, patients with stable chronic renal insufficiency and controlled blood pressure should probably not be considered for revascularization. With rare exception (subacute decline in renal function with normal-sized kidneys), patients with advanced renal insufficiency (serum creatinine >3.0 mg/dL) do not benefit from revascularization.

As noted previously, in some patients with bilateral renal artery stenosis, lowering of systemic pressure with any drug combination reduces renal perfusion pressure below the autoregulatory range, causing an acute and progressive decline in renal function. In such patients, adequate control of blood pressure and stable renal function cannot be achieved and revascularization should be considered. In patients who demonstrate acute renal failure with ACEI or ARB therapy and in whom a compelling indication for use of these drugs exists, revascularization may be reasonable.

Lastly, bilateral atherosclerotic renal artery stenosis can be an important precipitating cause of recurrent episodes of flash pulmonary edema and congestive heart failure. Revascularization has been shown to be effective in reducing the frequency of such events in association with significant decreases in blood pressure.[64]

PERCUTANEOUS INTERVENTION

Percutaneous angioplasty is the treatment of choice for amenable lesions due to fibromuscular dysplasia. The major indication is hypertension because this disease rarely progresses to total occlusion with loss of renal function. The majority of patients are young and have normal renal function; thus the risks of intervention are minimal. Technical success rates are >90%. Cure rates of hypertension range from 14% to 59%, and improvement rates range from 21% to 59%. Failure rates range from 2% to 30%.[7] Restenosis rates are <10%. Stenting is rarely required but is used if angioplasty results are inadequate or if renal artery dissection occurs.

Stent-supported angioplasty has supplanted surgery in most centers for the treatment of atherosclerotic renal artery stenosis. Stenting is required for ostial lesions. Compared with angioplasty alone, stent-supported angioplasty is associated with a higher technical success rate and a lower restenosis rate in follow-up.[65] Currently, restenosis at 1 year occurs in approximately 26% of patients treated with angioplasty alone compared with 17% treated with stent-supported angioplasty.

Complications of percutaneous intervention occur in 7% to 11% of cases. The most frequent complication is groin hematoma. More severe complications include renal failure, segmental renal infarction, renal artery rupture, dissection or thrombosis, and atheroembolization. The use of distal protection devices to trap embolic debris may lessen the latter complication, but this needs further study.

SURGERY

Surgical revascularization is largely reserved for patients who have lesions that are not amenable to percutaneous intervention or in whom percutaneous therapy has failed. In addition, surgery is the treatment of choice when concomitant replacement of the aorta (aneurysm or severe aorto-iliac disease) is required. Long-term results of surgery on blood pressure and renal function have been favorable.[66] In patients with minimal aortic disease, aorto-renal bypass using an autogenous segment of the saphenous vein or hypogastric artery is commonly performed. A synthetic graft can be placed if an autogenous graft is not available. Renal artery endarterectomy is also commonly performed. In older patients with severe atherosclerosis of the abdominal aorta, hepato-renal bypass on the right and spleno-renal bypass on the left can be performed. Such interventions require a patent celiac artery. Additionally, in these patients, renal artery bypass to the supra-celiac or lower thoracic aorta can be considered. Operative mortality ranges from 2% to 8% and is higher in patients who require aortic replacement. The most common causes of death are myocardial infarction and stroke. Evaluation for and correction of significant coronary or carotid disease before renal revascularization is advocated by some experts, but the impact on operative mortality has not been formally assessed. Lastly, nephrectomy can be considered for atrophic kidneys due to renal artery occlusion. Lateralization of renal vein renin levels to the affected kidney predicts an increased likelihood of lower blood pressure with surgery.[32] Laparoscopic techniques have lessened the morbidity associated with this procedure.

Chapter 34

Treatment of Hypertension in the Patient with Cardiovascular Disease

George Chrysant and Suzanne Oparil

CHAPTER CONTENTS

Approximately 70 million Americans have CVD including 65 million with HTN, 13 million with CHD, 5.5 million with stroke, 1 million with congenital heart disease, and 5 million with HF (Fig. 34–1).[1,2] HTN both accelerates the progression of atherosclerotic disease and leads to LVH, resulting in diminished coronary reserve and exacerbating the ischemic effects of obstructive CHD. Approximately 50% of CHD events and 65% to 70% of strokes are due to suboptimal control of blood pressure.[3]

The risk of CVD in the patient with HTN can be greatly reduced with effective antihypertensive therapy, and the major reductions in CVD morbidity and mortality over the past 50 years have been attributed, in part, to the increased availability and utilization of antihypertensive therapy.[4] The use of antihypertensive drugs has greatly increased in the past 50 years. For example, in the Framingham Heart Study cohort, antihypertensive drug use increased from 2.3% to 24.6% in men and from 5.7% to 27.7% in women over this period. This correlated with a decline in the prevalence of high BP, particularly severe HTN (SBP > 160 mm Hg or DBP > 100 mm Hg) from 18.5% to 9.2% in men and 28% to 7.7% in women, as well as a reduction in the prevalence of LVH over the same period. Reductions of 4 to 8 mm Hg in mean BP reduce the risk of stroke and CHD by 28% to 38% and 20% to 22%, respectively.[5]

Abbreviations: ACEI, angiotensin converting enzyme inhibitor; ACS, acute coronary syndromes; AF, atrial fibrillation; MI, myocardial infarction; ARB, angiotensin II type 1 receptor blocker; BB, beta-adrenergic receptor blocker; BP, blood pressure; CCB, calcium channel blocker; CVD, cardiovascular disease; CHD, coronary heart disease; DM, diabetes mellitus; DBP, diastolic blood pressure; ESRD, end-stage renal disease; HF, heart failure; HTN, hypertension; ISH, isolated systolic hypertension; LVEF, left ventricular ejection fraction; LVMI, left ventricular mass index; LVH, left ventricular hypertrophy; PP, pulse pressure; PAD, peripheral arterial disease; PWV, pressure wave velocity; RAAS, renin-angiotensin-aldosterone system; RWT, relative wall thickness; SBP, systolic blood pressure; U.S., United States.

In a meta-analysis of 61 studies of 1 million adults with no previous vascular disease recorded at baseline, BP was directly related to fatal CHD, fatal stroke, and overall mortality over the entire range down to a BP of 115/75 mm Hg.[6] For persons 40 to 69 years of age, each reduction in SBP of 20 mm Hg (or 10 mm Hg in DBP) reduced the relative risk of fatal stroke (hazard ratio 0.36 to 0.43), fatal CHD (0.49 to 0.54), and death by more than half (Fig. 34–2A and B). Absolute risk of these outcomes increases greatly with age, such that for any given SBP the absolute risk of fatal stroke or CHD is increased more than 15-fold for persons aged 80- to 89-years-old compared with those aged 50- to 59-years-old. Accordingly, for any given reduction in SBP, the reduction in absolute risk of fatal stroke or CHD is more than 15-fold greater in the older than in the younger age groups, supporting the concept that treating hypertension in the elderly is highly beneficial.

The risk of CVD morbidity and mortality in persons with HTN is also influenced by concomitant CVD risk factors, target organ damage, or established CVD. A 25-year observational study of men from different parts of the world (U.S., Japan, Serbia, Northern Europe, Mediterranean southern Europe, inland southern Europe) showed that, although the relative increase in mortality from CHD for a given increase in BP did not differ significantly among the six groups, the absolute age-adjusted mortality risk from CHD at the same level of BP elevation varied by a factor of > 3 among populations.[7] These findings highlight the importance of assessing total CVD risk when considering treatment options for persons with HTN (Table 34–1).[8] Hypertensive persons with established CVD, diabetes, or renal insufficiency are at the highest risk for CVD morbidity and mortality and deserve the most aggressive treatment. This chapter discusses the assessment and therapy of hypertensive persons with concomitant CVD. Treatment considerations for diabetics and persons with renal insufficiency are discussed in Chapter 35.

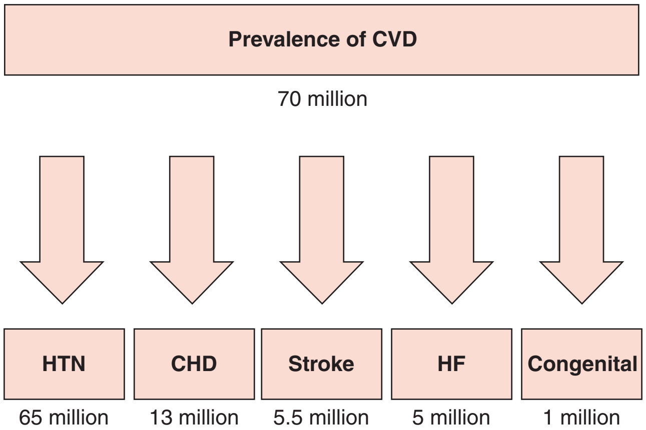

Figure 34–1 The prevalence of hypertension, coronary heart disease, stroke, congenital heart disease, and heart failure in the United States. From NHLBI Morbidity and Mortality Chart Book, 2005. (Reproduced with modification from Morbidity and Mortality: 2005 Chartbook on Cardiovascular, Lung and Blood Diseases. National Institute of Health. National Heart, Lung and Blood Institute).

SYSTOLIC BLOOD PRESSURE, ISOLATED SYSTOLIC HYPERTENSION, PULSE PRESSURE, AND CARDIOVASCULAR DISEASE RISK

SBP is a more robust predictor of HTN-related morbidity and mortality than is DBP in persons 50 years or older, in whom it represents a form of target organ damage resulting from prolonged BP elevation. Further, randomized controlled outcomes trials of antihypertensive treatment have demonstrated a robust linear relationship between treatment-related reduction in SBP and risk for a variety of outcomes including stroke, CHD, CVD death, total mortality, and major CVD events, independent of drug class administered.[5] Accordingly, current hypertension treatment guidelines recommend targeting SBP rather than DBP in managing the older hypertensive patient.[8] In persons who have elevated or high normal BP at an early age, the increased wall tension leads to thinning, fragmenting, and fracture of elastin fibers, as well as increased collagen deposition in the central arteries, resulting in progressive stiffening and decreased compliance of these vessels. In addition to these structural abnormalities, endothelial dysfunction, which develops over time as a consequence of both aging and HTN, contributes functionally to increased arterial rigidity in elderly persons with a widened PP and subsequent ISH.[9-12] Reduced nitric oxide (NO) synthesis or release in this setting, or both, results in diminished endothelium-dependent vasodilation of forearm vessels and contributes to increased wall thickness of conductance vessels, such as the common carotid artery.[13]

Isolated elevation of SBP is common with increasing age because SBP rises continuously until the eighth or ninth decade of life, while DBP levels off or declines after the sixth decade.[12,14] In older individuals, the diagnosis of HTN is more often made on the basis of SBP than DBP. The combination of increased SBP and decreased DBP creates a widened PP and contributes to the increased prevalence of ISH with advancing age. ISH (BP > 160/ < 90 mm Hg) occurs in 15% of men and women aged 60 years or older and in more than 20% of those aged 80 years and older.[14] As PP widens, it begins to correlate closely with SBP due to increased arterial stiffness and decreased compliance.[12] PP has been linked to advanced atherosclerotic disease and CVD events, such as fatal and nonfatal MI and stroke, and is a better predictor of CVD risk than SBP or DBP alone.

Compliance is defined as "the relationship between changes in distending pressure (ΔP) inside the artery and concomitant changes in radius [or in volume (ΔV)]," and is represented by the slope of $\Delta V/\Delta P$. As arterial stiffness increases, a higher distending pressure is required for a given change in the radius of the artery.[15] Increasing arterial stiffness, as indexed by PWV, contributes to a greater PP. A pressure wave is generated with each ejection of blood from the LV. The pressure wave moves away from the heart at a finite speed that is dependent on compliance. The wave is reflected at any point of discontinuity in the arterial tree, and the reflected wave returns to the aorta and LV. In younger persons, the PWV averages 5 m/s. At this speed, the reflected wave usually reaches the aortic valve after closure, leading to a higher DBP and enhancing coronary perfusion by providing a "boosting" effect. As persons age and central arterial compliance decreases, PWV can reach 20 m/sec. At this speed the reflective wave reaches the aortic valve before closure, leading to both a higher SBP and afterload and a decreased DBP, in some cases compromising coronary perfusion pressure.[16] Other factors, such as a slow heart rate, can also affect PWV and augmentation of central aortic systolic pressure. Augmentation of central aortic systolic pressure, as seen in aging and in the presence of hypertension or arterial disease, or both, greatly increases cardiac work and pressure-related cardiac pathology because it is the pressure against which the LV must eject blood into the systemic circulation.[17]

Direct measurement of central aortic pressure is not practical in a clinical setting because it requires invasive arterial catheterization. Instead, central aortic pressure waveforms are derived from peripheral (radial) artery pressure waveforms recorded directly by applanation tonometry using a validated generalized transfer function.[18-21] Computerized analysis is used to delineate first (outgoing) and second (reflected) pressure wave components (T1, T2) during systole (Fig. 34–3). The pressure at the peak of the outgoing pressure wave is identified as P1, and the pressure difference between this point and the maximal pressure during systole (ΔP, or augmentation) is identified as the reflected pressure wave occurring during systole. Augmentation index is defined as the ratio of augmentation to central pulse pressure and is expressed as a percentage ($A|x = (\Delta P/PP) \times 100$). Pulse pressure amplification is expressed as the ratio of central pulse pressure (CPP) to peripheral (brachial) pulse pressure (PPP) (PP amplification = PPP/CPP). This methodology, although technically challenging, is being applied in the research setting to mechanistic and outcome studies of antihypertensive therapies.

The measurement of PWV involves recording the time interval of the pulse between two points, which are usually the carotid artery and the femoral artery using two pressure transducers and the distance traveled (PWV [m/sec] = distance [m]/transit time [sec]). This can be achieved using two methods. The first is to manually record the time interval between the carotid and femoral arteries over the course of 10 heart beats followed by correcting for the paper speed (time

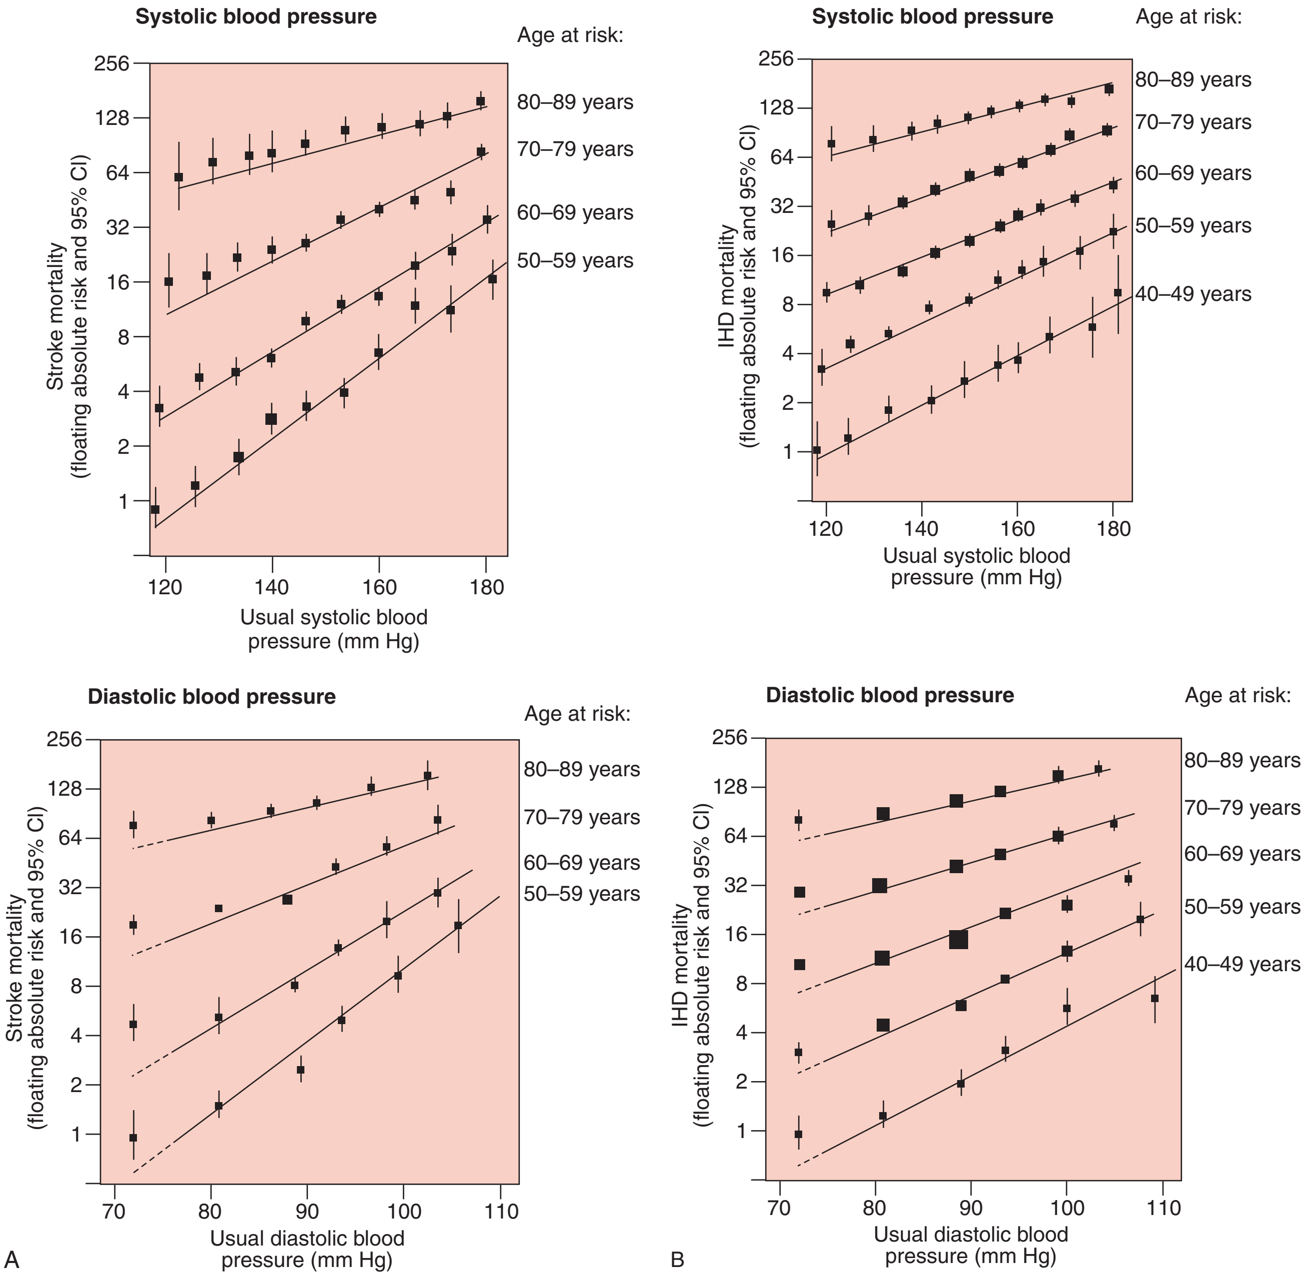

Figure 34–2 **A,** Stroke mortality rate in each decade versus usual blood pressure at the start of that decade. **B,** Ischemic heart disease (IHD) mortality in each decade versus usual blood pressure at the start of that decade. Lancet 2002;360:1903-13.)

interval = interval/paper speed). The average of the 10 heart beats is then used as the PWV. The other method is to use one of several automatic devices to measure the PWV [the Complior (Artech-Medical, Pantin, France), the SphygmoCor system (AtCor Medical, Lisle, Ill, USA), the CV Profilor device (Hypertension Diagnostics, Inc., Minneapolis), and the Wall Track System (Pie Medical, Maastricht, the Netherlands).[22]

Antihypertensive drugs from different classes have been shown to have differential effects on PWV, central aortic pressure, and PP, and some have concluded that these effects may be more important determinants of outcome than brachial arterial pressure per se.[17,21-26] The effects of short-term (4 weeks) administration of representatives of the four major classes of antihypertensive drugs on central aortic pressure and acute pressure augmentation were compared with each other and with placebo in a double-blind crossover study involving 32 previously untreated elderly patients with systolic hypertension.[17] Applanation tonometry was performed in the radial artery using the SphygmoCor apparatus. The patients received, in randomized order, a low-dose and then a high-dose placebo, 1 and 2 tablets; the BB atenolol, 25 and 50 mg; the ACEI perindopril, 4 and 8 mg or enalapril, 20 mg and 40 mg; the CCB felodipine, 5 and 10 mg or amlodipine, 5 and 10 mg; and the thiazide diuretic hydrochlorothiazide 25 and 50 mg.

Table 34–1 Clinical Trial and Guideline Basis for Compelling Indications for Individual Drug Classes

High-Risk Conditions With Compelling Indications*	Recommended Drugs: Diuretic	β-Blocker	ACE Inhibitor	ARB	CCB	Aldosterone Antagonist	Clinical Trial Basis†

Interestingly, only the CCBs had dose-dependent effects on central and peripheral SBP; the other drug classes had flat dose responses. High-dose CCBs and diuretics caused greater reductions in brachial artery SBP than ACEIs or BBs; reductions in SBP were greater than in DBP, causing PP to fall (Fig. 34–4). Compared with central aortic pressures, brachial artery pressure measurements underestimated the change in SBP in patients on ACEIs and CCBs. The changes in PP were underestimated in patients on ACEIs and overestimated in patients on BBs. The PP reduction was statistically significant only for CCBs and diuretics. Heart rate was reduced by approximately 8 beats/min with BBs and was unaffected by other medications.

The first (outgoing pressure wave) peak in the systolic waveform was reduced by all drugs, but the decrease with CCBs was greater than with ACEIs or diuretics. The second (reflected pressure wave) peak in the systolic waveform was not reduced significantly by BBs, but was with the other three drugs. The peak aortic SBP and the aortic SBP at the end of ejection were lower with CCBs than with the other drugs. The augmentation pressures calculated from these data were reduced compared with placebo by ACEIs, CCBs, and diuretics, while the augmentation pressure on BBs was numerically but not statistically significantly higher than on placebo (Table 34–2). Augmentation indices tended to follow the same pattern (see Table 34–2), but the changes in augmentation indices were not as pronounced as the changes in augmentation pressure because of the differences in the central PP. On placebo, central aorta augmentation pressure and index were 23 mm Hg and 33.3%; on ACEIs the values were 18 mm Hg and 30%; on BBs, 26 mm Hg and 38.5%; on CCBs, 16 mm Hg and 28%; and on diuretics 17 mm Hg and 28.8%. Thus the augmentation pressure on BBs was statistically significantly greater than on the other three drug classes ($P < 0.05$), and numerically but not statistically greater than on placebo. The lowest central aortic pressures were achieved with CCBs and diuretics.

The major finding of this study is that the alteration in brachial artery BP with different drug therapies may not accurately predict the changes in central aortic pressure. Specifically, BBs reduced brachial but not central aortic SBP, while CCBs effected the greatest reductions in both central and peripheral pressures, and ACEIs caused greater reductions in central than peripheral pressures. These hemodynamic findings are consistent with the deleterious effects of BBs

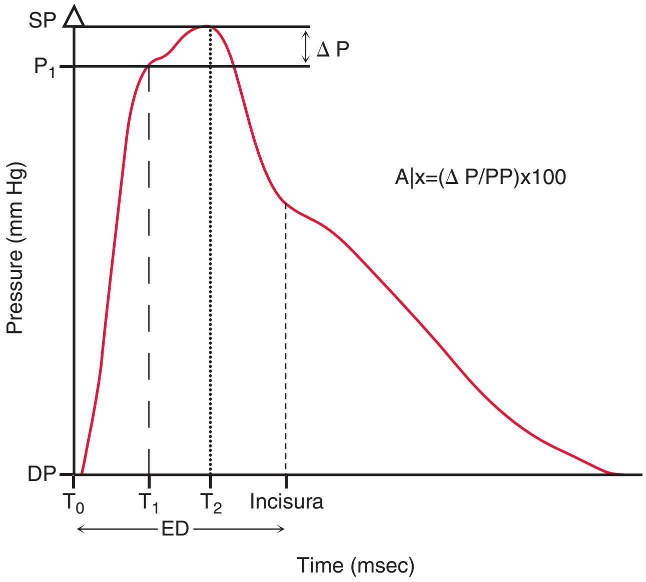

Figure 34–3 Hemodynamic parameters derived by pulse wave analysis of the central aortic pressure wave. and the apparent benefits "beyond BP lowering" of CCBs and ACEIs observed in outcome studies.[21]

The pREterax in regression of Arterial Stiffness in a contrOlled double-bliNd study (REASON) compared the effects of a low-dose combination of indapamide (0.625 mg) and perindopril (2 mg)(Per/Ind) with the BB atenolol (50 mg) on SBP, PP, aortic PWV (automatic measurements), and wave reflections (pulse wave analysis, applanation tonometry) in 471 patients with essential hypertension who were followed for 12 months.[23] For the same DBP reduction, Per/Ind decreased brachial SBP and PP significantly more than atenolol. Both antihypertensive agents decreased PWV to a similar degree, but only Per/Ind significantly attenuated carotid wave reflections, with resulting selective decreases in SBP and PP.

A subsequent report delineated the hemodynamic mechanisms underlying the selective central SBP reduction seen with Per/Ind in REASON (i.e., wave reflection and arterial stiffness) and determined whether these differ in the central and peripheral compartments of the arterial tree.[24] The selective effect of the Per/Ind regimen on central SBP became significant only after 1 year of follow-up, consistent with the known ability of the ACEIs to effect structural remodeling (reduced wall/lumen ratio) of distal muscular arteries and arterioles and to improve endothelial function and vascular smooth muscle tone. These structural changes would tend to alter (prolong) the transit time from the peripheral reflection

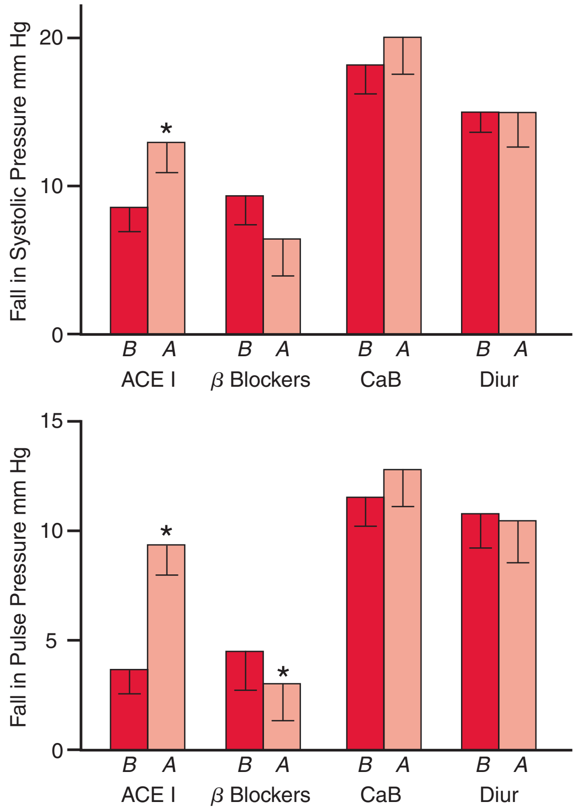

Figure 34–4 Fall in systolic blood pressure in the brachial artery *(B)* and aortic root *(A) (second peak)* and the fall in pulse pressure at the two sites with the different drug classes. sites toward the central arteries and change the timing of incident and reflected waves, resulting in reductions in reflection coefficients of distal muscular arteries and arterioles and decreased amplitude of the backward pressure wave. All of these effects would contribute to reductions in central SBP with Per/Ind treatment compared with the BB without need to invoke alterations in PWV or LV ejection time, which were not observed in REASON.

A substudy of 146 subjects selected from the REASON study population compared the effects of the Per/Ind and atenolol regimens on echocardiographically determined LVM and related the changes in LVM to alterations in central and brachial SBP and PP.[25] At 1 year, reductions in LVM were greater with Per/Ind than with atenolol and were significantly linked to central, but not brachial, PP and SBP change and a longer delay in central return of wave reflections. This interesting observation provides a mechanistic explanation for previous findings that inhibitors of the RAAS reduce LVM more than BBs despite similar effects on brachial artery pressures and supports the general concept that hypertension-induced target organ damage and CVD morbidity/mortality are more closely related to central than peripheral BPs.

Differential effects of ACEI treatment on central and peripheral arterial pressures have been invoked to explain the impressive benefits of ACEI (ramipril) treatment in CVD prevention reported in the Heart Outcomes Prevention Evaluation (HOPE) trial, which could not be accounted for by reductions in conventional (cuff) brachial artery SBP and DBP.[26,27] Hemodynamic (cuff brachial artery pressure, central aortic pressure assessed by radial artery tonometry and PWV in aorta, upper limb, and lower limb arteries) responses to acute (5-hour) administration of ramipril, atenolol, and placebo were assessed in 30 patients in a randomized double blind trial.[26] Ramipril and atenolol treatment produced similar reductions in DBP in both brachial artery and aorta, but ramipril resulted in more than a 5 mm Hg greater reduction in aortic SBP. The aortic SBP reduction with ramipril was accompanied by a large reduction in the augmentation index, indicative of a reduction in peripheral wave reflection. There was also a differential effect of treatment on peripheral PWV (reduced with ramipril, unchanged with atenolol) but not aortic PWV, which paralleled the fall in DBP. Thus ramipril treatment was associated with decreased stiffness of peripheral but not central arteries. The authors concluded that the greater reduction in central versus brachial artery SBP could account for the clinical benefit of ramipril in the HOPE study, although other mechanisms including greater 24-hour BP reduction[28] also apply. This acute study raises the possibility that antihypertensive drugs elicit differential central BP responses, which may affect the outcome if sustained long term.

The Conduit Artery Function Evaluation (CAFÉ) study, a substudy of central arterial BP in the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT), is the first study to test the hypothesis that different antihypertensive drugs/drug combinations affect central aortic pressures differently despite similar effects on brachial BP in a major CV outcomes trial with repeated measurements throughout the study in a large cohort of patients.[21] Analyses of representative averaged radial artery waveforms and the resulting derived central aortic waveforms from individual patients with similar brachial BPs, treated with either atenolol or amlodipine monotherapy in the CAFÉ study, show clear differences in the morphology of both the radial and central aortic arterial waveforms (Fig. 34–5). Atenolol monotherapy was associated with a broader peripheral waveform and a more prominent late systolic peak in the central aortic waveform. Final results of the CAFÉ study revealed significantly greater reductions in central aortic SBP and PP with CCB ± ACEI compared with BB ± diuretic treatment despite similar brachial BP measurements. Coupled with the impressive clinical benefits of the CCB ± ACEI treatment regimen in the ASCOT BP lowering trial,[29] these findings lend strong support to the concept that central arterial pressure is clinically important in assessing prognosis and treatment responses in hypertensive patients.

A meta-analysis of placebo-controlled outcome trials involving more than 15,000 older persons with ISH showed overall reductions of 13% in all-cause mortality and 18% in CV mortality from active treatment compared with placebo.[30] For nonfatal and fatal outcomes combined, active treatment resulted in reductions of 26% for all CV endpoints, 30% for stroke, and 23% for MI including sudden cardiac death. The number of patients needed to treat (NNT) for 5 years to prevent one major CV event was lower in men (18 vs. 38), in those older than age 70 (19 vs. 39) and in those with pre-existing CVD (16 vs. 37). These results show that antihypertensive treatment is highly effective in preventing CVD morbidity and mortality in elderly persons with ISH.

DIASTOLIC BLOOD PRESSURE AND CARDIOVASCULAR DISEASE RISK

Reductions in DBP have been observed in large studies to correlate with reduced stroke and CHD risk.[31,32] For example, in 9 prospective observational studies of 420,000 individuals, reductions of 5, 7.5, and 10 mm Hg were shown to be associated with 34%, 46%, and 56% less stroke and 21%, 29%, and 37% less CHD, respectively.[31] Early outcome trials of antihypertensive treatment involving large numbers of patients used decreases in DBP to establish reductions in risk of both stroke and coronary events. In 14 unconfounded, randomized trials of 37,000 individuals treated for an average of 5 years, a decrease in DBP of 5 to 6 mm Hg was associated with 35% to 40% less stroke and 20% to 25% less CHD, respectively.[32]

Although increased peripheral vascular resistance leads to increases in both SBP and DBP, increased arterial stiffness leads to an increase in SBP and a decrease in DBP.[12,14] DBP is influenced by arterial resistance and stiffness, both of which are independent risk factors for CVD. Changes in BP with aging reflect the evolution of alterations in both structure and function of the arterial system.

Current guidelines recommend goal BPs previously considered below normal, leading to a growing concern that some persons are being overtreated and are experiencing more CVD events due to a lower DBP, the “J-curve phenomenon”.[33] For the past 10 to 20 years, there has been considerable debate over the existence of a J-curve. Explanations that have been offered to account for a J curve of DBP include the following:

1. Aggressive treatment of HTN in patients with underlying CHD compromises coronary perfusion, which occurs almost exclusively during diastole, leading to tissue ischemia and subsequent coronary events.

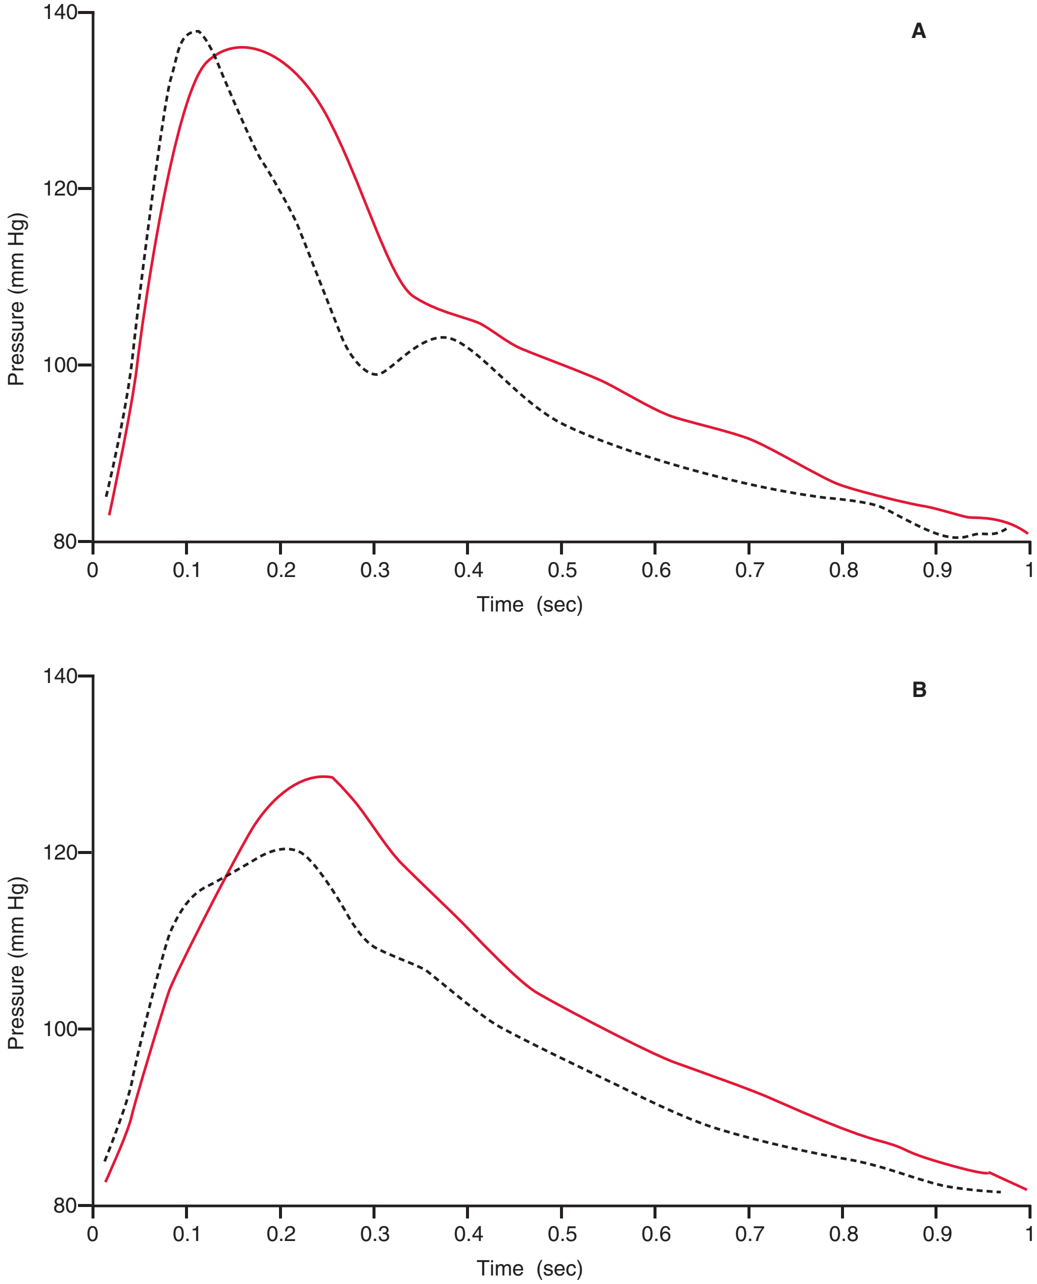

Figure 34–5 Examples of **(A)** peripheral and **(B)** corresponding derived central aortic waveform from patients of equal age treated with atenolol *(solid line)* or amlodipine *(dashed line),* as monotherapy, achieving equivalent brachial blood pressures. (Reproduced from The CAFÉ Investigators for the ASCOT Investigators: Differential impact of blood pressure lowering drugs on central aortic pressure and clinical outcomes—principal results of the Conduit Artery Function Evaluation study: The CAFÉ study. Circulation 2006;113:1213-25.)

2. Excessively low DBP results from increased PP due to progressive stiffening of the central arteries and advancing atherosclerotic disease. In particular, the increased PWV seen in older persons can lead to arrival of the pressure wave before closure of the aortic valve and a lower aortic DBP, resulting in a loss of any "boosting" effect to the coronary circulation.[15,16]
3. The poor autoregulatory reserve of the coronary circulation, especially in the presence of rigid atherosclerotic arteries, and the increased oxygen requirement of the hypertrophic LV in hypertensive patients enhance the probability of developing ischemia and CVD events when DBP falls.
4. The adverse metabolic effects of antihypertensive therapy (i.e., hypokalemia, hyperglycemia, and hyperlipidemia) could become more important at low levels of coronary perfusion, thus favoring a J-shaped relationship for cardiac events.

Studies that have looked for a J-shaped relationship between DBP and CVD events have yielded mixed results, in part dependent on the patient population studied.[33-42] A study by

Cruickshank supporting the existence of a J-curve involved 902 patients with moderate to severe HTN who received a BB (atenolol) alone or with other antihypertensive agents, such as a thiazide diuretic, a vasodilator (hydralazine or prazosin, and nifedipine), or methyldopa or bethanidine as needed to achieve a BP of 140/90 mm Hg.[33] The mean initial BP was 183/109 mm Hg, and the mean BP on treatment was 145/87 mm Hg. Results were analyzed by DBP group (>90 mm Hg, 85 to 90 mm Hg, and < 85 mm Hg), and by whether CHD was present or absent. An increase in mortality from MI was found in patients with CHD at DBP levels below 85 to 90 mm Hg, while no increase in mortality was noted in these patients at DBP > 85 mm Hg or in those without CHD.

A subsequent meta-analysis of data from 13 outcome studies of antihypertensive treatment that included more than 48,000 participants addressed the question of whether there is a point beyond which BP (mainly DBP) reduction is no longer beneficial and possibly even deleterious.[34] Although no consistent J-shaped relationship between treated BP level and stroke incidence or mortality was seen, studies consistently demonstrated a J-shaped relationship between treated DBP and cardiac event incidence and mortality. SBP relationships often were not addressed or gave conflicting results. The authors observed that treated DBPs below the beneficial therapeutic threshold point of 85 mm Hg were associated with increased risk of cardiac events. They further noted that, as in the Cruickshank study, the J-shaped relationship appeared to be most marked in subjects with preexisting cardiac disease and was observed consistently in untreated or placebo-treated control subjects, as well as treated individuals. Their main conclusion was that the J-curve is probably independent of treatment and that it reflects a relation between cardiac events and absolute DBP, with treatment merely shifting ischemic hypertensive patients from a fairly safe part to a less safe part of the curve, where cardiac mortality is increased. Although acknowledging the limitations of their data (i.e., the lack of a randomized trial that evaluates different treatment thresholds and targets), the authors suggested that prudence dictates caution in lowering DBP levels below 85 mm Hg in patients with known ischemic heart disease.

The Hypertension Optimal Treatment (HOT) study is the only randomized prospective outcome trial that has tested the J-curve hypothesis in a rigorous fashion. A goal of HOT was to determine the optimal target DBP in the treatment of HTN.[35] A total of 18,790 patients between 50 and 80 years old with DBP between 110 and 115 mm Hg were assigned at random to three DBP target groups (DBP ≤ 90, ≤ 85 or ≤ 80 mm Hg, respectively). Baseline therapy was a dihydropyridine CCB (felodipine) with a five-step titration scheme including the addition of an ACEI or BBs and, if necessary, a diuretic. At the end of the study, DBP was reduced by 20.3, 22.3, and 24.9 mm Hg in the ≤ 90 mm Hg, ≤ 85 mm Hg, and ≤ 80 mm Hg target groups, respectively. The lowest incidence of major CV events occurred at a DBP of 82.6 mm Hg, while the lowest risk of CV mortality occurred at a DBP of 86.5 mm Hg. Although the study failed to demonstrate a significant benefit in lowering BP below approximately 140/85 Hg in nondiabetic patients with CHD, no adverse effects of intensive treatment of BP were seen (i.e., no J-curve).

The diabetic subgroup in the HOT trial did benefit significantly from aggressive BP lowering, however. Among the 1501 diabetic patients, a significant 50% reduction in major CV events and CV mortality ($P = 0.005$ and $P = 0.016$) was seen in those randomized to a target DBP of ≤ 80 mm Hg compared with the target group ≤ 90 mm Hg. **On the basis of these data and data from other large, randomized, controlled trials that have provided evidence that patients with diabetes achieve greater reductions in risk of major CVD events and CV death with regimens targeting lower BP goals,[36] intensive BP lowering to a goal of < 130/80 mm Hg is recommended for hypertensive diabetic patients.[8] However, in patients with known CHD, a DBP lower than 80 mm Hg may lead to an increase in cardiac events.**

Evidence for a J-curve has been shown in the elderly population with ISH, as well as in patients with established CHD. Examination of the effect of DBP on CVD events in SHEP participants demonstrated that in the active treatment group (2358 subjects), a 5-mm Hg decrease in DBP was associated with increased stroke (relative risk [RR] 1.14; 95% CI: 1.05 to 1.22, $P < 0.01$), CHD (RR 1.08; 95% CI: 1.00 to 1.16, $P < 0.05$), and CVD (RR 1.11; 95% CI: 1.05 to 1.16, $P < 0.01$).[37] Significant adverse events were first observed at a DBP of 70 mm Hg and were more noticeable at lower DBP (DBP ≤ 60 mm Hg). This effect was seen only with CVD and only in the treated group. The results of this study suggest that in older persons with ISH, a DBP < 70 mm Hg (or perhaps < 60 mm Hg) is a risk factor for future adverse CVD events.

Analysis of data from the MRC Mild Hypertension Trial confirmed that the predicted risk of a CHD event exhibits a J-shaped relationship with DBP, while stroke risk declines continuously as DBP falls within the physiologic range.[38] Hence patients with the greatest PP are at highest risk for CHD events but not for stroke across the range of SBP. The mechanisms linking PP to increased CHD risk include increased arterial wall stiffness, increased PWV, and early return of the reflected pressure wave to the heart, all of which tend to increase LV work and oxygen requirements and diminish coronary perfusion. In contrast, cerebral blood flow occurs throughout the cardiac cycle and the relationship between PP and stroke is weak (i.e., there is no J-curve for stroke). The authors speculated that this may explain why most trials in hypertension have shown a greater benefit of treatment on stroke than on CHD events.

Broader applicability of the J-curve concept was found in a meta-analysis of 7 randomized clinical trials from the INdividual Data ANalysis of Antihypertensive (INDANA) intervention database, which included 40,233 persons with hypertension, of whom 1655 died during a trial.[39] A J-shaped relationship between DBP and risk for death was observed for total and cardiovascular mortality in treated patients (nadir, 84 and 80 mm Hg, respectively) and untreated patients (nadir, 90 and 85 mm Hg, respectively). For noncardiovascular deaths, the relationship was J-shaped in the treated group (nadir, 84 mm Hg) only. Similar results were observed for SBP. Thus the increased risk for events observed in patients with low BP was not related to antihypertensive treatment and was not specific to BP-related events. The authors concluded that reverse causality (i.e., poor health conditions leading to low BP and an increased risk for death) probably explains the J-shaped curve.

The original and offspring Framingham cohorts have been prospectively analyzed for the occurrence of a J-curve relating BP to CVD risk.[40] Over 12 years of follow-up, a significant increase in CVD events was discovered at DBP < 80 mm Hg;

Figure 34–6 Incidence of Total MI and Total Stroke by DBP Strata. Modified from Messerli FH, Mancia G, Conti CR, et al: Dogma Disputed: The J-Curve in Hypertensive Patients With Coronary Artery Disease: The International Verapamil-Trandolapril Study (INVEST). (Reproduced from Messerli FH, Mancia G, Conti CR, et al: Dogma disputed: Can aggressively lowering blood pressure in hypertensive patients with coronary artery disease be dangerous? Ann Intern Med 2006;144:884-93).

however, this was only evident in those persons with a concomitant SBP of > 140 mm Hg and, consequently, a PP of > 46 mm Hg, consistent with the concept that the alterations in central BP dynamics and pulse wave reflection described previously are responsible for the J-curve.

The International Verapamil-Trandolapril Study (INVEST) was a randomized, open label study of 22,576 patients with HTN and known CHD aged 50 years and older.[41] In INVEST, the relationship between average on-treatment (verapamil SR or atenolol-based) BP and risk for the primary outcome (all-cause death, nonfatal stroke, nonfatal MI), all-cause death, and total MI, but not total stroke was J-shaped, particularly for DBP, with a nadir at 119/84 (Fig. 34–6).[42] Although the J-curve was relatively shallow for SBP, lower DBP led to nearly doubling and tripling of the risk for primary outcome in the DBP strata > 60 to ≤ 70 mm Hg and ≤ 60 mm Hg. At lower DBP there was a significant preponderance of MIs over strokes. A significant interaction for the primary outcome was observed with decreased DBP and history of revascularization; low DBP was associated with relatively lower risk of the primary outcome in revascularized compared with nonrevascularized patients. Findings from this large trial in which all enrollees had hypertension and CHD reinforce the conclusion that there is a prominent J-curve for the relationship between treated DBP and CHD events in this high-risk population, in whom DBPs below 70 to 80 mm Hg could be harmful.

CHRONOBIOLOGY AND CORONARY HEART DISEASE

Appreciation of the diurnal rhythm of BP and CVD events has given rise to the development of chronotherapeutic agents, specifically formulated drug delivery systems designed to provide drug concentrations that vary in synchrony with biological needs, thus enhancing both the efficacy and safety of treatment. An example of such a chronotherapeutic agent is a controlled-onset extended release CCB (COER-verapamil) that is taken at bedtime and allows lower drug concentrations during sleep and maximal drug delivery during the early morning hours.[43] The chronotherapeutic approach was not shown to be superior to conventional treatment in the Controlled ONset Verapamil INvestigation of Cardiovascular Endpoints (CONVINCE) Trial.[44] However, the results of this trial are inconclusive due to the premature termination of the study for nonmedical reasons.

Differences in efficacy or adverse effects depending on the circadian time of administration have been clearly identified for a variety of BP-lowering drugs and drug combinations.[45] In particular, evening dosing of standard antihypertensive agents has become useful as an alternative chronobiologic strategy for lowering BP. This is especially important for patients with the nondipper BP pattern (<10% decline in nocturnal mean relative to diurnal mean BP), which is associated with target organ damage including LVH, AMI, stroke, albuminuria, and progression to ESRD, as well as with other CVD risk factors (e.g., fibrinogen levels). Nondipping BP patterns are also associated with the absence of 24-hour therapeutic coverage in patients treated with single morning doses of antihypertensive drugs. A study that investigated the impact of treatment time on BP control, circadian BP pattern, and biochemical indices of CVD risk in patients with resistant hypertension revealed significant reductions in 24-hour mean SBP and DBP, particularly prominent reductions in nighttime BPs and decreases in prevalence of nondipping, in patients taking one drug at bedtime compared with those taking all drugs on awakening (Fig. 34–7).[46] Importantly, BP control rates in subjects who were dosed at

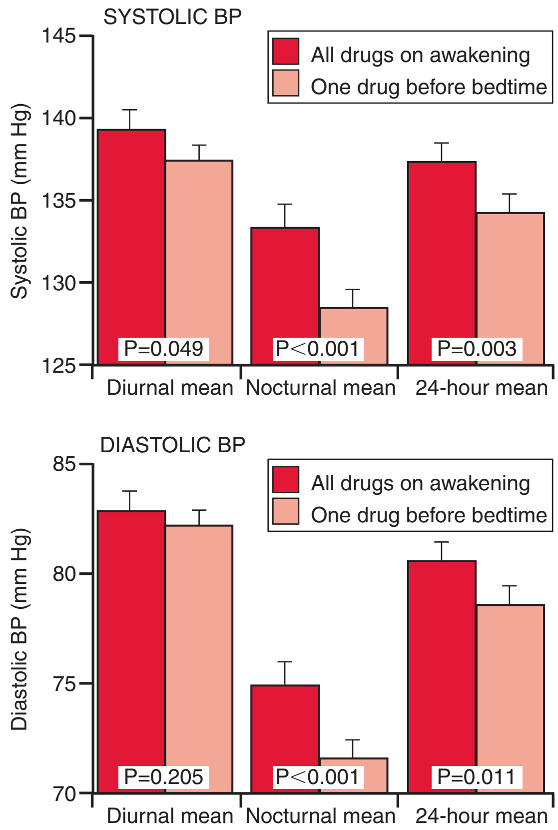

Figure 34–7 Diurnal, nocturnal, and 24-hour means of systolic blood pressure *(top)* and diastolic blood pressure *(bottom)* in patients with resistant hypertension receiving all antihypertensive drugs on awakening, or receiving 1 of the drugs at bedtime, studied by 48-hour ABPM. (Reproduced from Hermida RC, Ayala DE, Calvo C, et al: Effects of time of day of treatment on ambulatory blood pressure pattern of patients with resistant hypertension. Hypertension 2005;46:1053-9.)

bedtime were almost double those seen in patients who received all of their drugs on awakening. Those who took one drug at bedtime also showed significant reductions in glucose, cholesterol, and fibrinogen levels, as well as urinary albumin excretion. Although the effects of antihypertensive treatment time on CVD outcomes have not been formally tested in a randomized trial, some have attributed the impressive benefits of ramipril in the HOPE trial, at least in part, to evening dosing of the drug.[28]

CORONARY HEART DISEASE: CHRONIC STABLE ANGINA AND SILENT ISCHEMIA

Hypertensive patients with chronic stable angina are at particular risk due to the enhanced myocardial oxygen demand created by increased BP (SBP in particular) and HR.[47] Persons with both stable angina (with or without silent ischemic episodes) and HTN derive particular benefit from treatment with BBs and CCBs.[48] The pharmacologic treatment of chronic stable angina has evolved into a two-armed approach (Fig. 34–8). The first arm includes the agents aimed at reducing angina (BBs, CCBs, and nitrates). The second arm includes agents that slow the progression of atherosclerosis, stabilize atherosclerotic plaque, and promote the health of the vascular endothelium.[47] When planning a regimen of therapy for persons with HTN and CAD, pharmacologic agents from both arms should be employed.

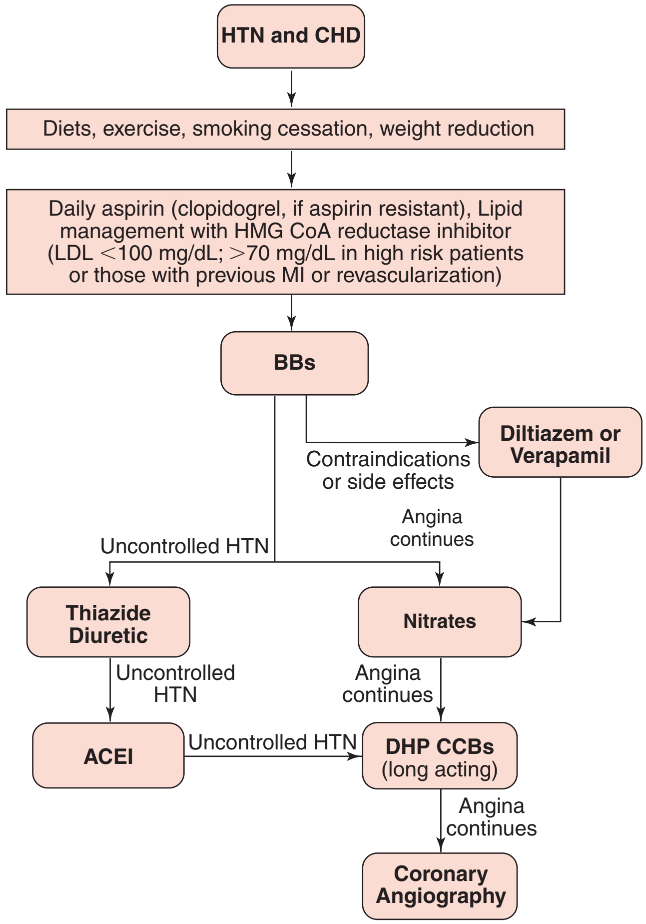

Figure 34–8 Algorithm for the management of a patient who presents with hypertension and angina. Doses of drugs should normally be titrated to the usual maximal dose before a second agent is tried. The recommended calcium antagonists are cardiac-slowing agents, such as verapamil or diltiazem. Inadequate control of angina is defined as continuing limiting symptoms. Inadequate control of hypertension is defined as blood pressure above goal.

The goals of treating patients with HTN and angina are to lower BP, reduce ischemia, relieve chest discomfort, and prevent future CVD events. Pharmacologic therapy should be initiated with a BB unless contraindicated. In variant (Prinzmetal's) angina, the treatment of choice is a dihydropyridine CCB. BBs are first-line agents in the treatment of patients with coexisting HTN and angina.[47,48] Beneficial effects for the patients include reduction of myocardial oxygen consumption and enhancement of coronary flow. Although, for the reasons stated earlier, concomitant angina is a compelling indication for BB use in hypertensive patients, meta-analyses of randomized controlled outcome trials of antihypertensive treatment have found that BB-based treatment is no better than placebo for prevention of CVD outcomes.[49,50] Accordingly, many authorities no longer recommend BBs as

first-line treatment for hypertensive patients in the absence of compelling indications (HF, post MI, high CHD risk, angina) for their use.[50a]

If angina continues, long-acting CCBs can be added to the regimen. CCBs decrease total peripheral resistance, which leads to a decrease in BP and in wall tension, thus reducing myocardial O_2 consumption. CCBs also decrease coronary resistance (helpful in relieving spasm, which may be associated with Prinzmetal's angina) and enhance poststenotic coronary perfusion, which increases myocardial O_2 supply. **Nondihydropyridine CCBs have the additional benefit of decreasing heart rate. Short-acting dihydropyridine CCBs should be avoided due to increased mortality, particularly in the setting of acute MI.[51] Although nondihydropyridine CCBs can be used as antianginals in combination with a BB, there is an associated risk due to the potential for severe bradycardia or heart block, or both.**

Long-acting dihydropyridine CCBs are effective antianginal agents and do not share the disadvantage of bradycardia/heart block. Therefore if a CCB is necessary in addition to a BB to control angina in a hypertensive patient, it should be a long-acting dihydropyridine CCB.[48] The Comparison of Amlodipine versus Enalapril to Limit Occurrences of Thrombosis (CAMELOT) trial showed no difference between amlodipine and enalapril in the occurrence of the primary endpoint of CV death, nonfatal MI, revascularization, hospitalization for angina or HF, cardiac arrest, stroke, or PAD in patients with CHD and normal BP or prehypertension.[52] In an intravascular ultrasound subgroup analysis, amlodipine appeared to have a significant retarding effect on atheroma progression in those with higher BPs that was not seen with enalapril or placebo. Data from the ALLHAT, VALUE, and ASCOT trials have demonstrated that it is safe to use dihydropyridine CCBs in high-risk hypertensive patients without concern for a higher morbidity or mortality, or both, from a CV cause.[29,53,54] If angina is not controlled on a BB-CCB regimen, nitrates can be added.

Use of ACEI in high-risk persons (those with a history of CHD, stroke, PAD, DM) with a normal LVEF and no evidence of HF or LV dysfunction has been shown to be beneficial in the Heart Outcomes Prevention Evaluation (HOPE) trial.[27] Patients randomized to an ACEI (ramipril) had significantly fewer MIs, strokes, or deaths from CV causes and were less likely to require revascularization or hospitalization for unstable angina or for complications related to DM. Patients randomized to ramipril also had fewer cardiac arrests, less angina, and less HF compared with placebo. On the basis of these positive findings, ACEIs became widely prescribed for all patients with vascular disease.

The HOPE–The Ongoing Outcomes (HOPE-TOO) trial assessed whether the benefits observed during the HOPE trial were sustained during an additional 2.6 years of follow-up after trial cessation.[55] During the post-trial follow-up, despite similar rates of use of ACEIs in the two groups (72% ramipril vs. 68% placebo), patients originally allocated to ramipril had a 19% further reduction in relative risk of MI, a 16% reduction in risk of revascularization, and a 34% reduction in risk of new-onset DM, independent of baseline risk and ancillary treatments. There was no difference in stroke or CV deaths. The investigators concluded that the ACEI likely had favorable effects on endothelial function, vascular structure/function, and glucose metabolism that were sustained beyond the blinded period of the trial and that ACEIs may provide lifelong preventive benefit. They urged longer-term follow-up of prevention trials in order to obtain better estimates of long-term effects (benefits) of treatment.

The vast majority of patients in HOPE were not hypertensive (average BP was 139/79 for both groups) during the trial, and the benefits of the ACEI were reported by the investigators to be greater than could be accounted for by the reduction in BP seen with ramipril treatment. The conclusion that the benefit of the ACEI in HOPE was independent of BP has been challenged on the basis of the manner in which BP was monitored in the trial and the finding of a large (–10/4 mm Hg over 24 hours, –17/8 mm Hg during nighttime) reduction in BP in the ramipril group compared with placebo in a substudy that used ambulatory blood pressure monitoring (ABPM).[28] Importantly, participants in HOPE were instructed to take the study drug at bedtime, perhaps exploiting the benefit of a peak BP effect of the ACEI in early morning.

The EURopean trial On reduction of cardiac events with Perindopril in stable coronary Artery disease (EUROPA) compared perindopril with matched placebo in 12,218 persons with stable CHD, the majority of whom had experienced a prior MI or had been revascularized, or both.[56] Most patients were on antiplatelet therapy, BBs, and lipid-lowering therapy. The primary endpoint, a composite of CV death, MI, or cardiac arrest, was reduced significantly in the perindopril group compared with the placebo group. The number needed to treat (NNT) with perindopril for 4 years to prevent one CVD event was determined to be 50. Based largely on the results of this trial, perindopril was given FDA approval for the indication of reducing CV mortality and nonfatal MI in patients with stable CHD.

The Prevention of Events with Angiotensin-Converting Enzyme inhibition (PEACE) trial compared trandolapril with placebo in 8290 persons with preserved LV function and stable CHD.[57] The primary endpoint was a composite of cardiovascular death, MI, or revascularization. In contrast to HOPE and EUROPA, no significant difference in outcomes was demonstrated between the ACEI and placebo groups in PEACE. The negative findings of PEACE have been attributed to low event rates: the placebo group in PEACE had lower event rates than either the placebo or active treatment group in HOPE (Fig. 34–9). In fact, the annualized rate of death from all causes in PEACE was similar to that of an age- and sex-matched general population. The fall in event rates likely resulted from more intensive management of risk factors and underlying CVD. At baseline, 70% of the patients in PEACE (vs. 29% in HOPE and 56% in EUROPA) were receiving lipid-lowering therapy, and 72% of patients in PEACE, as compared with 54% in EUROPA and 40% in HOPE, had undergone coronary revascularization before enrollment. **The results of the PEACE trial provide evidence that CHD patients with preserved LV function who are receiving intensive medical therapy and revascularization, in whom rates of CVD events are low, may not derive further benefit from ACEI treatment. However, as in HOPE and EUROPA, only a minority of patients enrolled in PEACE had documented hypertension. The presence of CHD in a person with hypertension remains a compelling indication for ACEI therapy.[8]**

Some evidence indicates that ARBs may be less effective than ACEIs in reversing endothelial dysfunction and preventing coronary events, and it has even been suggested that

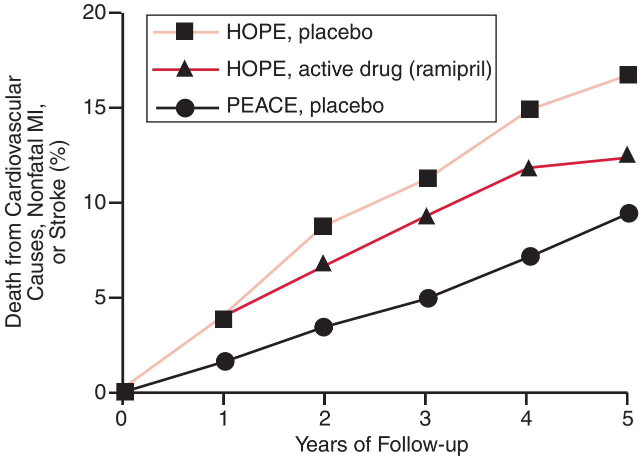

Figure 34–9 Comparison of Outcomes in the PEACE and HOPE trials. (Reprinted from The PEACE Trial Investigators: Angiotensin-converting enzyme inhibition in stable coronary artery disease. N Engl J Med 2004;351:2058-68.)

use of ARBs may be associated with higher rates of MI.[58] To examine these issues, a meta-analysis of 19 controlled clinical trials with 31,569 participants that compared ARBs with ACEIs or placebo has been carried out.[59] Of note, only two of these studies examined the use of ARBs in hypertensive patients; others focused on patients with diabetes and nephropathy, HF, or recent MI/ischemic syndrome. Use of ARBs was not associated with a statistically significant increased risk of MI compared with either placebo or ACEIs. The 95% confidence limits of the statistical analysis did not exclude an increase of up to 16% or a decrease of up to 25% in risk of MI, however. The ARB-placebo comparison included the CHARM-Alternative trial, the only study to show a statistically significant increase in MI rates with ARB treatment.[60] CV mortality fell with ARB treatment in CHARM-Alternative, despite the increase in MI, and there was no increase in MI with ARB treatment in other HF trials, including CHARM-Added[61] and ValHEFT.[62] Thus this analysis showed neither benefit nor harm of ARB treatment compared with placebo in prevention of acute MI. The ARB-ACEI comparison was driven by the large post-MI OPTIMAAL trial,[63] in which the ARB losartan was not found to be superior or noninferior to the ACE inhibitor captopril with respect to overall mortality. Data from the larger VALIANT trial[64] were not available for analysis, and the LIFE[65] and VALUE[54] trials were excluded because they lacked placebo or ACEI control groups.

A meta-analysis by the Blood Pressure Lowering Treatment Trialists examined 3 large-scale randomized outcome trials including over 18,000 participants with acute myocardial infarction or HF that made direct head-to-head comparisons between ACEIs and ARBs.[66] They found no differences between ACEI and ARB treatment for any outcome. Since no head to head ACEI-ARB comparison trials in patients with HTN and/or increased risk of CVD are available, the Trialists carried out meta-regression analyses of relative risk reductions and corresponding followup BP differences in trials that compared the effects of ACEI or ARB treatment to treatment with placebo or an active comparator.[66] Data from 26 trials including over 146,000 patients with analyzed. The meta-regressions provided indirect evidence that for CHD outcomes, ACEIs but not ARBs provided risk reduction beyond that achieved by BP lowering. This relationship did not hold for other outcomes (i.e., stroke and HF). Limitations of the meta-analysis, acknowledged by the authors, include the indirect nature of the class comparisons and the absence of a direct confirmatory result from a head-to-head comparison of ACEI vs. ARB treatment in a high risk population.

The Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET) and the Telmisartan Randomized Assessment Study in ACE Intolerant Subjects with Cardiovascular Disease (TRANSCEND) will provide the first head to head comparison of ACE inhibitor versus ACE inhibitor–ARB combination and ARB versus placebo treatment in high-risk patients with underlying CVD.[67] Pending the results of these trials, compelling indications for the use of ACE inhibitors or ARBs in hypertensive patients are largely overlapping.[8] The major advantage of the ARB class is that its side effect profile resembles that of placebo. Acute renal failure, hyperkalemia, cough, and angioedema are rare with the ARBs.

CORONARY HEART DISEASE: ACUTE MYOCARDIAL INFARCTION

Elevated BP can contribute to the occurrence of an acute coronary syndrome because increased shear forces from sudden changes in pressure can cause plaque fissuring. Increased sympathetic tone and catecholamine release contribute to both BP elevation and increased wall tension, which worsens ischemia by increasing O_2 demand, and can precipitate acute MI.[68] The presence of antecedent HTN increases the risk of MI twofold to threefold.[69] The increased risk of CHD in hypertensive patients is also related to the high frequency (30% to 40%) of associated risk factors (hypercholesterolemia, DM, tobacco use, and obesity) in this patient population. A history of HTN in patients who have had an MI is an independent risk factor for reinfarction and may confer an increased risk of mortality in the hospital, as well as following discharge.[69-71]

The goals of therapy in hypertensive patients with MI are to control BP, pain, and HR; reduce morbidity and mortality; and decrease the likelihood of future CVD events (Fig. 34–10). BBs (non-ISA) are first-line agents for patients with coexisting MI and HTN. Their benefit in this setting is related to their ability to limit infarct size, decrease the risk of recurrent MI, improve survival, and decrease the incidence of sudden cardiac death (believed to be due to fatal arrhythmias).[72-75] Common adverse effects and precautions regarding use of BBs in hypertensive patients with CVD are listed in Table 34–3.

The combined α- and β-adrenergic blocker carvedilol was studied in a post-MI population of 1959 patients with LV dysfunction in the Carvedilol Post-Infarct Survival Control in LV Dysfunction (CAPRICORN) trial.[76] All patients had a proven MI and LVEF ≤ 40%. CAPRICORN was not a hypertension trial, but more than 50% of patients in CAPRICORN were also hypertensive. Over a mean follow-up period of 1.3 years, all-cause mortality, CVD mortality, nonfatal MI, and all-cause mortality or nonfatal MI were lower in the carvedilol group than in the placebo group. The 23% observed reduction in mortality was in addition to the benefits conferred by ACEI and reperfusion therapies, which were prescribed in 98% and 46% of the patients, respectively. CAPRICORN is the first

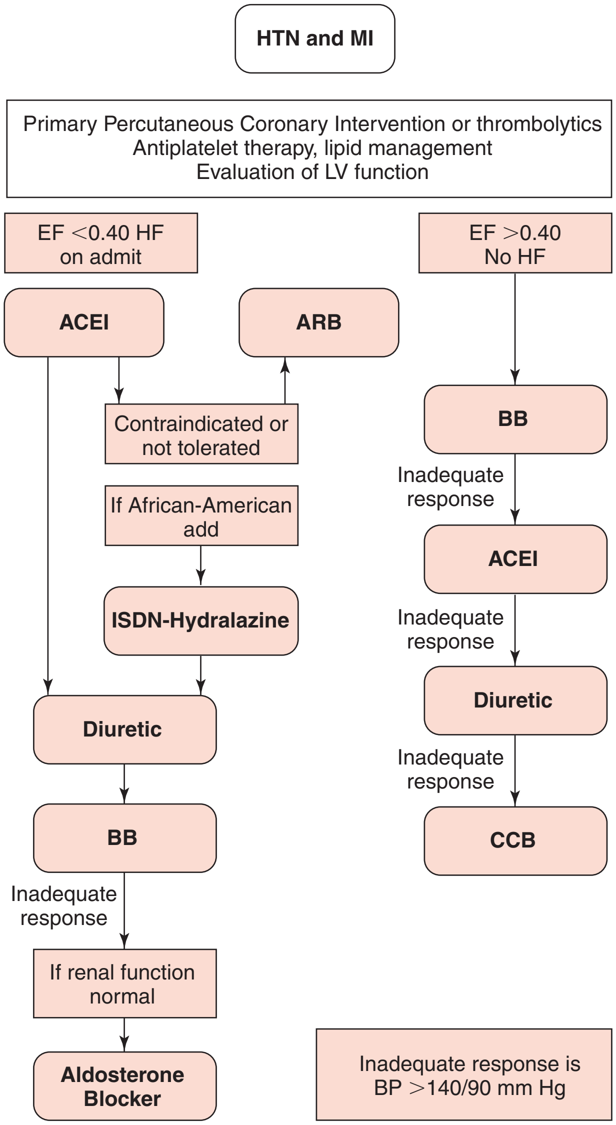

Figure 34–10 Algorithm for the management of hypertension in a patient with a myocardial infarction. Doses of drugs should normally be titrated to the usual maximal dose before a second agent is tried. The recommended calcium antagonists are cardiac-slowing agents, such as verapamil or diltiazem.

study to demonstrate the beneficial effects of BBs post-MI in the postreperfusion era. It also shows the benefit conferred on post-MI patients with LV dysfunction—a population excluded from prior BB trials in acute MI.

In the setting of acute MI, CCBs can be used in situations where BB therapy is inadequate to control angina or a related condition (e.g., elevated BP or supraventricular tachycardia) or if BBs are poorly tolerated or contraindicated.[75,77-79] In the setting of unstable angina and concomitant BB use, long-acting dihydropyridine CCBs may be preferable to nondihydropyridine CCBs due to the possibility of excessive bradycardia or heart block associated with the latter agents. Short-acting dihydropyridine CCBs should be avoided in patients with acute MI, pulmonary edema, or LV dysfunction. Compared with patients treated with other antihypertensive agents (diuretics and BBs), hypertensive patients treated with short-acting CCBs have a 60% higher risk of MI.[80]

Randomized trials of nondihydropyridine CCBs in patients with acute MI have shown benefit in preventing CVD events but no significant influence on overall mortality. Verapamil use was associated with a 20% reduction in first major events due to CV causes (death and reinfarction) in the Danish Verapamil Infarction Trial II[81] and a significant 19% decrease in reinfarction in a meta-analysis of 28 randomized trials in approximately 19,000 post-MI patients.[82] However, in these and other trials, no significant decrease in mortality has been shown with verapamil treatment. A large trial (the Multicenter Diltiazem Postinfarction Trial [MDPIT]) demonstrated no reduction in mortality or reinfarction with diltiazem treatment.[83] In patients with depressed LV function or pulmonary edema, or both, a 41% increase in CVD events (death from a cardiac cause and nonfatal MI) was noted in persons receiving diltiazem. **Thus CCBs do not reduce mortality in the setting of AMI and are not recommended except in situations where BBs are poorly tolerated or inadequate to control concomitant conditions (e.g., BP, angina, supraventricular tachycardia)**.[75]

ACEIs are indicated in all patients with acute MI who can tolerate them. In a hemodynamically (SBP $\geq$ 90 to 100 mm Hg) stable patient post-MI, an oral ACEI should be initiated, generally within 24 hours of onset of the event, particularly if the MI is anterior and associated with depressed LV function (LVEF < 40%) or HF, or both.[75] The patient's creatinine and electrolytes should be measured before initiation of ACEI therapy and periodically until the highest tolerated dose of the agent has been given and the patient has shown stable renal function. Although guidelines do not specify any particular level of serum creatinine (or estimated glomerular filtration rate) above which ACEIs or ARBs should not be administered, the outcome trials on which they are based have generally excluded patients with a serum creatinine $\geq$ 2.5 mg/dL. Accordingly, evidence of benefit in this patient group is lacking. As in patients with renal disease, modest (<30%) increases in serum creatinine are seen frequently in patients with acute MI following initiation of ACEI or ARB treatment and should not be a cause for concern (see Chapter 35). Greater increases may signify excessive volume depletion, worsening HF, or bilateral renal artery stenosis, and the patient should be evaluated carefully for these conditions. Hyperkalemia ($K^+ \geq 5.0$ mEq/L) associated with ACEI use can sometimes be dealt with by adjusting diuretic doses and stopping K^+ supplements and other agents known to increase K^+ (e.g., NSAIDS) and modifying diet. Use of ACEIs after acute MI has led to a significant reduction in mortality. ACEI therapy is particularly beneficial in patients classified as high risk (Killip class 2 or 3, HR $\geq$ 100 bpm). Current guidelines recommend that ACEI be initiated routinely after acute MI and continued for an indefinite period.[75]

ARBs are indicated for patients with acute MI who are intolerant of ACEIs and have clinical or radiological signs of HF or LVEF < 0.40. Further, ARBs are an accepted alternative to ACEIs in this patient group even if among persons who can tolerate ACEIs.[75] Valsartan and candesartan have established efficacy for this recommendation. ACE-ARB combinations can be considered in the long-term management of these patients if symptomatic HF and LVEF < 0.40 persist or if BP is uncontrolled, or both. Further, aldosterone blockade is recommended for post-MI patients without significant renal dysfunction (Cr $\leq$ 2.5 mg/dL in men, $\leq$ 2.0 mg/DL in women) or hyperkalemia ($K^+ \geq 5.0$ mEq/L) who are receiving therapeutic doses of an ACEI and have an LVEF $\leq$ 0.40 and either

Table 34–3 Common Adverse Effects and Precautions Regarding Use of Antihypertensive Drugs

Drug Class	Adverse Effects	Precautions and Special Conditions
β-Blockers	Bradycardia, negative inotropic effect, fatigue, insomnia, bizarre dreams, sexual dysfunction, hypertriglyceridemia, decreased HDL cholesterol, may mask hypoglycemic symptoms, may worsen symptoms of PAOD, may suppress exercise tolerance, rebound hypertension or angina, or both, can occur with abrupt withdrawal	Should not be used in patients with asthma, chronic obstructive pulmonary disease, second- or third-degree heart block, particularly when nondihydropyridine CCBs are administered concomitantly, and sick sinus syndrome: use in HF requires careful titration, special precautions: use with caution in patients with diabetes and peripheral vascular disease: sudden withdrawal of these drugs may be hazardous
ACE inhibitors	Cough, much less common are angioedema, rash, hyperkalemia	Can cause renal failure in patients with severe HF, who are overdiuresed, hemodynamically unstable after AMI, or who have bilateral renal artery stenosis: creatinine and electrolytes should be measured before initiation of therapy and periodically until dose titration is complete: contraindicated in pregnancy because of possible teratogenic effects: neutropenia may occur in patients with autoimmune collagen disorders
Angiotensin receptor blockers	Hyperkalemia, angioedema (rare)	May share adverse effects of ACE inhibitors other than cough: contraindicated in pregnancy because of possible teratogenic effects: more clinical experience in high-risk patients is necessary for full assessment of risk
Aldosterone receptor blockers	Hyperkalemia, gynecomastia, mastodynia, sexual dysfunction	Potassium levels must be monitored, particularly in patients treated with ACE inhibitiors, angiotensin receptor blockers, potassium-sparing diuretics, or potassium supplementation
Calcium channel blockers Dihydropyridines	Ankle edema, flushing, headache, gingival hypertrophy (uncommon), increase in heart rate may occur	Short-acting dihydropyridines should be avoided in patients with AMI, pulmonary edema, or left ventricular dysfunction: long-acting dihydropyridines in AMI should be reserved for situations where β-blockers or other agents, or both, are inadequate to control concomitant conditions (e.g., blood pressure, angina, severe ventricular tachycardia): not useful in HF
Nondihydro-pyridines	Constipation, first-degree heart block, bradycardia, worsening of systolic dysfunction	Use with caution in patients with HF, heart block, sick sinus syndrome, bradycardia, particularly when β-blockers are administered concomitantly; in AMI, should be reserved for situations where β-blockers or other agents, or both, are inadequate to control concomitant conditions

symptomatic HF or diabetes. BP control with a combination of lifestyle modification and antihypertensive drugs is critical for the post-MI patient, and guidelines suggest an aggressive target goal of 120/80 mm Hg.

HEART FAILURE

HF is the only form of CVD that is increasing in incidence, prevalence, and overall mortality. Importantly, 40% to 50% of patients with symptoms of HF may have preserved systolic function. These patients are more likely to have hypertension, LVH, and isolated diastolic dysfunction and are more likely to be women.[8,84] Data from the Framingham Heart Study show that in 91% of new cases, HTN antedated the development of HF.[85] In a multivariate analysis, HTN was associated with 39% of HF cases in men and 59% in women, with a twofold to threefold increased risk for HF overall. Survival rates for HF are dismal: 25% in men and 38% in women at 5 years. As HTN detection, treatment, and control have improved, prior MI has become increasingly important as a risk factor for HF. According to some reports, 60% to 70% of HF patients have had a prior MI and have developed symptoms due to LV remodeling.[86]

The path from HTN to HF involves the interplay of HTN and MI, as well as LVH and ventricular remodeling, and is mediated by a complex array of neurohormonal and mechanical changes over time (Fig. 34–11A). Norepinephrine, angiotensin II, endothelin, aldosterone, and tumor necrosis factor-alpha (TNF-α) contribute to the progression of HF and provide targets for pharmacologic therapy.[87-89] Therapy in the acute setting includes diuretics with or without inotropes and vasodilators. These agents decrease preload and help relieve symptoms related to volume overload (see Fig. 34–11B). The strategies of antagonizing salt and fluid retention or improving hemodynamics (increasing cardiac output, reducing systemic vascular resistance), or both, do not prevent the progression of HF or improve life expectancy for patients with

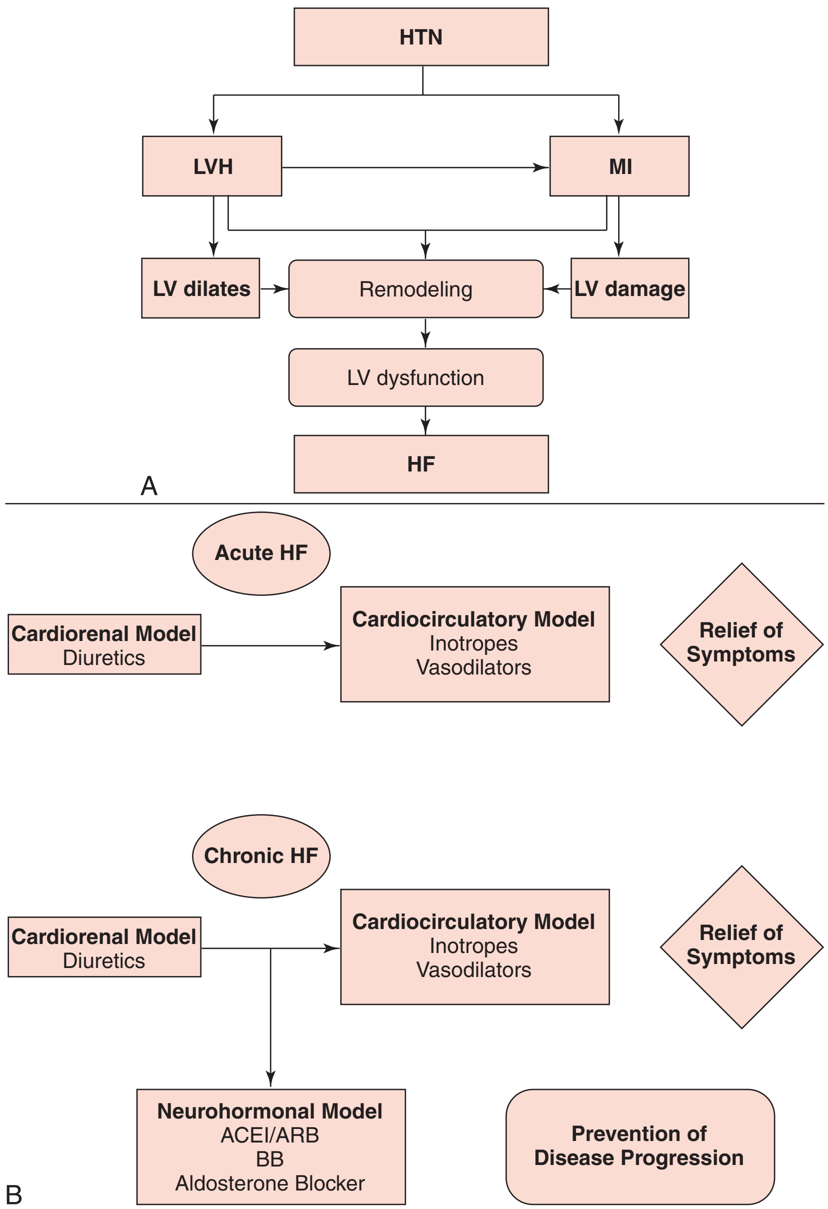

Figure 34–11 **A,** Schematic depiction of various steps responsible for the progression from hypertension to congestive heart failure. Am J Hypertens 1997;10:280S-8S.) **B,** Treatment of acute heart failure or cardiac decompensation, or both. Combinatorial use of the cardiorenal (diuretics) and cardiocirculatory models (vasodilators and inotropes) represents an effective strategy for treating patient symptoms related to excessive volume overload. Treatment of chronic heart failure. Neurohormonal antagonists (ACE inhibitors, ARBs and aldosterone blockers and β-blockers) should be used to prevent disease progression in heart failure. Moreover, combinatorial use of diuretics (cardiorenal model) is indicated in order to treat symptoms related to excessive volume overload. (Reprinted from Mann DL: Mechanisms and models in heart failure. Circulation 1999;100:999-1008.)

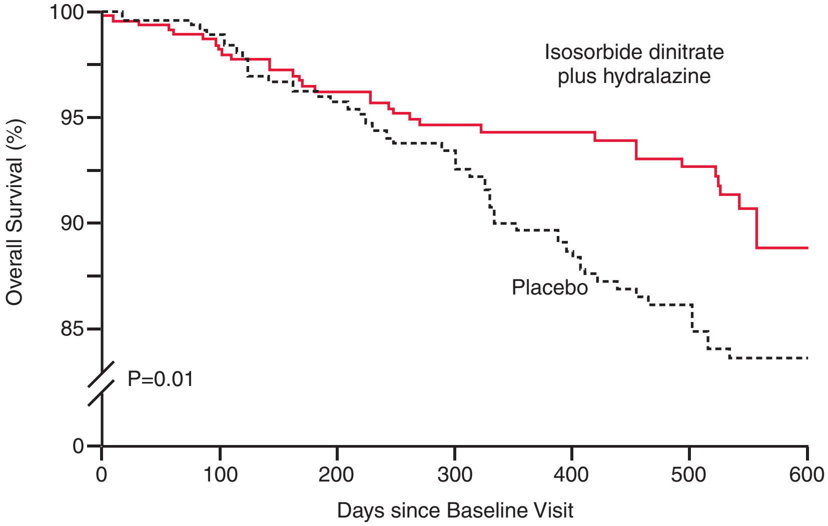
moderate to severe disease but are necessary for symptom relief in patients with acute or chronic HF.

HF is a "compelling indication" for the use of ACEIs in the patient with HTN.[8] Abundant evidence exists to justify their use with all stages of HF (see Table 34–1).[90] Most importantly, elevated levels of BP, especially SBP, are major risk factors for the development of HF,[85,91] and long-term treatment of HTN has been shown to effectively reduce the risk of HF.[92,93] Optimal BP control decreases the risk of new HF by approximately 50%.[94] In addition, ACEIs decrease both preload and afterload and have favorable effects on LV remodeling and endothelial function.[95-99] Thus ACEI therapy reduces morbidity and mortality in patients with established HF.[100,101] These outcome benefits likely relate to their anti-thrombotic and prothrombolytic effects and their favorable effects on oxidative stress in the vasculature and the myocardium, as well as their beneficial effects on LV and vascular remodeling. The benefits of ACEI therapy in HF are independent of age, sex, and the use of other pharmacologic agents, such as diuretics, aspirin, and BBs. Importantly, major clinical trials in HF or LV dysfunction including SOLVD, AIRE, SMILE, TRACE, and CONSENSUS have reported sustained post-trial benefits with ACEIs.[102-105] The sustained and incremental post-trial benefit in these studies is thought to be related to the favorable impact of ACEI therapy on LV remodeling in patients with LV dysfunction and myocardial damage.

An analysis of pooled data from the SOLVD trial has shown that there appears to be less benefit of ACEI therapy in black HF patients compared with white HF patients.[106] The combination of hydralazine and nitrates, when added to standard therapy, has been shown to reduce mortality significantly in African-American patients with HF when compared with placebo (Fig. 34–12).[107] This combination has received FDA approval for the treatment of HF in African-American patients, making it the first race-specific CV pharmacologic therapy. However, on the basis of the large body of evidence available, it is recommended that all



No. at Risk							
Placebo	532	466	401	340	285	232	24
Isosorbide dinitrate plus hydralazine	518	463	407	359	313	251	13

Figure 34–12 Kaplan-Meier survival analysis shows a 43% increase in survival in African-American patients with HF treated with isosorbide dinitrate + hydralazine compared with placebo. (Reproduced from Taylor AL, Ziesche S, Yancy C, et al: Combination of isosorbide dinitrate and hydralazine in blacks with heart failure. N Engl J Med 2004;351:2049-57.)

patients with HF, including African-Americans, be placed on ACEI therapy unless contraindicated.

ARBs and mineralocorticoid (aldosterone) receptor antagonists provide alternative mechanisms for disruption of the RAAS. These agents have been tested as alternatives or additions, or both, to ACEI therapy in HF.[60,62,108-114] In general, these trials have shown benefit with ARB treatment, particularly in ACEI-intolerant patients. The mineralocorticoid receptor antagonists spironolactone and eplerenone are recommended for use in HF (usually in combination with a diuretic) as a result of the reduced morbidity and mortality shown in the Randomized Aldactone Evaluation Study (RALES) and the Eplerenone Post-AMI Heart Failure Efficacy and Survival Study (EPHESUS).[113,114] The benefit of these agents in HF is believed to be related to blockade of mineralocorticoid receptors in the heart and vasculature, with related cardioprotective and vasoprotective effects rather than their diuretic actions. Hyperkalemia is a risk with aldosterone antagonists, even at low doses (especially because most patients are taking ACEIs or ARBs), but its incidence can be reduced by limiting therapy to patients with serum creatinine < 2.5 mg/dL and monitoring serum potassium carefully.

BBs (both nonselective and β-1 selective) appear to benefit patients with HF and HTN because of their ability to block sympathetic activation, which is believed to play an important part in the progression of HF, as well as the pathogenesis of HTN. In addition, the nonselective BB carvedilol has both α- and β-adrenergic blocking effects, which help to reduce cardiac norepinephrine levels,[115] as well as antioxidant effects, which may protect against cardiac myocyte loss. The morbidity and mortality benefits of BBs in HF have been shown in a number of large trials, as reviewed in detail in Chapter 14.[116-125]

BP targets in HF have not been firmly established, but lowering SBP is almost uniformly beneficial.[8] In most successful trials, SBPs were lowered to the range of 110 to 130 mm Hg. One trial demonstrated benefits of BBs in patients with SBP > 85 mm Hg, suggesting that low BPs (e.g., SBP < 100 mm Hg) may be desirable in some HF patients.[122]

Unlike the ACEIs, ARBs, mineralocorticoid receptor antagonists, BBs, and diuretics, the CCBs have not been shown to provide benefit to patients with HF.[126-128] **On the basis of these findings, CCB use in HF is not recommended.** Further, in randomized controlled outcome trials of antihypertensive treatment, CCBs have been shown to be less effective than other drug classes in preventing HF.[5,8,53] **Similarly, α-adrenergic blockers have not been shown to be effective in preventing HF in patients with HTN and are not recommended for that indication.[129]**

HYPERTENSION AND CEREBROVASCULAR DISEASE

HTN is the most powerful risk factor, after age, for stroke. Elevated SBP, DBP, and a widened PP are all associated with higher stroke rates.[130] Data from the Framingham Heart Study show an age-adjusted relative risk of stroke in persons with HTN of 3.1 for men and 2.9 for women.[131] Randomized controlled trials have shown that all of the major classes of antihypertensive agents including diuretics, BBs, CCBs, ACEIs, and ARBs are effective in preventing stroke compared with placebo or, in the case of ARBs, an active comparator.

A prospectively designed overview of data from 29 randomized controlled trials with 162,344 participants revealed that weighted mean SBP differences between randomized groups are directly associated with differences in risk of stroke.[5] In this analysis, CCB-based regimens tended to be more effective than either ACEI-based (12% reduction) or diuretic-BB-based regimens (7% reduction) in preventing this outcome, although none of these differences achieved statistical significance. Greater risk reductions were seen with regimens targeting lower BP goals (23% reduction) independent of

drug class. Subsequent meta-analyses have concluded that CCBs decrease the risk of stroke more effectively than other treatments in patients with essential hypertension and that the benefit may not be completely explained by a better BP response.[132,133]

Subgroup analyses of trials with dihydropyridine and nondihydropyridine CCBs revealed significant reduction in stroke risk with dihydropyridines but not with nondihydropyridines compared with control active treatment regimens.[132] Meta-regression analysis showed that CCBs were superior to ACEIs for prevention of stroke and that the difference could not be accounted for by BP differences.[133] Posthoc analyses from the ALLHAT trial confirmed the superiority of dihydropyridine CCB compared with ACEI treatment for stroke prevention, particularly in blacks (51% risk reduction) and women (45% risk reduction); diuretic-based treatment decreased stroke risk by 40% compared with ACEI treatment in blacks.[53,134] Time-dependent BP adjustment did not significantly alter differences in outcome. The ASCOT trial, not included in the meta-analysis because of its later publication date, showed a significant 25% reduction in stroke with dihydropyridine CCB-based compared with BB-based treatment, an effect that could not be accounted for by BP differences but may be related to selective reduction of central arterial pressure with CCBs compared with BBs, as demonstrated in the CAFÉ substudy.[21,29]

Active comparator trials of ARB-based versus BB- or conventional therapy–based treatment have provided the strongest evidence for BP independent benefits of any drug class in stroke prevention.[65,135-138] The LIFE trial demonstrated a 25% reduction in stroke with ARB (losartan)-based compared with BB (atenolol)-based treatment despite minimal differences in achieved BPs in more than 9000 patients with hypertension and LVH by ECG.[65,135,136] Mechanisms that have been adduced to account for this benefit of losartan include favorable effects on endothelial function, reflected in selective reductions in microalbuminuria;[139] favorable effects on vascular remodeling/atherosclerosis, reflected in reduced carotid intima/media thickness; reductions in LVH and left atrial size[140,141]; uricosuria[142]; and reductions in new onset atrial fibrillation, as well as in stroke incidence in patients with established atrial fibrillation.[136,143] Further study is necessary to evaluate the generalizability of these findings to patients without LVH, to other ARBs, and to different comparator regimens.

The Study on Cognition and Prognosis in the Elderly (SCOPE) trial compared candesartan-based with conventional antihypertensive therapy (diuretic, BB, CCB, ACEI) in 4964 elderly patients with mild to moderate HTN.[137,138] The candesartan group experienced a significant 28% reduction in nonfatal stroke, as well as a trend toward significant reduction in all stroke of 23% when compared with the control group. In a substudy of SCOPE, elderly patients with ISH experienced a robust 40% reduction with candesartan treatment compared with conventional therapy.[138]

Two major outcome trials have tested various classes of antihypertensive drugs in the secondary prevention of stroke.[144,145] The Perindopril Protection Against Recurrent Stroke Study (PROGRESS) compared ACEI therapy with and without a diuretic to placebo in more than 6100 patients with a prior stroke or transient ischemic attack.[144] The combination of ACEI and diuretic led to a reduction in BP of 12/5 mm Hg and a reduction in risk of stroke of 43%. No significant difference in the risk of recurrent stroke was seen in the perindopril-only group, which showed a 5 mm Hg reduction in SBP. Interestingly, the benefits of ACEI + diuretic treatment were seen in both normotensive and hypertensive persons and in those with and without diabetes.[146] Both ischemic and hemorrhagic stroke were prevented with this treatment regimen.

The MOrbidity and mortality after Stroke-Eprosartan compared with nitrendipine in Secondary prevention (MOSES) study compared ARB-based and dihydropyridine CCB-based treatment in prevention of secondary stroke.[145] Despite equal BP reductions in both arms, the ARB arm produced significant reductions (21%) in the primary endpoint (total mortality, total CV, and cerebrovascular events) and in stroke (25%) and a trend toward reduction in CV events. Results of the MOSES trial reaffirm the effectiveness of the ARB class of antihypertensive drugs in stroke prevention and the suggestion that these agents may have benefits beyond BP reduction.

HYPERTENSION AND PERIPHERAL ARTERIAL DISEASE

HTN, DM, and smoking are major risk factors for PAD. Symptomatic PAD is associated with a greatly increased risk of death from CVD, in part because diffuse atherosclerosis, CHD, and renovascular disease frequently coexist in these patients.[8] Therefore the threshold for screening for these related CV disorders in patients with PAD should be low (see Chapter 33). In particular, renovascular hypertension should be strongly considered in this population if BP is uncontrolled and if ACEI or ARB treatment is being considered.

Antihypertensive drug treatment is ineffective in relieving symptoms of PAD. Vasodilator agents, such as ACEIs, CCBs, α-adrenergic blockers, and direct vasodilators, have not been shown to improve walking distance or symptoms of claudication in patients with PAD.[147] Whether this is due to the inability of diseased vessels to dilate further because they are maximally dilated during exercise, to a "steal" phenomenon in which blood flow increases in nondiseased vascular beds at the expense of diseased beds, or to the possibility that BP reduction distal to occluded areas of diseased arteries decreases forward blood flow due to a loss of "driving" pressure is unknown. BBs may precipitate peripheral vasoconstriction and increase the frequency of intermittent claudication in patients with PAD.[148-150] However, studies have shown that BBs do not decrease walking distance or calf blood flow in these patients.[148] Thus BBs can be used in PAD patients, particularly for the treatment of concomitant conditions (e.g., CHD or HF.[8,151] ACEIs are also recommended for symptomatic patients with lower extremity PAD to reduce the risk of adverse CVD events.[151]

PAD has begun to emerge as a prespecified endpoint in controlled outcome trials of antihypertensive therapy. In the United Kingdom Prospective Diabetes Study Group (UKPDS) trial, tight BP control (mean achieved BP = 144/82 mm Hg vs. 154/87 in the less tight control group) in patients with HTN and DM led to significant reductions in risk of death, complications related to DM, and stroke and microvascular disease but no significant decrease in PAD risk.[152] Within the tight BP

control group in UKPDS, patients were further randomized to ACEI (captopril) or BB (atenolol) treatment.[153] Although the ACEI and BB were equally effective in reducing the risk of macrovascular endpoints, including PAD, this relatively small study (≈400 participants/treatment group) lacked the power to detect small but possibly clinically important differences in outcomes. Importantly, compliance with assigned treatments was significantly lower in the BB group, in part due to an increased incidence of intermittent claudication or cold feet.

The larger ASCOT trial, in which PAD was a tertiary endpoint, showed a statistically significant 35% excess of PAD with the atenolol-based compared with the amlodipine-based regimen.[29] This finding, coupled with the excess of peripheral coldness noted as an adverse event in the atenolol-based group, suggests that a BB may not be a desirable first drug for prevention of PAD in patients with HTN and other CVD risk factors. In contrast, results of the ALLHAT trial showed that risk of developing hospitalized or treated PAD did not differ significantly among diuretic (chlorthalidone)–, CCB (amlodipine)–, and ACEI (lisinopril)–based treatment groups.[53]

Because no class of antihypertensive medications offers particular benefit to the patient with PAD, treatment choices should be made on the basis of concomitant conditions (CHD, DM, HF).[8,151] ACEIs are recommended to reduce the risk of adverse CVD events, as in other high-risk patient populations. Evidence for this recommendation comes from the HOPE trial, which showed that, in patients with symptomatic PAD, the ACEI ramipril reduced the risk of MI, stroke, or vascular death by approximately 25%, an effect size comparable to that achieved in the study population as a whole.[27] BBs are not contraindicated in PAD but have disadvantages in terms of symptomatic adverse events. Renal artery stenosis should be ruled out in this high-risk population before initiation of ACEI or ARB treatment. If the agents mentioned earlier fail to control BP or are poorly tolerated, or both, or if the patient has Raynaud's phenomenon, CCBs can be used.

Lifestyle modification plays a particularly important role in the management of patients with HTN and PAD.[8] A structured walking program has been shown to increase the pain-free and maximum walking distances in patients with intermittent claudication.[154] Smoking cessation may be the most important factor in whether PAD progresses. Accordingly, patients should be encouraged and assisted to stop smoking. Lipid abnormalities should be controlled using lifestyle modification and drugs as appropriate. Coexisting glucose intolerance or insulin resistance calls for increased exercise and weight reduction, and aggressive management of diabetes is indicated. In addition, antiplatelet therapy is critical in these patients to reduce the risk of limb ischemia.[151]

HYPERTENSION AND ATRIAL FIBRILLATION

ACEIs and ARBs can prevent the onset and reduce the recurrence of AF.[155] Mechanisms responsible may include beneficial structural remodeling of the atria and LV, reductions in atrial interstitial fibrosis and angiotensin II–induced norepinephrine release, and possibly direct antiarrhythmic effects.[156] In a subanalysis from the LIFE study, after 5 years of follow-up, 150 patients in the losartan arm developed new-onset AF compared with 221 in the atenolol arm, a significant reduction.[136] In a study of 79 patients treated with irbesartan (150 to 300 mg/d) in combination with amiodarone (400 mg/d) versus 75 patients treated with amiodarone alone (400 mg/d), 80% of patients in the combination arm remained in sinus rhythm approximately 9 months after successful cardioversion from AF compared with 56% of those treated with amiodarone monotherapy.[157] A meta-analysis of 11 studies with 56,308 participants showed a 28% reduction in relative risk of AF in those treated with ACEIs or ARBs.[155] The greatest effect was demonstrated in HF patients, who experienced a 44% relative risk reduction. The Atrial fibrillation Clopidogrel Trial with Irbesartan for prevention of Vascular Events (ACTIVE-I) trial will randomize 14,000 AF patients with and without HTN to an ARB or placebo. Three years of follow-up will occur, and the primary endpoint will be a composite of stroke, MI, or vascular death. The irbesartan arm of this trial will provide more conclusive data on the effects of ARBs on AF.

Chapter 35

Treatment of Hypertension in Patients with Renal Disease

Nitin Khosla and George L. Bakris

CHAPTER CONTENTS

INTRODUCTION

A survey of the National Health and Nutrition Examination Survey (NHANES) database estimates that 50 million Americans have high blood pressure.[1] The degree and duration of elevation in either systolic or diastolic blood pressure (BP) substantially increases the risk of developing a cardiovascular event or renal disease.[2] In fact, for every increment of 20 mm Hg in systolic BP and 10 mm Hg in diastolic blood pressure over 115/75 mm Hg, the risk for a cardiovascular event doubles.[3] People with kidney disease are at a particularly high risk of developing cardiovascular complications from elevated blood pressures.[4,5] This is especially true among those with proteinuria >300 mg/day.[6,7] Current guidelines suggest that lowering blood pressure to <130/80 mm Hg in this cohort can prevent or delay the onset of kidney failure.[2,8]

The results of any clinical trial that evaluates antihypertensive treatment on kidney disease progression must be considered in the context of the following factors: (a) goal blood pressure achieved and time to achieve goal; (b) stage of the kidney disease at the inception of a trial; and (c) presence or absence of macroalbuminuria (proteinuria, i.e., >300 mg/d albumin in urine). These factors are important because earlier intervention is much more likely to arrest kidney disease progression than later intervention that will only slow disease progression. This is illustrated by the results of two different renal outcome trials with widely divergent baseline glomerular filtration rates (GFR) and levels of proteinuria. In The Appropriate Blood Pressure Control in Diabetes (ABCD) trial, the average GFR was more than 80 mL/min at the start of the trial, whereas in other diabetes trials the GFR is generally less than 50 mL/min at baseline.[9] Early and aggressive BP lowering (i.e., <130/80 mm Hg) in the ABCD trial was associated with GFR decline being slowed to rates seen in people with normal kidney function. Conversely, in other trials of more advanced kidney disease, GFR loss occurred at a rate of 2 to 7 mL/min/yr.[8,10] Thus, results of clinical trials in patients with advanced renal disease should not be extrapolated to patients with early disease because rates of decline in renal function are not comparable unless baselines are similar.

This chapter deals exclusively with the management of hypertension in chronic renal disease. Management of this condition focuses on agents that not only lower BP but also reduce microalbuminuria (MA) or macroalbuminuria (proteinuria), or both. The presence of MA is an independent risk marker associated with a higher incidence of cardiovascular events in all subjects independent of kidney disease or diabetes.[11-14]

MA is defined as a protein excretion of 30 to 299 mg/d or 20 to 200 mcg/min present on two different occasions. Protein excretion >300 mg/d or >200 mcg/min represents overt proteinuria.[15] Urinary protein excretion is best assessed by the albumin-to-creatinine (mg/g) ratio in a spot urine specimen. A guide to the evaluation of MA is presented in Figure 35–1.[15] The overall treatment goal in patients with hypertension and any level of albuminuria is to achieve target BP goal using agents that also reduce MA or proteinuria. The reason for this is that blood pressure lowering alone does not totally account for the magnitude of albuminuria reduction. Reduction in macroalbuminuria (proteinuria) has been shown in five outcome trials to delay markedly the need for dialysis in people with advanced proteinuric kidney disease, Table 35–1. This benefit on kidney disease progression could not be explained by blood pressure lowering alone in these trials.[16-19] In three of these studies a reduction in proteinuria of more than 35% resulted in a 39% to 72% risk reduction for dialysis at 3 to 5 years.[17-19] The data on cardiovascular benefit from MA reduction are less clear; however, data from the LIFE trial indicated a benefit of early MA reduction on cardiovascular events extending out to 5 years.[20]

NONDIABETIC RENAL PARENCHYMAL DISEASE

The incidence of renal insufficiency progressively increases with every 10 mm Hg increment in systolic pressure.[21] End-stage renal disease (ESRD) resulting from causes unrelated to diabetes is most often attributed to hypertensive nephrosclerosis. Pathologically, this is represented by hyalinization and

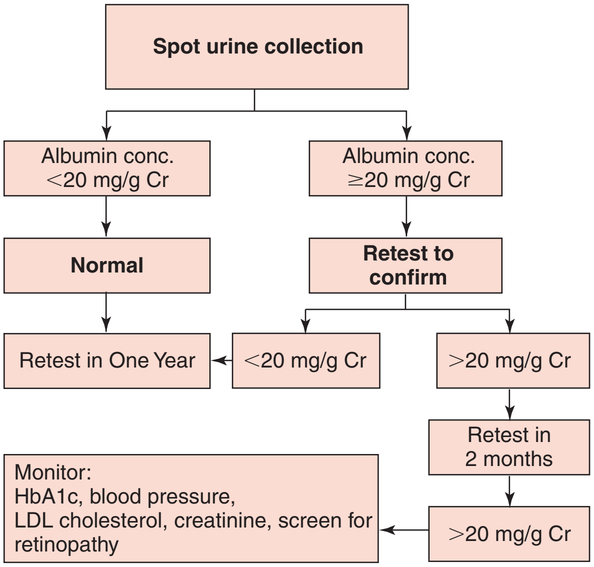

Figure 35–1 Evaluation and work-up of microalbuminuria. (Modified from Keane WF, Eknoyan G: Proteinuria, albuminuria, risk, assessment, detection, elimination (PARADE): A position paper of the National Kidney Foundation. Am J Kidney Dis 33:1004-10, 1999.)

sclerosis of the walls of the afferent arterioles. The other major finding that heralds the development of hypertensive renal disease is the development of MA, which is felt to be both a marker of impaired endothelial responsiveness and a likely factor in the initiation and progression of tubulointerstitial renal injury.[22,23]

Some of the earlier trials that evaluated progression of kidney disease resulting from causes other than diabetes include The Ramipril Efficacy in Nephropathy (REIN), Angiotensin-Converting Enzyme Inhibition in Progressive Renal Insufficiency (AIPRI), and Modification of Dietary Protein in Renal Disease (MDRD) trials, as well as other smaller trials. These trials all demonstrate the importance of lowering BP to slow progression of nondiabetic kidney disease.[24,25]

Although BP reduction is important, consideration must be given to agents that preferentially reduce albuminuria because that is an independent factor affecting progression of kidney disease. This is further demonstrated by a meta-analysis of clinical trials in patients with nondiabetic renal disease, which found that the use of angiotensin-converting enzyme (ACE) inhibitors delays the progression of renal disease, an effect shown to relate to the magnitude of proteinuria reduction, as well as BP.[26] Perhaps the most compelling data come from the substudy of the COOPERATE trial. In this trial of IgA nephropathic patients with an average GFR of <50 mL/min and 2.3 g of proteinuria, using the combination of an ACE inhibitor with an angiotensin receptor blocker (ARB) in the same doses used individually resulted in greater slowing of kidney disease progression, an effect that could not be explained by differences in 24-hour ambulatory blood pressure data (Fig. 35–2).[19] It should be noted that use of an ACE inhibitor with ARB at high doses of each does *not* offer a significant BP advantage but rather has only been shown to benefit outcome in people with advanced nephropathic disease and not cardiovascular disease, such as post myocardial infarction or heart failure.[27,28]

Table 35–1 Clinical Renal Outcomes Trials in the Context of the Primary Outcome in Relation to Changes Observed in Proteinuria*

Increased Time to Dialysis (30-35% Proteinuria Reduction)	No Change in Time to Dialysis (No Proteinuria Reduction)
Captopril Trial[89]	IDNT (DHPCCB arm)[60]
AASK Trial[90]	AASK (DHPCCB arm)[90]
RENAAL[59]	
IDNT[60]	
COOPERATE[61]	

*In the RENAAL, COOPERATE, and AASK trials these results were independent of changes in glomerular filtration rate (GFR) or baseline GFR and achieved blood pressure reduction.

DIABETES AND CHRONIC RENAL DISEASE

In patients with type 1 diabetes, the onset of hypertension closely correlates with the development of renal disease. The incidence of hypertension rises from 5% at 10 years to 33% at 20 years and 70% at 40 years, but hypertension is present in only 2% to 3% of those without clinically evident renal involvement. Such patients may have underlying essential hypertension rather than elevated blood pressure related to their diabetes. This is in contrast to patients with type 2 diabetes.

Both hypertension and an abnormal circadian BP profile are strongly correlated with the presence of albuminuria and are powerful predictors of cardiovascular or renal events.[29] A retrospective study collected ambulatory blood pressure monitoring in a clinic setting in 75 patients with diabetes and followed them for a median of 42 months. Over time, dippers had a lower mortality than nondippers, with 8% deaths in the cohort of dippers and 26% deaths in the cohort of nondippers. They also noted that age, duration of diabetes, and baseline renal function were independent risk factors for mortality in nondippers. They also noted a fourfold increase in mortality in those who had normal kidney function and converted to nondipping BP status. This study suggests a role for ambulatory BP monitoring in day-to-day clinical practice to select patients with nephropathy who are at greatest risk and to focus aggressively on treatments that may alter outcome.[30]

The risk of target organ damage resulting from hypertension is highest in blacks with diabetes, who are also at much greater risk for renal failure from diabetic nephropathy. Early studies showed an increased risk of renal disease in certain ethnic groups related to ACEI/D polymorphisms (which could increase ACE levels) interacting with angiotensinogen M 235T polymorphisms (which could increase angiotensinogen levels). Moreover, those who do not have clinically evident diabetes but with a genetic predisposition to diabetic nephropathy have higher BP levels than those with no family

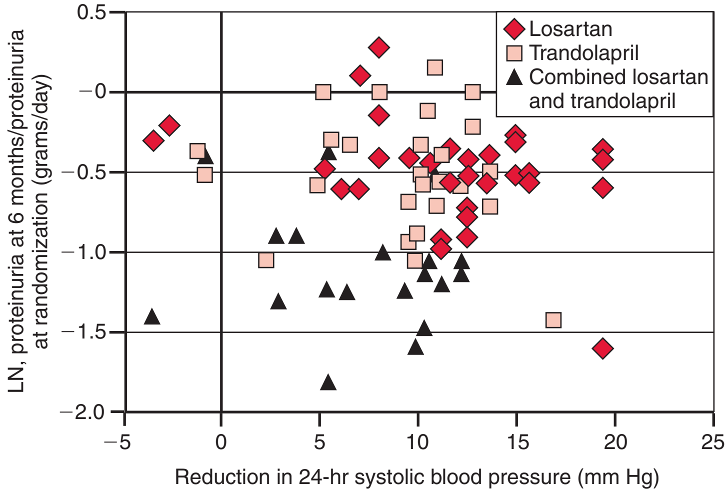

Figure 35–2 The change in ambulatory blood pressure and proteinuria following 6 months of treatment of advanced nondiabetic kidney disease predicted outcome at 3 years. Note that the dose of losartan was 100 mg/d, of trandolapril was 3 mg/d, and the combination was the same doses combined. (Modified from Nakao N, Seno H, Kasuga H, et al: Effects of combination treatment with losartan and trandolapril on office and ambulatory blood pressures in nondiabetic renal disease: A COOPERATE-ABP substudy. Am J Nephrol 2004;24:543-8.

history of the disease. These observations have been verified in a meta-analysis of more than 14,000 patients and emphasize the especially high risk in the Asian population.[31] The actual genetic link to predicting nephropathy in diabetes is inconclusive. A review of all such factors including studies of genes related to inflammatory markers has not revealed a clear answer.[32] Ongoing studies may provide an answer within the next decade.

The strongest risk factors for nephropathy development and progression in those with diabetes are presence of hypertension and poor glycemic control and development of macroalbuminuria (proteinuria).[33,34] Detection of MA is a predictor of overall cardiovascular morbidity and does not predict nephropathy development unless it increases to macroalbuminuria or proteinuria.[35,36] Development of proteinuria despite adequate BP control is a clue that renal disease is present and progressing. The presence of proteinuria of >2.5 g per day is an uncommon consequence of hypertension alone and should prompt a renal biopsy to determine the etiology of renal disease or at least an evaluation for occult diabetes. More than 40% of patients with diabetes develop the syndrome of diabetic nephropathy defined by increases in arterial pressure, persistent proteinuria, and decline in GFR. The presence of nephropathy is associated with increased morbidity and mortality rates because of both increased cardiovascular events and end-stage renal failure.[37]

Patients with diabetes and macroalbuminuria are 20 times more likely to die of cardiovascular disease than those without albuminuria. Hence treatment is aimed at both lowering arterial pressure to a stated goal and reducing proteinuria by at least 30% to 50% from baseline.[8,37,38] The person with diabetes should be started on antihypertensive medications even if the BP is in the high-normal range (>130/80 mm Hg) because of the greatly heightened cardiovascular and renal risks.[2,8]

THERAPEUTIC APPROACHES TO HYPERTENSION IN KIDNEY DISEASE

Lifestyle approaches to treating blood pressure in those with early kidney disease are summarized in Table 35–2.[2,8] Specific attention is given to sodium intake because it contributes relatively more to increasing BP than do other lifestyle factors.

Table 35–2 Summary of Lifestyle Modifications[2]

Modification	Approximate SBP Reduction (Range)
Weight reduction	5-20 mm Hg/10 kg weight loss
Adopt DASH eating plan	8-14 mm Hg
Dietary sodium reduction	2-8 mm Hg
Physical activity	4-9 mm Hg
Moderation of alcohol consumption	2-4 mm Hg

DASH, Dietary Approaches to Stop Hypertension.
Modified from the JNC 7-SBP systolic blood pressure.

Sodium Restriction

Sodium retention is a major pathophysiological mechanism of hypertension development in chronic renal disease. Sodium retention is also a major contributor to BP elevation in the presence of insulin resistance because insulin increases proximal tubular sodium reabsorption.[39,40] Hence, those who are obese or have diabetes are relatively volume expanded.[41] Therefore, limitation of daily sodium intake to 2 to 4 g/d is a logical initial therapeutic approach. Salt restriction is also important because excessive dietary sodium intake (i.e., >6 g/d) attenuates the effects of ACE inhibitors and ARBs on proteinuria reduction.[42] Further, because blacks with essential hypertension demonstrate greater angiographic and histological evidence of arteriolar nephrosclerosis than whites and because both normotensive and hypertensive blacks excrete a lower sodium load than their white counterparts, sodium restriction is particularly important in blacks with essential hypertension.[42] The importance of this difference in renal sodium handling is borne out by the results of the DASH diet, in which hypertensive black females had a 6 mm Hg greater reduction in BP compared with hypertensive white females on this low-sodium, high-potassium diet.[43] Note that this diet can be given to those with up to early stage 3 nephropathy (GFR>30<59). After that, the high potassium intake should be reduced.

This sluggish response to sodium loading in the black population is associated with a higher prevalence of salt-sensitive hypertension and lower plasma renin activity than in white

hypertensive patients. Lastly, sodium restriction clearly contributes to the maintenance of BP reductions in elderly patients with established hypertension.[44]

Pharmacologic Treatment

The guidelines of both the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) and the National Kidney Foundation (NKF) state that all patients with kidney disease should receive either an ACE inhibitor or ARB along with lifestyle modifications and dietary changes if BP is >140 mm Hg.[2,10] Figure 35–3 illustrates an updated, integrated approach to achieve BP goal amalgamating the JNC 7, NKF, and American Diabetes Association (ADA) guidelines for those with kidney disease or diabetes, or both.[2,8,45,46]

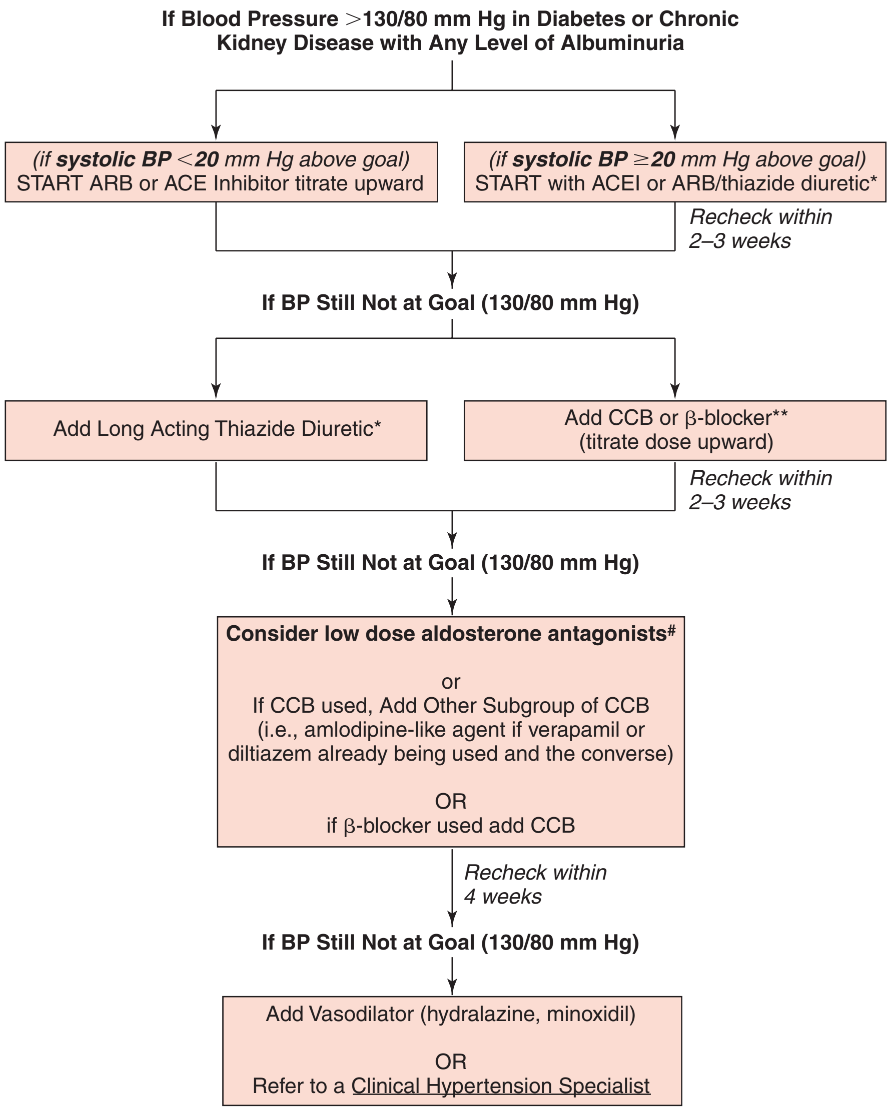

Figure 35–3 An approach to lower arterial pressure to goal in patients with kidney disease, diabetes, or albuminuria. An integration of the guidelines of the JNC 7, National Kidney Foundation, and American Diabetes Association. #, All patients with diabetes or renal insufficiency, or both, should be instructed on *lifestyle modifications* as per the JNC 7. All patients, however, should be started on therapy if blood pressure is >130/80 mm Hg. Note: If BP < 20/10 mm Hg above goal (130/80 mm Hg), then ACE inhibitor or ARB, titrated to maximal doses, alone may be used. *, Nondihydropyridine CCBs (verapamil and diltiazem have been shown to reduce both CV mortality, proteinuria, and diabetic nephropathy progression independent of ACE inhibitors or ARBs). β-Blockers may be substituted for calcium channel blockers if the patient has angina, heart failure, arrhythmia, or a high heart rate (i.e., >84 beats/min at rest) necessitating their use. β-Blockers with proven efficacy to reduce CV events and the lowest side-effect profile are preferred; of those available, carvedilol meets these criteria. *Note that use of a β-blocker with a nondihydropyridine CCB should be avoided in the elderly and those with conduction abnormalities.* Otherwise, such combinations are safe and particularly effective for lowering blood pressure. NOTE: Other agents, such as minoxidil, hydralazine, and clonidine or methyldopa can be used as adjunctive agents to help achieve goal blood pressure. Clonidine should NOT be used with β-blockers or high-dose verapamil for numerous reasons, not the least of which is a high likelihood of severe bradycardia.

ANTIHYPERTENSIVE AGENTS

Renin Angiotensin-Aldosterone System Blockade

Angiotension-Converting Enzyme Inhibitors

Although early clinical trial data supported the use of ACE inhibitors as agents that may provide additional protection against nephropathy progression, independent of blood pressure, this has not been borne out in larger studies of people with early-stage nephropathy (i.e., stage 2 [GFR 60 to 89 mL/min]).[47,48] In both the posthoc analysis of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack (ALLHAT) trial and in well-controlled animal studies, using 24-hour BP monitors, there was no evidence favoring the concept that ACE inhibitors have unique effects, independent of BP control, on preservation of renal function.[48,49] In addition to ALLHAT, the United Kingdom Prospective Diabetes Study (UKPDS) magnifies the issue that ACE inhibitors are not superior to other antihypertensive agents for reducing cardiovascular risk.[50] In this trial, captopril and atenolol had similar outcomes in hypertensive type 2 diabetic patients. This difference in outcome between trials may relate to several issues. First, in the earlier clinical studies with ACE inhibitors, all patients had advanced kidney disease (i.e., GFR <50 mL/min) and all had more than 500 mg/d proteinuria. Because macroalbuminuria is clearly associated with increased risk of nephropathy progression, a reduction in albuminuria should correlate with preservation of renal function. This has been shown in three postanalyses of large renal outcome trials.[16,17,51] Because ALLHAT had no proteinuria data, it is unclear what its results mean because the benefit of these agents on hard outcomes has been described only in patients with proteinuria and advanced nephropathy. Moreover, meta-analyses support the use of ACE inhibitors as antihypertensive agents in patients with diabetic nephropathy, in part because they reduce proteinuria.[29]

This benefit in people with advanced nephropathy and proteinuria is exemplified by results in the captopril nephropathy trial of people with type 1 diabetes. In this study, those whose serum creatinine values were >2.0 mg/dL derived the greatest benefit from adding ACE inhibition to a standard antihypertensive regimen in order to lower BP to <140/90 mm Hg. The ACE inhibitor group had a 74% reduction in the risk of doubling serum creatinine and a 75% reduction in the incidence of death, dialysis, and kidney transplantation compared with the placebo group. Conversely, patients with a serum creatinine value <1.0 mg/dL and similar degrees of BP reduction with an ACE inhibitor experienced only a 4% reduction in this endpoint. In the REIN trial, patients who had serum creatinine values higher than 2.0 mg/dL and >3.0 g/d proteinuria had a 62% reduction in renal disease progression during the same 42-month follow-up, and those with MA had a 22% reduction in renal disease progression.[52] Similar findings have been noted in meta-analyses of nondiabetic renal disease.

ACE inhibitors have been shown to reduce cardiovascular events in normotensive patients who are at high cardiovascular risk (i.e., patients with type 2 diabetes or ischemic heart disease, or both).[53] Their effects are even more pronounced on cardiovascular (CV) event reduction in the presence of proteinuria or kidney disease.[33,54] ACE inhibitors reduce proteinuria, a known risk factor for CV and renal disease, more than other antihypertensive agents at similar levels of BP lowering.[47] Additionally, unlike ALLHAT, these studies used diuretics as the second agent necessary for BP control, which also may have contributed to the differences in outcome among these studies.

ACE inhibitors may also protect renal function via their effect on "renal reserve." These agents blunt the rise in GFR that follows a protein load.[55] The nephron responds to a variety of factors, such as increased protein intake with an elevation in GFR. This is referred to as *renal reserve* because it reflects the ability of the kidney to increase its clearance rate in the presence of higher urea genesis. The increase in GFR is due to afferent glomerular arteriolar dilation in response to various amino acids.

A simple way to conceptualize the benefits of ACE inhibitors to the kidney is through an analogy with cardiac function. ACE inhibitors reduce the maximal response of a given nephron to excrete metabolic waste products by reducing its baseline GFR, analogous to β-blocker–induced reduction in baseline heart rate, blunting the maximal increase in heart rate and BP during exercise, in part by decreasing the work of the heart and improving coronary flow. β-Blockers reduce cardiac mortality in those with diabetes and kidney disease.[56] When β-blockers are stopped, heart rate and myocardial work increase. We postulate that ACE inhibitors reduce the work of individual functional nephrons in much the same way and thus preserve nephron function.

In keeping with the aforementioned concept, increases in serum creatinine are commonly seen within a few weeks of starting ACE inhibitors and angiotensin receptor blockers (ARBs), especially in those with later-stage nephropathy, who have lost their renal reserve. A rise in serum creatinine limited to 30% to 35% within the first 4 months of starting renin angiotensin-aldosterone system (RAAS) blocking therapy, however, correlates with preservation of kidney function over a mean follow-up period of 3 or more years.[8,57] This correlation between a limited early rise in serum creatinine and long-term preservation of kidney function was restricted to patients with baseline serum creatinine values ≤3.5 mg/dL who were younger than age 66. If acute increases in serum creatinine of >40% occur in less than 4 months of RAAS blocker therapy, the physician should evaluate the patient for (1) volume depletion (the most common etiology); (2) worsened heart failure; or (3) bilateral renal artery stenosis.[57] Elevations in serum potassium become clinically relevant only at levels markedly exceeding 5.5 mEq/L or 5 mEq/L in the presence of digitalis preparations. Hyperkalemia can be addressed by appropriately dosing diuretics and stopping agents known to increase potassium, such as nonsteroidal anti-inflammatory agents and increased intake of fruits and many vegetables.

In summary, the data on ACE inhibitors indicate that they are efficacious in slowing progression of advanced proteinuric nephropathy when used as part of a regimen to achieve BP and proteinuria lowering. In contrast, the data do not support the notion that these agents are superior to other BP-lowering agents for reducing CV mortality or preventing long-term consequences of early stage 2 nephropathy (i.e., GFR > 75 but < 90 mL/min).[58]

Angiotensin Receptor Blockers

Animal data support the concept that ARBs provide renoprotection similar to that of ACE inhibitors.[49] Two renal outcome trials, the Reduction of Endpoints in Non-insulin dependent diabetes mellitus with the Angiotensin II Antagonist Losartan (RENAAL) trial and the Irbesartan in Diabetic Nephropathy Trial (IDNT), demonstrated that in advanced nephropathy secondary to diabetes, use of an ARB as part of an antihypertensive regimen to achieve BP reductions slows nephropathy progression to a greater extent than other agents (i.e., amlodipine or β-blockers/diuretics).[59,60] The primary composite endpoint for both studies was time to doubling of baseline serum creatinine concentration, onset of ESRD, or death. In the RENAAL study of 1513 patients, followed for an average of 3.4 years, and the IDNT of 1715 patients, followed for an average of 2.7 years, there were 16% and 37% risk reductions by losartan and irbesartan, respectively, for the primary endpoint. In RENAAL, there was a 28% reduction in time to ESRD. It was estimated that losartan could delay the need for dialysis or transplantation for 2 years.[59]

These trials clearly reinforce the earlier point about selecting agents that not only help achieve the BP goal but also reduce proteinuria (see Table 35–1). On the basis of these results, all guidelines include ARBs as first-line therapy for patients with diabetes and evidence of nephropathy.[2,8,45]

ARBs appear to be comparable to ACE inhibitors in patients following a myocardial infarction,[27] but only limited data directly compare the two classes in terms of renal outcomes. The COOPERATE trial sought to answer this question by randomizing patients to receive a dose of an ACE inhibitor alone or ARB alone, predefined to yield the greatest reduction in albuminuria. These doses were compared with either ARB or ACE inhibitor alone or in combination on renal outcomes.[61] Although the study found that all three treatment groups had similar reductions in blood pressure throughout the 3 years of the study, patients in the combination group had the greatest reduction in proteinuria and slowest progression to ESRD.[61]

In addition to similar renoprotective properties, ARBs and ACE inhibitors share several other properties: (a) they reduce new-onset diabetes,[62] and (b) they reduce the incidence of recurrent stroke.[63,64] ARBs, however, are generally better tolerated than ACE inhibitors in that they are associated with a lower incidence of cough, angioedema, and hyperkalemia.[65]

Diuretics

Diuretics are the oldest class of antihypertensive agents that have consistently demonstrated their ability to reduce CV mortality. Thiazide diuretics, in particular, have gained a renewed importance in treating hypertension since the publication of ALLHAT.[66] The trial compared the effects of a thiazide diuretic, a dihydropyridine calcium channel blocker, an α–adrenergic blocker, and an ACE inhibitor on CV outcomes in a group of more than 42,000 people at high CV risk with hypertension. The study found no differences in the primary outcome (i.e., fatal CHD or nonfatal myocardial infarction combined) between the treatment groups over the 6-year follow-up. On the basis of these and many other outcome trials, JNC 7 states that diuretics should be used as initial therapy in most (those older than age 50) patient populations.

The beneficial effect of thiazide diuretics in those with diabetes was further demonstrated by programs like Systolic Hypertension in the Elderly, which showed that chlorthalidone, the diuretic used in most positive outcome trials, reduced CV mortality.[67] Although JNC 7 recommends the use of any one of the thiazide-like diuretics, special consideration should be given to the specific thiazide chosen. In the Multiple Risk Factor Intervention Trial, chlorthalidone was shown to be superior to hydrochlorothiazide in terms of CV outcomes. Although the two drugs are thought to have similar efficacy, chlorthalidone is likely more potent because of its longer half-life (44 hours, chlorthalidone vs. 12 hours, hydrochlorothiazide).[68,69] This difference in duration of action translated into an additional 7 mm Hg reduction in systolic BP when substituted for hydrochlorothiazide.[68]

In general, thiazide diuretics are quite effective in patients who have serum creatinine values <1.7 mg/dL. At higher levels of serum creatinine or if the estimated GFR is <50 mL/min, only loop diuretics given twice daily are effective for volume removal and BP reduction. For diuretic-resistant patients, generally those with hypoalbuminemia or heart failure, combining a diuretic that inhibits at the loop of Henle with one that acts at the proximal or distal tubule, such as furosemide with metolazone, may yield a response when neither is effective alone.

Clinicians should avoid excessive diuresis, as well as interference with diuretic action by nonsteroidal anti-inflammatory drugs (NSAIDs). Potassium-sparing diuretics should also be avoided in patients with preexisting hyperkalemia (i.e., serum potassium > 5.5 mEq/L from either diabetes or severe renal disease of other etiologies). Use of aldosterone receptor antagonists, such as spironolactone and epleronone in low doses, may be indicated in heart failure and renal insufficiency or in proteinuric kidney disease, as they have been shown to be protective both in human heart failure and in animal models of renal disease.[70-72] When used with other diuretics at low doses, the incidence of hyperkalemia with aldosterone receptor antagonists was low in the heart failure trials. A benefit of significant risk reduction occurred when added to maximal therapy including an ACE inhibitor, β-blocker, and nitrates in heart failure, and there were additive antiproteinuric effects to ACE inhibitors or ARBs in diabetes.

Although moderate to high doses of diuretics worsen insulin resistance and increase the risk for new-onset diabetes, at the currently recommended low doses or when they are taken in combination with an ACE inhibitor or ARB, their effects on insulin sensitivity and other metabolic parameters are negligible.[73] Sodium restriction is critically important in all patients taking diuretics, as sodium intake in excess of 200 mEq/day not only blunts the antihypertensive and antiproteinuric actions of the ACE inhibitors but also increases the risk of hyperkalemia development.

Calcium Channel Blockers

The available data from both preclinical and clinical studies indicate that dihydropyridine calcium channel blockers, such as amlodipine, do not reduce albuminuria to the same extent as nondihydropyridine calcium channel blockers, such as verapamil or diltiazem.[74,75] The mechanism for this difference in advanced nephropathy relates to differences in glomerular permeability.[75,76] This difference in antiproteinuric effect

has translated into poorer renal outcomes in advanced nephropathy with proteinuria compared with blockers of the RAAS.[75]

This effect on proteinuria, however, is only relevant in advanced nephropathy. In the Bergamo Nephrologic Diabetes Complications Trial (BENEDICT), which compared nondihydropyridine calcium channel blockers with ACE inhibitors, alone or in combination, in patients with hypertension, type 2 diabetes mellitus, and normal urinary albumin excretion, no significant effect was seen with verapamil alone.[77] MA development, the primary endpoint, occurred with similar frequency in the verapamil and placebo group. This is not surprising because the calcium channel blockers (CCBs) are not considered agents that affect inflammation of the vasculature, which is reflected by the presence of microalbuminuria.[14,38,78]

Earlier concerns about safety of calcium channel blockers in hypertensive patients have been unfounded on the basis of trial results.[66] However, in advanced proteinuric kidney disease, both animal models and human studies show a failure of dihydropyridine CCBs, when used in the absence of an ACE inhibitor or ARB, to optimally slow nephropathy progression despite BP reduction.[60,79] Thus the NKF notes that dihydropyridine CCBs should not be given in the absence of an ACE inhibitor or ARB maximally dosed to reduce BP in patients with proteinuric kidney disease, regardless of etiology.

β-Adrenergic Blockers

Despite a high adverse-effect profile, β-blockers reduce CV mortality in high-risk patients.[56] In the UKPDS study, atenolol was as effective as captopril in both arterial pressure lowering and protection against microvascular and macrovascular disease.[50] In a large meta-analysis of more than one million high CV-risk people, β-blockers offered a high degree of protection against myocardial events, albeit less for stroke protection.[80] Thus, although these agents are not considered first-line agents except under certain compelling circumstances, they are excellent add-on agents to reduce risk and achieve BP targets.

Newer agents in this class have neutral or beneficial effects on metabolic and renal profiles. One α- and β-blocker of note is carvedilol. This agent has demonstrated reduced CV morbidity and mortality rates and also has a neutral effect on glycemic and lipid parameters, as well as a reduced risk of new-onset MA in patients with hypertension and diabetes.[81] Moreover, it has been shown to reduce mortality in people with nephropathy.[82] This may be a useful β-blocker for such high-risk patients.

α-Adrenergic Blockers

α-Adrenergic antagonists, although effective in reducing BP, have not been shown to slow renal disease progression or reduce albuminuria in either animal models or patients with type 2 diabetes.[83] This class of agents also fails to reduce CV events in patients who have or develop heart failure. This is evidenced by the results of the long-acting α-blocker arm of ALLHAT, which was stopped early due to increased events.[84] Hence, this class is not a preferred modality of initial treatment for hypertension in those with kidney disease, despite its favorable metabolic profile. α-Adrenergic blockers are useful as third-line treatment for hypertension, especially in older men with urinary stream problems.

TREATMENT RECOMMENDATIONS AND CAVEATS

The goal BP for patients with renal disease or diabetes, or both, as outlined by all guidelines is <130/80 mm Hg. The average number of agents necessary to approach this goal in clinical trials has been 3.3 agents at maximally tolerated doses (Fig. 35–4). A retrospective analysis of renal outcome trials (i.e., people with baseline GFR values <50 mL/min) demonstrates that those with BPs that approach 130/80 mm Hg have slower rates of decline in kidney function (Fig. 35–5). Lowering BP to this range also slows progression of advanced kidney disease to a greater extent than allowing pressures to remain elevated. Guidelines for control of hypertension in patients with diabetes from various international consensus committees are summarized in Table 35–3.

The NKF and American Diabetes Association (ADA) guidelines make the point that antihypertensive agents with the ability to reduce both BP and albuminuria are preferred first-line agents to preserve kidney function[8,85] (see Fig. 35–3).[8,45] Thus, the optimal initial therapy for hypertensive diabetic patients is a blocker of the RAAS because of proven efficacy in both of these areas and excellent tolerability. If

Table 35–3 Summary of Guidelines for Control of Hypertension in People with Kidney Disease or Diabetes from Various Consensus Committees Around the World

Group	Goal Blood Pressure (mm Hg)	Initial Therapy
American Diabetes Association (2005)	<130/80	ACE Inhibitor/ARB*
Japanese Hypertension Society (2005)	≤130/80	ARB*†
National Kidney Foundation (2004)	<130/80	ACE Inhibitor/ARB*
British Hypertension Society (2004)	≤130/80	ACE Inhibitor/ARB
JNC 7 (2003)	<130/80	ACE Inhibitor/ARB*
ISH/ESC (2003)	<130/80	ACE Inhibitor/ARB
Canadian Hypertension Society (2002)	≤130/80	ACE Inhibitor/ARB
Australia-New Zealand (2002)	<130/85	ACE Inhibitor
WHO/ISH (1999)	<130/85	ACE Inhibitor

*Indicates use of combination therapy with a diuretic if blood pressure is substantially higher than goal.
†Calcium antagonists could also be combined.

the BP at baseline is >20/10 mm Hg above the goal (i.e., >150/90 mm Hg when the goal is <130/80 mm Hg), the combination of a RAAS blocker with a thiazide diuretic is appropriate. In cases of allergies to thiazides, then CCBs may be substituted. A vasodilating β-blocker should be strongly considered as an early add-on for BP control and should be preferred to a CCB if pulse rate is >84 beats/min.[46] A central α-adrenergic agonist, such as clonidine, is appropriate if β-blockers are contraindicated.

The potential risks of aggressive BP lowering, particularly in elderly patients with type 2 diabetes, has caused concern. Reducing diastolic BP to <80 mm Hg has been thought to increase CV risk in this group, but no convincing evidence of this possibility has been found in prospective clinical trials.[50,86] Retrospective data analyses of data suggested that there might be a J-shaped relationship between diastolic BP and CV disease mortality in patients with established symptomatic coronary artery disease or unstable angina. However, a posthoc analysis of three separate renal outcome trials has failed to demonstrate a J curve for BP until levels get to <115/55 mm Hg.[79,87] Thus the putative J curve should not serve as a deterrent to lowering BP to recommended goals in the absence of any clear evidence of coronary disease or unstable angina.

BP goal should be achieved within 3 to 4 months in most patients, longer in those with previous strokes or autonomic dysfunction. BP should be monitored with patients in both the sitting and the upright position to exclude the possibility of orthostatic hypotension because autonomic denervation is frequent among patients with type 2 diabetes who have nephropathy and polyneuropathy.

Data from NHANES 1999-2000 in the cohort with diabetes reported that only about 32% achieved the BP goal of <130/80 mm Hg, while the goal for Healthy People 2000 was 50%.[88] Many reasons exist, both on the part of the patient and the physician, for not achieving this lower BP goal in a higher percentage of the patients. One main reason for the failure to achieve this goal is inadequate drug dosing, which is related to emotion-based rather than evidence-based medicine. Physicians recall that there are increased side effects of drugs as doses increase. Although this is true for older antihypertensive agents, it is not true for ACE inhibitors or ARBs. Thus to optimize CV and renal risk reduction, physicians should establish BP, lipid, and glucose goals in writing with their patients, keep a copy in the chart, and give one to the patient. In order to maximize reduction in CV and renal mortality, the patient and the physician should be aware of treatment goals and discuss progress toward them at each visit.

Resistant Hypertension

Mari K. Nishizaka and David A. Calhoun

CHAPTER CONTENTS

DEFINITION

Resistant hypertension is defined as blood pressure (BP) that remains uncontrolled despite the use of three antihypertensive agents. Ideally, one of the agents should be a diuretic and all of the agents should be prescribed at doses that provide maximal or near-maximal benefit. Patients with resistant hypertension are at high risk of having reversible causes of hypertension and therefore may benefit from special diagnostic and therapeutic considerations. Historically, the definition of resistant hypertension has required obligatory use of a diuretic. Although a diuretic is, in general, useful in maximizing antihypertensive treatment, a group of patients cannot or will not use a diuretic because of real or perceived adverse effects. Such patients, if failing multidrug regimens, will likely benefit from being identified as having resistant hypertension because they are also at increased risk of having reversible causes of hypertension.

The traditional definition of resistant hypertension described uncontrolled hypertension with use of three or more medications, the implication being that, if the blood pressure is controlled, regardless of the number of medications required, then resistant hypertension is excluded. Such an interpretation does not reflect the degree of drug resistance among patients with controlled hypertension. Patients requiring four, five, or six antihypertensive medications are clearly resistant to treatment and have an increased likelihood of having potentially reversible causes of hypertension. With the current definition, patients requiring more than three antihypertensive agents, even if their BP is controlled, are considered to have resistant hypertension and deserve aggressive diagnostic evaluation.

PREVALENCE

The prevalence of resistant hypertension is unknown because accurately determining the percentage of patients whose BP cannot be controlled with three agents would require a forced-titration study of a large hypertensive cohort. However, resistance to antihypertensive therapy is clearly common, as indicated by cross-sectional analyses and clinical trials. In the most recent National Health and Nutrition Examination Survey (NHANES 1999-2000), only 53% of persons being treated for hypertension were controlled to <140/90 mm Hg.[1] The control rate in treated persons 60 years of age or older was only 44%. In a cross-sectional evaluation of primary care patients in Germany, the control rate in obese persons (BMI ≥30 kg/m^2) receiving treatment for high BP was <20% in both men and women.[2] A similar evaluation of diabetic patients in the United States found that only 23% of African-American and 31% of Caucasian patients were controlled to <130/80 mm Hg despite being prescribed an average of 2.7 and 2.2 antihypertensive medications, respectively.[3]

Contemporary hypertension outcome trials may provide the best estimate of the prevalence of resistant hypertension. In these studies the medications are usually provided at no charge to subjects, adherence is monitored, and the protocols mandate continued titration if the BP remains above goal. These studies likely underestimate the true prevalence of resistant hypertension because patients with known drug resistance are generally excluded from enrolling. Even with this limitation, these trials demonstrate that resistant hypertension is common.

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) may be the most relevant in estimating the prevalence of resistant hypertension in the United States because it is the largest outcome trial to date, enrolling more than 42,000 subjects, and is ethnically diverse, with 35% of subjects being African American or Afro-Caribbean.[4] In ALLHAT, subjects 55 years of age or older were randomized to chlorthalidone 12.5 to 25 mg, amlodipine 2.5 to 10 mg, lisinopril 10 to 40 mg, or doxazosin 2 to 8 mg daily with additional agents from other classes added as needed if BP remained >140/90 mm Hg. After 5 years of follow-up, 34% of subjects remained uncontrolled with an average use of

2 antihypertensive medications and approximately 27% of subjects were receiving 3 or more medications.

In ALLHAT, approximately 8% of subjects were prescribed four or more medications.[5] This percentage, added to the percentage of subjects who remained uncontrolled on three medications, should approximate the prevalence of resistant subjects in ALLHAT (it would not include the subjects uncontrolled on fewer than three medications who would have ended up needing four or more medications). This combined figure is not yet available from the published ALLHAT data. If one third of the subjects on three medications were never controlled (the same rate achieved overall), this percentage added to subjects on four or more medications would be about 15% of the entire cohort. A 15% prevalence of resistant hypertension is likely an underestimate relative to similarly aged hypertensive patients because subjects with known resistant hypertension (i.e., uncontrolled on more than two antihypertensive medications) were excluded from ALLHAT.

Although the percentage of patients with resistant hypertension (based on needing four or more medications) cannot be determined from published data, other clinical trials are consistent with ALLHAT in demonstrating a high degree of uncontrolled hypertension despite use of multidrug regimens. In the Controlled Onset Verapamil Investigation of Cardiovascular End Points (CONVINCE) trial, hypertensive persons at least 55 years of age and with 1 cardiovascular risk factor other than hypertension were randomized to controlled-onset, extended-release verapamil or atenolol or hydrochlorothiazide.[6] Other agents were added in stepwise fashion as needed for uncontrolled hypertension. At the end of the study, 33% of the subjects remained uncontrolled (<140/90 mm Hg) with 18% of subjects being on three or more medications. In the Valsartan Antihypertensive Long-Term Use Evaluation (VALUE) study, hypertensive persons at least 50 years of age with multiple cardiovascular risk factors were randomized to valsartan or amlodipine with hydrochlorothiazide and other agents being added to lower BP to <140/90 mm Hg.[7] At 30 months of follow-up, 40% of subjects had not achieved goal BP. Among the 15% of subjects receiving 3 or more drugs, BP remained elevated in 61%.

These cross-sectional and outcome studies suggest that resistance to multidrug antihypertensive regimens is not uncommon. Extrapolation from the ALLHAT results suggests that at least 15% of older hypertensive persons may have resistant hypertension. Further analysis of the ALLHAT database will allow for a more definitive estimate of the prevalence of resistant hypertension in the United States.

PROGNOSIS

The long-term outcome of patients with resistant hypertension compared with patients with more easily controlled hypertension has not been assessed. Presumably, cardiovascular risk is increased, given that patients with resistant hypertension often have had a longstanding history of severe hypertension and risk has been shown to be directly related to BP. Further, patients with resistant hypertension have a high prevalence of concomitant conditions (diabetes, sleep apnea, endothelial dysfunction, left ventricular hypertrophy, chronic kidney disease) that contribute to cardiovascular disease outcomes.

PATIENT CHARACTERISTICS

Treatment-resistant hypertension is generally due to persistently high systolic BP. In ALLHAT, systolic BP remained elevated at 3 years in 36% of subjects, while diastolic BP remained elevated in only 10%.[5] Similarly, in the VALUE trial, systolic BP at 30 months follow-up remained elevated in 38% of subjects, while diastolic BP was uncontrolled in only 10%.[7] In CONVINCE after 2 years of treatment, systolic BP was >140 mm Hg in 30% of subjects compared with 10% of subjects in whom diastolic BP was >90 mm Hg.[6]

Older age is one of the strongest predictors of poor blood pressure control. In NHANES III, the highest relative risk of uncontrolled hypertension, which includes untreated and undertreated hypertension, as well as resistant hypertension, was in those 65 years of age or older.[1] Among treated persons, BP was controlled in 65% of those 25 to 44 years old, 52% of those 45 to 64 years old, and 34% of those 65 years old or older. In the Framingham Heart Study, cross-sectional analysis indicated that increasing age was significantly associated with uncontrolled systolic BP.[8] In a prospective observation, those 55 years of age or older were only two thirds as likely to have controlled BP as subjects younger than 55 years of age.[9] In ALLHAT, older age also predicted lack of BP control. In participants 55 to 59 years old, the control rate for systolic BP was 62%, while in those 80 years old or older, control rates were less than 50%.[5]

In general, the more severe the hypertension, the more medications are necessary to effectively achieve goal BP. In the Framingham Heart Study, participants with systolic BP levels >160 mm Hg were twice as likely to remain uncontrolled as those with systolic BPs between 140 and 159 mm Hg.[9] Likewise, in ALLHAT, higher baseline systolic BP levels were strongly associated with a lower likelihood of reaching goal BP.[5]

Other patient characteristics associated with resistant hypertension include obesity, diabetes, chronic kidney disease, black race, female sex, and the presence of left ventricular hypertrophy (LVH). In both cross-sectional studies and treatment trials, obesity is associated with use of an increased number of antihypertensive medications and an increased likelihood of never achieving BP control. Clinical trials indicate that diabetics are more resistant to antihypertensive treatment than nondiabetics, requiring more medications to achieve the same level of BP reduction. In general, as renal function declines, more antihypertensive medications are required and achievement of goal BP becomes progressively less likely. Black race and female sex are also associated with increased resistance to treatment. In ALLHAT, BP control rates were best in nonblack men (70%) and worst in black women (59%).[5] Presence of LVH also predicts difficulty in achieving BP control, but it is unknown if LVH merely reflects more severe hypertension or has an independent effect on treatment resistance. Further, regional differences in BP control have been observed. In ALLHAT control rates were worse in participants living in the Southeastern United States.[5] The reason for this regional effect is unknown, but it was not due to use of fewer medications.

GENETICS

Because resistant hypertension represents an extreme phenotype of a much more common disorder, it seems likely that

genetic causes may be more prevalent than in the general hypertensive population, but few genetic screenings of this high-risk subgroup have been conducted. In one evaluation, Finnish persons with treatment-resistant hypertension were screened for mutations in the epithelial sodium channel (ENaC).[10] Such mutations can cause constitutive activation of ENaC, resulting in Liddle's syndrome, characterized by inappropriate sodium and fluid retention, which would be expected to suppress both renin and aldosterone. Genetic variants of ENaC subunits were significantly more common in the Finnish subjects with resistant hypertension compared with normotensive controls, but presence of the variants was not related to renin or aldosterone levels. Thus it was not obvious that the higher prevalence of the genetic variants had a meaningful physiologic effect.

Allele variants of CYP3A5, an enzyme that catalyzes the metabolization of cortisol and corticosterone, have been linked to higher BP levels in African Americans. In a subgroup analysis of a larger evaluation, presence of the CYP3A5*1 allele was associated with treatment-resistant hypertension in black subjects.[11] Although the study is small, it is provocative in suggesting a possible genetic cause of resistant hypertension and supports broader genetic screenings of similar patients.

ADHERENCE

Nonadherence is an important cause of uncontrolled hypertension, which is distinct from resistant hypertension. The diagnosis of resistant hypertension requires demonstration of failure of a three-drug regimen that is taken correctly. In general hypertensive populations, nonadherence to prescribed antihypertensive therapies may exceed 60% over several years of follow-up.[12] Multidrug regimens, complicated dosing regimens, and frequent medication changes worsen adherence.[13]

Although nonadherence is a common cause of lack of BP response in the general hypertensive population, it is likely to be less common in those who are referred to and keep their appointments with specialists. In an analysis of patients referred to and seen by hypertension specialists at Rush University Medical Center, investigators estimated that lack of BP control was attributable to medication nonadherence only 16% of the time.[14] This suggests that most nonadherent patients are effectively recognized by primary care physicians before referral or that nonadherent patients decline referral to specialists for their poorly controlled hypertension, or both.

Ultimately, nonadherence can only be confirmed by patient self-report. Therefore establishing and maintaining good rapport with the patient is essential. Adherence should be discussed in a nonthreatening fashion with particular attention being paid to out-of-pocket costs, dosing regimens, and possible adverse effects. The input of family members, in the presence of the patient, should be encouraged. Nonadherence might be suspected in patients chronically unfamiliar with the prescribed medications or dosing schedules or in whom anticipated adverse effects are absent, or both.

WHITE COAT EFFECT

Significant white coat effects (elevated office but normal or significantly reduced ambulatory BP levels) are likely as common in patients with resistant hypertension as in those with more easily controlled hypertension, with a prevalence of 20% to 30%.[15,16] As in general hypertensive populations, patients with resistant clinic hypertension but lower ambulatory BP levels are probably at lower risk of cardiac complications than those with higher ambulatory BP levels.[17] Unknown is to what degree antihypertensive medications can be withdrawn from patients with "white coat" resistant hypertension and low ambulatory BP levels.

White coat effects should be suspected in patients with persistently high BP levels measured in the clinic but much lower levels when measured outside of the clinic (home or work); in patients with high BP levels measured in the clinic but symptoms of low BP, particularly orthostatic symptoms; and in patients with sustained clinic hypertension but an absence of evidence of target-organ damage (LVH, retinopathy, chronic kidney disease). In such cases, 24-hour ambulatory monitoring is indicated to evaluate for a significant white coat effect. If present, out-of-clinic BP measurements should be relied on to guide therapy.

DIETARY SODIUM

On a population basis, high dietary salt ingestion is related to increased BP levels.[18] In hypertensive persons, high salt ingestion has been shown to blunt the antihypertensive benefit of pharmacologic therapy.[19] Studies of dietary salt restriction demonstrate reductions in systolic BP in salt-sensitive hypertensive persons of up to 5 to 10 mm Hg.[20,21] BP reductions in salt-sensitive subgroups, such as African Americans, the elderly, the obese, and patients with chronic kidney disease, tend to be larger than in the general hypertensive population, where treatment effects of dietary sodium reduction are generally in the range of 2 to 8 mm Hg in systolic BP. Benefit of dietary salt restriction has not been specifically evaluated in patients with resistant hypertension, but benefit has been described in hypertensive subjects uncontrolled with an ACE inhibitor or an ACE inhibitor in combination with a diuretic.[22,23] Accordingly, dietary salt restriction, ideally to <100 mEq of sodium/24-hour, should be recommended to all patients with resistant hypertension.

OBESITY

Obesity is associated with more severe hypertension, need for an increased number of antihypertensive medications, and increased likelihood of never achieving BP control.[2,5] Mechanisms of obesity-induced hypertension are complex and not fully elucidated but include impaired sodium excretion, increased sympathetic activation, and stimulation of the renin-angiotensin-aldosterone system.[24] Benefit of weight reduction has not been specifically evaluated in persons with resistant hypertension. In a review of long-term weight-reduction studies, a 10-kg weight loss was associated with a 6 mm Hg reduction in systolic and a 5 mm Hg reduction in diastolic BP.[25] Although admittedly difficult to accomplish and even more difficult to maintain, weight reduction should be recommended to all overweight and obese patients with resistant hypertension because it will likely assist BP reduction and reduce the need for antihypertensive treatment.

ALCOHOL

Heavy alcohol ingestion is associated with a significantly increased risk of having hypertension that is uncontrolled with treatment. In a cross-sectional analysis of Chinese adults, ingesting ≥30 drinks a week increased the risk of having hypertension by 12% to 14%.[26] In a Finnish hypertension clinic, patients with elevated γ-glutamyltransferase (GGT) levels, a marker of heavy alcohol ingestion, were much less likely to have their BP controlled during a 2-year follow-up compared with patients with normal GGT levels.[27] Prospectively, cessation of heavy alcohol ingestion by a small group of patients reduced 24-hour ambulatory systolic BP by 7.2 mm Hg and diastolic BP by 6.6 mm Hg while reducing the prevalence of hypertension from 42% to 12%.[28] Whether through direct physiologic effects or improvements in adherence, or both, cessation of heavy alcohol use does improve hypertension control. Ingestion should be limited to 1 oz of alcohol a day (24 oz of beer, 10 oz of wine, or 2 oz of 100-proof liquor).

EXOGENOUS SUBSTANCES

Pharmacologic substances that can worsen BP control include non-narcotic analgesics, glucocorticoids, stimulants, sympathomimetics, and oral contraceptives (Table 36–1). The effects on BP of these substances vary widely among individuals, with most persons being able to tolerate them with no or minimal increases in BP. Some individuals, however, may be particularly sensitive to specific agents such that withdrawal should be attempted if possible.

Chronic use of non-narcotic analgesics including aspirin, acetaminophen, and nonsteroidal anti-inflammatory agents (NSAIDs) increases the risk of developing hypertension.[29,30] The effect is presumably from increased sodium and fluid retention caused by inhibition of prostaglandins in the kidney. Meta-analyses of the effects of NSAIDs have indicated average increases in mean arterial pressure of approximately 5.0 mm Hg.[31] NSAIDs can antagonize the effects of antihypertensive treatment, particularly ACE inhibitors, ARBs, and β-blockers.[32,33] These effects can also occur with selective cyclooxygenase-2 (COX-2) inhibitors, though perhaps to a lesser extent.[34,35]

Table 36–1 Exogenous Substances That Can Contribute to Development of Resistant Hypertension

Dietary salt
Non-narcotic analgesics
Nonsteroidal anti-inflammatory agents including selective COX-2 inhibitors
Acetaminophen
Alcohol
Stimulants (methylphenidate, dexmethylphenidate, dextroamphetamine, amphetamine, methamphetamine)
Sympathomimetic agents (decongestants, diet pills, cocaine, caffeine)
Oral contraceptives
Cyclosporine
Erythropoietin
Licorice

Although the average effect on BP of non-narcotic analgesics is modest, effects may be much more pronounced in some individuals. In sensitive individuals, significant increases in BP, fluid retention, or acute renal insufficiency may occur. Elderly patients, diabetics, and patients with chronic kidney disease are at increased risk of manifesting these adverse effects. Accordingly, in patients with resistant hypertension, non-narcotic analgesics should be reduced or even withdrawn if clinically possible.

Amphetamine-like stimulants, such as methylphenidate or dextroamphetamine, may increase BP or worsen BP control, or both. Glucocorticoids increase BP by causing sodium and fluid retention. Sympathomimetics, such as certain decongestants or diet pills, can raise BP. Oral contraceptives generally have modest effects on BP, but large increases can occur in some individuals. Cyclosporine and erythropoietin cause predictable increases in BP. Control can worsen with any of these agents, so BP should be monitored closely during their use. In patients with poorly controlled hypertension, these agents should be discontinued or reduced in dosage if possible.

SECONDARY HYPERTENSION

The most common secondary causes of resistant hypertension are obstructive sleep apnea, hyperaldosteronism, renal parenchymal disease, and renal artery stenosis (Table 36–2). The prevalence of secondary causes of hypertension increases with age largely due to an increasing prevalence of sleep apnea, chronic kidney disease, and renal artery stenosis.[36] Obstructive sleep apnea is particularly common in patients with resistant hypertension, with a prevalence exceeding 80%.[37] Prospective evaluations indicate that hyperaldosteronism is also a common cause of drug resistance, being present in approximately 20% of patients with difficult-to-control hypertension.[38]

OBSTRUCTIVE SLEEP APNEA

Untreated sleep apnea is strongly associated with an increased risk of having high BP, and sleep apnea increases the risk of becoming hypertensive.[39,40] Sleep apnea is more severe in patients with uncontrolled hypertension versus those with good BP control.[41] Also, persons with sleep apnea are less likely to achieve BP control with pharmacologic therapy than persons with similar body mass index but without sleep apnea.[42]

Obstructive sleep apnea is particularly common in patients with resistant hypertension. In a prospective study of 41 patients referred for evaluation of poorly controlled hypertension,

Table 36–2 Secondary Causes of Resistant Hypertension

Obstructive sleep apnea
Hyperaldosteronism
Renal parenchymal disease
Renal artery stenosis
Cushing's disease
Pheochromocytoma

83% were found to have unsuspected sleep apnea, with an apnea/hypopnea index of ≥10 events per hour determined during overnight sleep evaluation.[37] Nearly all of the men had sleep apnea, with a prevalence of 96% versus 65% of the women. This contrasts with a prevalence of sleep apnea of 24% in unselected middle-aged men and 9% in middle-aged women, based on an apnea/hypopnea index of ≥5.[43]

The mechanisms by which sleep apnea may contribute to antihypertensive treatment resistance are not fully elucidated. The best documented pathophysiologic mechanism to date is that sleep apnea induces intermittent hypoxemia, which, in turn, stimulates sustained increases in sympathetic output, which increases BP by increasing vascular resistance and cardiac output.[44,45] Preliminary studies in our laboratory have linked a risk of sleep apnea to hyperaldosteronism.[46] If confirmed, this would suggest that sleep apnea may independently stimulate aldosterone release.

The BP effects of treating sleep apnea with continuous positive airway pressure (CPAP) in patients with resistant hypertension have not been extensively evaluated. In a small, uncontrolled study, 2 months of CPAP use in 11 patients with uncontrolled hypertension reduced 24-hour systolic BP by 11 mm Hg and diastolic BP by 5 mm Hg. In this study, CPAP adherence averaged only 4 hours a night.[47] Although these results are provocative, randomized studies of CPAP in patients with uncontrolled hypertension are necessary to elucidate the antihypertensive benefit.

HYPERALDOSTERONISM

Prospective studies indicate that the prevalence of primary aldosteronism increases with worsening severity of the underlying hypertension. In one of the largest studies, more than 600 persons were evaluated for hyperaldosteronism.[48] Severity of hypertension was determined after withdrawal from antihypertensive treatment. The prevalence of primary aldosteronism was 6% overall and was positively related to the underlying severity of hypertension. In patients with stage 1 hypertension (<160/100 mm Hg), the prevalence of primary aldosteronism (2%) was not different from that in normotensive control subjects. In patients with BP between 160 and 179/100 and 109 mm Hg, the prevalence of primary aldosteronism was 8%, and in those with BP >180/110 mm Hg, the prevalence was 13%.

Several studies have been consistent in diagnosing primary aldosteronism in approximately 20% of patients with resistant hypertension (Fig. 36–1). In our own study at the University of Alabama at Birmingham, we evaluated 90 consecutive subjects with uncontrolled hypertension despite use of an average of 4 medications.[38] On the basis of suppressed renin activity and high 24-hour urinary aldosterone excretion in the setting of high dietary sodium ingestion, 20% of these were diagnosed with primary aldosteronism. These results are similar to those reported by investigators in Seattle, Washington and Oslo, Norway who reported a prevalence of primary aldosteronism in patients with resistant hypertension of 17% and 23%, respectively.[49,50]

The reason for the extremely high prevalence of aldosterone excess in patients with resistant hypertension remains unknown. Reports relating aldosterone excretion to obesity and sleep apnea potentially link three common characteristics of patients with resistant hypertension, but the mechanisms involved have not been identified.[46]

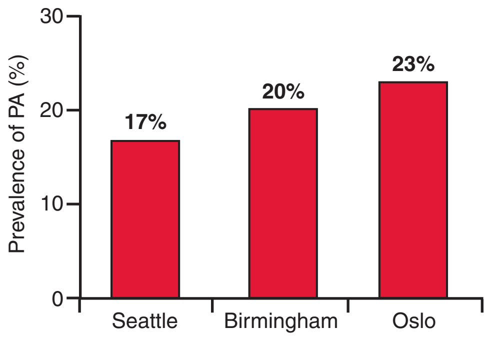

Figure 36–1 Prevalence of primary aldosteronism *(PA)* in patients with resistant hypertension as reported by three different laboratories.[38,49,50]

All subjects with resistant hypertension should be screened for primary aldosteronism, given its high prevalence. Since the large majority of patients diagnosed with primary aldosteronism are not hypokalemic, normal serum potassium levels should not preclude screening.[48] Screening is best accomplished by measuring a morning plasma aldosterone and renin concentration or plasma renin activity. Except for mineralocorticoid receptor antagonists, antihypertensive medications need not be discontinued with the initial screening, as the different classes of agents tend to either increase renin levels or suppress aldosterone levels, such that low renin and high aldosterone levels in the setting of ongoing treatment increase suspicion of aldosterone excess.[51] A suppressed renin level (<10 mUnits/mL) or renin activity (<1.0 mg/mL/min) and a high plasma aldosterone ≥15 ng/dL is suspicious but not diagnostic for primary aldosteronism and should be followed up by a clinician experienced in working up hyperaldosteronism (see Chapter 32). Hyperaldosteronism generally responds well to treatment, either with use of mineralocorticoid antagonists or with surgical resection of an aldosterone-producing adenoma.

RENAL PARENCHYMAL DISEASE

Chronic kidney disease is a common cause or complication, or both, of resistant hypertension. Patients with renal insufficiency often have volume-dependent hypertension secondary to excess sodium and fluid retention. Elevated serum creatinine suggests underlying renal insufficiency, but creatinine levels can be misleading, being normal in many persons with significant loss of kidney function. This is particularly true in the elderly. In all patients with resistant hypertension, renal function should be assessed by estimation of the glomerular filtration rate or by calculation of creatinine clearance.[52] In hypertensive patients with chronic kidney disease, restriction of dietary salt intake is particularly important. In addition, such patients will almost always require the use of diuretics, frequently loop diuretics, to control BP and manage fluid and electrolyte balance. ACE inhibitors or ARBs should be prescribed preferentially in an attempt to slow continued renal functional decline (see Chapter 35).

RENAL ARTERY STENOSIS

Renal artery stenosis is common in patients with hypertension with a prevalence of 20% at the time of coronary angiography.[53] Unknown, however, is the percentage of these lesions that are clinically relevant in terms of producing renovascular hypertension. Also unknown is the prevalence of clinically meaningful renal stenotic lesions in patients with resistant hypertension, although it is undoubtedly substantially higher than in patients with more easily controlled hypertension. The prevalence of renal artery stenosis increases with age and in the presence of aortic or peripheral arterial disease, or both.

More than 90% of renal artery lesions are atherosclerotic in origin. Clues to the diagnosis of atherosclerotic renal artery stenosis include older age; known atherosclerotic disease, especially peripheral arterial disease; unexplained renal insufficiency; and a history of flash pulmonary edema. Less than 10% of lesions are fibromuscular in etiology. These develop most commonly in women younger than 50 years of age.

Noninvasive screening for renal artery stenosis can be difficult. Duplex ultrasound and magnetic resonance angiography have good test characteristics in published studies, but the actual predictive value varies according to institutional experience. Equivocal or even negative studies in patients in whom there is a high level of suspicion may warrant repeat imaging with a different modality.

Angioplasty of fibromuscular lesions almost always benefits and often cures the associated hypertension and therefore is the recommended treatment of choice. Restenosis rates, however, may exceed 20% after 1 year.[54] In contrast, there is considerable controversy regarding medical versus endovascular treatment of atherosclerotic lesions. In patients with controlled BP, the relative benefit of intensive medical therapy versus angioplasty with stenting has not been clearly established. Such clarification is also lacking in patients with resistant hypertension, but given the known cardiovascular risks of poorly controlled hypertension, a general recommendation in favor of revascularization seems appropriate (see Chapter 33).

HISTORY AND PHYSICAL EXAMINATION

Evaluation of the patient with resistant hypertension should focus on identifying factors contributing to treatment resistance and documenting of the degree of target-organ damage. In most patients, causes contributing to the development of resistant hypertension are multiple including lifestyle, use of exogenous substances, and secondary causes of hypertension. Potential contributing factors should be screened for history, physical examination, biochemical evaluation, and radiographic imaging, as appropriate.

Special attention should be given to use of good BP measuring technique including having the patient sit quietly for 3 to 5 minutes before taking BP readings and using correctly sized cuffs to avoid falsely high readings. Supine and upright BPs should be measured at baseline and during follow-up to avoid orthostatic complications. Ambulatory BP monitoring is appropriate to screen for significant white coat effects. Acquisition of a 24-hour urine collection during the patient's normal dietary intake is recommended because dietary sodium and potassium ingestion, creatinine clearance, protein excretion, and aldosterone excretion can be quantified.

TREATMENT

Treatment of resistant hypertension is predicated on identifying and reversing contributing and secondary causes, which are almost always multiple. Rarely does a patient present with a single underlying cause of resistant hypertension. On the basis of observational studies, patients with resistant hypertension are typically obese and sedentary, ingest excessive amounts of sodium, and have sleep apnea. These factors should be anticipated and addressed if present.

Patients should be queried regarding barriers limiting adherence. Lifestyle changes including weight loss, dietary salt restriction, and regular exercise should be encouraged and emphasized regularly during follow-up. Withdrawal of exogenous substances that may interfere with pharmacologic treatment should be attempted if clinically possible. Sleep apnea should be evaluated for by polysomnographic monitoring and treated if present.

Pharmacologic therapy requires use of effective multidrug regimens. The combination of an ACE inhibitor or ARB, a calcium channel blocker, and a thiazide diuretic is generally effective and well tolerated. It can be accomplished with two pills using fixed-dosed combinations.

Studies of failure of multidrug antihypertensive regimens have generally shown lack of or underuse of diuretics.[12,55,56] Most patients with resistant hypertension have inappropriate sodium and fluid retention such that use of diuretics is essential for blood pressure lowering. In most patients, use of a long-acting thiazide or thiazide-like diuretic will be most effective. In patients with underlying renal insufficiency (creatinine clearance <60 mL/min), loop diuretics may be necessary for effective volume control. Furosemide is relatively short-acting and will require dosing at least twice a day. Alternatively, loop diuretics with a longer duration of action, such as torsemide or bumetanide, can be used.

Clinical studies indicate that mineralocorticoid receptor antagonists can provide significant additional BP reduction when used in patients with BP uncontrolled on multidrug regimens. In an open-label evaluation, spironolactone 12.5 to 50 mg daily was added to regimens that included a diuretic and ACE inhibitor or ARB in all patients.[57] At 6 months' follow-up, BP was reduced by an additional 25 ± 20/12 ± 12 mm Hg (Fig. 36–2). Interestingly, the BP reduction induced by spironolactone was similar in patients with and without primary aldosteronism and was not related to baseline plasma aldosterone concentration, renin level, or 24-hour urinary aldosterone excretion. In a similar experience, amiloride 2.5 mg daily added to multidrug regimens in patients with low-renin resistant hypertension lowered BP by 31 ± 21/15 ± 11 mm Hg at 2 weeks' follow-up.[50] Further reductions in BP were observed in a subset of patients in whom the amiloride was titrated to 5 mg daily.

The studies mentioned previously indicate that mineralocorticoid receptor antagonists can be effective as add-on agents in patients with resistant hypertension. In these studies, spironolactone and amiloride were generally well tolerated,

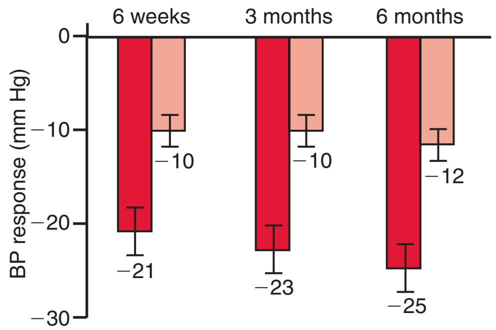

Figure 36–2 Spironolactone-induced reduction in systolic *(dark bars)* and diastolic blood pressure *(light bars)* at 6-week, 3-month, and 6-month follow-up in patients with resistant hypertension. (From Nishizaka MK, Zaman MA, Calhoun DA: Efficacy of low-dose spironolactone in subjects with resistant hypertension. Am J Hypertens 2003;16: 925-30.)

although spironolactone caused breast tenderness in about 10% of the male subjects.[57] Hyperkalemia with or without acute renal insufficiency is uncommon but can occur with mineralocorticoid receptor blockade, and therefore close monitoring is indicated. The risk is increased in patients already receiving an ACE inhibitor or ARB, or both, and in patients with chronic kidney disease including the elderly and diabetics.

Adherence is generally better in patients receiving fewer pills dosed once daily. However, a cross-sectional analysis of 24-hour ambulatory BP control indicated that patients taking at least one of their hypertensive agents at bedtime had better 24-hour mean BP levels and, in particular, lower nighttime systolic and diastolic BP values.[16] The latter difference may be particularly relevant, as studies have suggested that nighttime BP levels better predict cardiovascular risk.[58,59] Twice-daily dosing of nondiuretic BP medications may improve control rates in patients with resistant hypertension. That benefit, however, would have to be reconciled with reductions in adherence that would inevitably occur with use of less convenient and potentially more expensive dosing regimens.

HYPERTENSION SPECIALIST

Studies of clinical outcomes indicate that patients with resistant hypertension do benefit from referral to a hypertension specialist.[14] In a retrospective evaluation of patients referred to a hypertension clinic, BP had declined by 18/9 mm Hg at 1 year follow-up and control rates had increased from 26% to 55%.[60] These analyses suggest that the service provided by hypertension specialty clinics including a focused review of contributing factors, exclusion of secondary causes of hypertension, and tailoring of pharmacologic therapy by an expert does serve to maximize BP control.

Chapter 37

Hypertensive Emergencies

Radhika Katakam and Raymond R. Townsend

CHAPTER CONTENTS

INTRODUCTION

Hypertension affects millions of people in the United States and about a billion individuals worldwide. Approximately 1% of the prevalent cases of hypertension will experience a dramatic level of blood pressure (BP) elevation, receiving a clinical diagnosis of a hypertensive emergency or crisis.[1] This label applies when severe hypertension occurs with acute (or impending) target-organ damage. It is important to distinguish this from hypertensive urgency, where the BP values are high, but no target organ effect is evident and the treatment, usually as an outpatient, is instituted over days instead of minutes to hours as in the emergency situation. A more difficult distinction occurs when impressive increases in BP are present in patients with previous target organ damage (e.g., 1 year after a prior stroke). Hypertensive emergencies tend to occur more frequently in patients with previously diagnosed primary/essential hypertension who are not adherent to treatment.[2,3] This chapter discusses the definitions, epidemiology, pathophysiology, evaluation, and management of hypertensive emergencies, as well as caveats regarding the impact of potential complications on management.

DEFINITIONS

A hypertensive emergency is defined as a critical elevation in BP that results in acute or impending target organ damage. Differentiating between an emergency and an "urgency" is based on this criterion, not the extent to which the BP is increased per se.[4] Hypertensive emergencies generally require rapid reduction in BP, usually with parenteral medications given in a continuously monitored inpatient setting. Hypertensive urgencies also require medical attention, but BP can be lowered over 24 to 48 hours, most typically in a carefully followed-up outpatient setting. The rate of change in BP is particularly important in an emergency because longstanding elevations in BP are better tolerated (and typically constitute an "urgency") than rapidly climbing BP levels (over days to weeks). A rapid rise in BP can contribute significantly to target organ damage in a variety of situations: the previously normotensive patient (as in eclampsia), the patient with a process superimposed on previously well-controlled BP (such as an acute glomerulonephritis in a patient with stable prior renal function and BP control) and the patient who discontinues medications (particularly those directed against adrenergic nervous system activity, e.g., β-blockers or α_2-agonists like clonidine) and experiences a rapid loss of prior BP control. The most common causes and presentations of hypertensive emergency are shown in Table 37–1.

"Malignant" hypertension and "accelerated" hypertension are older terms used to describe critical elevations in BP. Malignant hypertension was defined by Volhard and Fahr in 1914 as a combination of severe hypertension, retinopathy with papilledema, renal insufficiency, fibrinoid necrosis of renal arterioles, and a rapidly progressive fatal clinical course.[5] The 1-year survival rate of patients presenting with these features was <30%, therefore warranting the term "malignant." The definition was later expanded to include severe hypertension accompanied by papilledema (grade IV retinopathy, according to the Keith-Wagener-Barker classification system) without concomitant renal insufficiency. Severe elevation of BP, usually marked by a diastolic BP >140 mm Hg in the presence of retinal hemorrhages and exudates but without papilledema (grade III Keith-Wagener-Barker retinopathy), was labeled "accelerated" hypertension.

EPIDEMIOLOGY AND ETIOLOGY

The exact incidence of hypertensive emergencies in the United States is not known with precision but appears to vary across different patient subpopulations. The incidence of hypertensive emergency is higher among African Americans and the elderly, occurring more often in poor, minority populations.[6] In one study hypertensive urgencies and emergencies accounted for more than one fourth of emergency department visits during a year of observation. Within these hypertensive urgency or emergency presentations, about one fourth presented as an emergency.[7]

Hypertensive emergency can occur at any age. It can affect neonates with congenital renal artery hypoplasia, children with acute glomerulonephritis, young pregnant women with eclampsia, middle-aged or older patients with treatment nonadherence, or elderly people with atherosclerotic renal artery stenosis. Such individuals typically are not accustomed to

Table 37–1 Presentations and Causes of Hypertensive Emergency

General
Abrupt increase in BP in patients with chronic hypertension
Ingestion of drugs, particularly sympathomimetic agents (e.g., cocaine, amphetamines, phencyclidine hydrochloride, lysergic acid diethylamide, diet pills, tricyclic antidepressants)
Withdrawal from antihypertensive agents (usually centrally acting agents, such as clonidine and β-antagonists)
Ingestion of tyramine-containing foods, tricyclic antidepressants, or other sympathomimetics combined with monoamine oxidase inhibitor therapy
Pheochromocytoma
Vasculitis
Autonomic hyperactivity in presence of Guillain-Barré or other spinal cord syndromes

Cardiac
Myocardial infarction and unstable angina
Acute pulmonary edema
Acute aortic dissection

Renal
Renovascular hypertension
Parenchymal renal disease (chronic) with increasing creatinine
Scleroderma renal crisis, other collagen vascular diseases
Acute glomerulonephritis
Renin-secreting tumor

Neurologic
Stroke, intracerebral hemorrhage, subarachnoid hemorrhage
Head injury
Encephalopathy

Obstetric/Gynecologic
Eclampsia

Postsurgical
Post–coronary artery bypass grafting
Post–carotid artery repair

significant elevations in BP and may present with signs and symptoms of hypertensive emergency at much lower BP levels than patients with long-standing, poorly controlled hypertension who can tolerate severe elevation in BP with less risk of target organ damage.[8]

Hypertensive emergency is more prevalent among patients with secondary hypertension, especially hypertension due to renal-artery stenosis or renal parenchymal disease than among patients with essential hypertension. Therefore, once BP is stabilized, patients presenting with hypertensive emergency should be considered for secondary causes of hypertension. However, because the prevalence of essential hypertension is so much higher than that of secondary hypertension, essential hypertension is still the most common underlying condition.

PATHOPHYSIOLOGY

The pathophysiology underlying the development of hypertensive emergency is centered on the dysregulation of pressure-dependent blood flow in critical vascular beds (especially the cerebral, cardiac, and renal circulations), which can deteriorate into frank vasculitis and ischemia. Although blood vessels normally autoregulate blood flow over a wide range of mean arterial pressure (Fig. 37–1), when the systemic pressure exceeds the autoregulatory capacity, vasoconstriction can no longer compensate and superperfusion of the tissue occurs, leading to target organ damage. In animal models of hypertensive emergency with central nervous system involvement, the arterial circulation takes on a "sausage-string" appearance from the severe vasoconstriction, with areas of intense vasoconstriction alternating with areas of vascular exhaustion and dilation (Fig. 37–2).

The flip side of this pathophysiology is equally important. Chronic hypertension results in functional and structural changes in the arterial walls, which shift the vascular autoregulatory curve to the right (see Fig. 37–1). This allows patients with hypertension to maintain normal organ perfusion by reducing or controlling the excessive blood flow that should result from the increased levels of pressure. The purposeful lowering of BP by medication during a hypertensive emergency into a range that could be considered "normal" can reduce the pressure below the autoregulatory capacity of the hypertension-adapted circulation, leading to reduced tissue perfusion and precipitating ischemia and even infarction.

Many potential factors in addition to the physical elevation of the BP itself contribute to hypertensive emergency.[9] Among locally produced factors are prostaglandins, free radicals, mitogenic and chemoattractant factors, proliferation factors, and cytokines. Endothelial damage, smooth muscle proliferation, and platelet aggregation contribute to the tissue injury seen in these patients. Among the systemic factors are increases in renin and angiotensin II, catecholamines, endothelin, and vasopressin levels. Pressure natriuresis occurs in this setting, leading to hypovolemia, which potentiates the further release of vasoconstrictor substances, such as renin and catecholamines. These factors conspire to increase BP, aggravate the endothelial damage, and ultimately lead to tissue ischemia and damage, as shown in Figure 37–3. One interesting study showed a possible association of a polymorphism of the angiotensin-converting enzyme (ACE), the DD genotype, with hypertensive emergencies in men, suggesting that there is a genetic facet to hypertensive emergency.[10] Despite the impressive array of pathogenic factors, treatment remains largely empirical (as opposed to remedying a specific mechanism) in most situations, with a limited number of reliable potent antihypertensive agents.

EVALUATION OF HYPERTENSIVE EMERGENCIES

History

The history should be brief and focused on previously diagnosed hypertension including duration, severity, and level of control. A listing of key history items is shown in Table 37–2. Less effective BP control, based on outpatient systolic BP

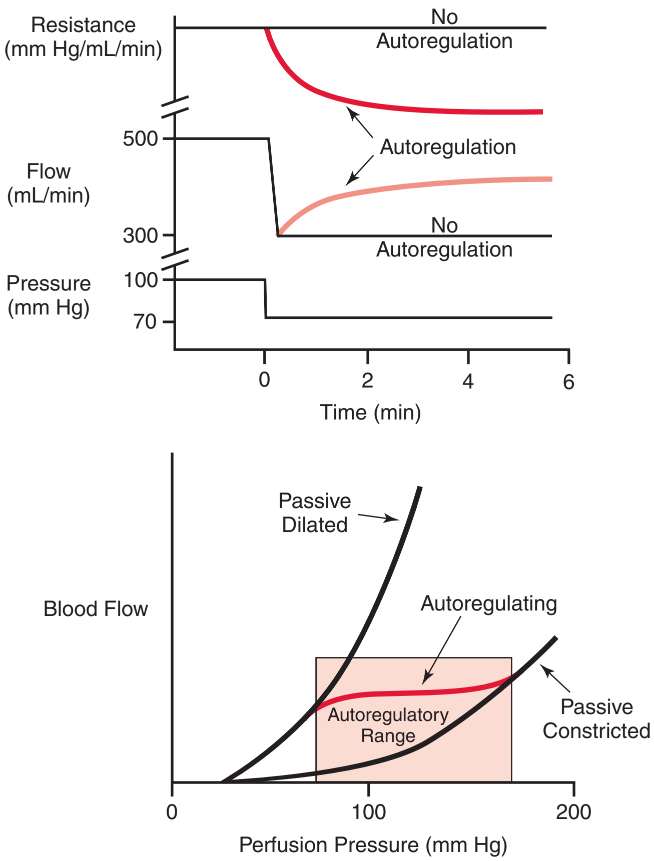

Figure 37–1 Autoregulation of blood flow *(top).* If perfusion pressure is reduced from 100 to 70 mm Hg, this causes flow to decrease initially by approximately 30%. Over the next few minutes, however, flow begins to increase back toward baseline (autoregulation—*red lines*) because vascular resistance falls. When perfusion pressure is both increased and decreased over a wide range of pressures, and the steady-state autoregulatory flow response measured, then the relationship between steady-state flow and perfusion pressure can be plotted as shown *(bottom).* The *red line* representing the autoregulatory response shows that flow changes relatively little despite a large change in perfusion pressure *(bottom).* If a vasodilator drug is infused into an organ so that its vasculature is maximally dilated and incapable of autoregulatory behavior, the curve labeled *"Passive Dilated"* is generated as perfusion pressure is changed. It is nonlinear because blood vessels passively dilate with increasing pressures, thereby reducing resistance to flow. If a vasodilator is not infused so that the organ can undergo autoregulation, then there will be a range of perfusion pressures where flow will not follow the *"Passive Dilated"* curve. The flow over a particular range of perfusion pressures (i.e., autoregulatory range) may change little as shown (e.g., as found in coronary and cerebral circulations). The *"Passive Constricted"* curve represents the pressure-flow relationship when the vasculature is maximally constricted. The *bottom panel* also shows that there is a pressure below which an organ is incapable of autoregulating its flow because it is maximally dilated. This perfusion pressure, depending on the organ, may be between 50 and 70 mm Hg. Below this perfusion pressure, blood flow decreases passively in response to further reductions in perfusion pressure. (From Klabunde RE: Cardiovascular Physiology Concepts. http://www.cvphysiology.com/blood%20flow/BF004.htm. Accessed October 4, 2005.)

measurements, is an independent risk factor for hypertensive emergency.[11] Patients should be asked about all current medications including prescription and nonprescription drugs, their adherence to medications, and their use of recreational drugs. Symptoms related to severe elevations in BP, particularly those that suggest impending or ongoing target-organ damage, should be rapidly assessed.

Physical Examination

The physical examination should begin with several assessments of BP, using an appropriate-size cuff in both upper extremities and in a lower extremity if peripheral pulses are markedly reduced. Although an absolute level of BP is not necessary for the diagnosis of hypertensive crisis, most patients with a hypertensive emergency present with BPs at or above 200/120 mm Hg.[7,11] Pressure-induced natriuresis is a common development that may produce subtle or overt volume depletion; thus BP should be measured while the patient is both supine and standing, if possible. A checklist of key items in the examination is found in Table 37–3.

The cardiovascular examination should focus on signs of left ventricular decompensation, such as rales, a new mitral or aortic insufficiency murmur, or an S_3 gallop rhythm. The cardiovascular examination includes documentation of BP in

Table 37–2 History Checklist in Hypertensive Emergency

Precipitating Factors	Evidence of Possible Target Organ Damage
Medication compliance?	Vision blurry or doubled?
Recreational drug use?	Headache (include severity/location)?
Duration of hypertension?	Nausea and vomiting?
Smoker?	Chest pain?
Current medications including OTC?	Shortness of breath?
Prior: stroke, MI, kidney disease, CHF?	Family/friends may be available re: history of confusion or ↓ cognition
	Sweating/heart racing?
	Localized weakness?

CHF, congestive heart failure; MI, myocardial infarction; OTC, over-the-counter medications, such as cough/cold preparations.

both upper extremities, particularly if thoracic aortic dissection is in the presenting differential diagnosis.

The neurologic examination should include an assessment of mental status and a funduscopic examination to detect hemorrhages, exudates, and papilledema. Hypertensive encephalopathy can reduce cognition, as well as cause focal neurologic deficits and seizure activity. Keep in mind that hypertensive encephalopathy is an exclusionary diagnosis, established after other lesions, such as stroke, subarachnoid hemorrhage, and mass lesions, have been ruled out.[4]

Initial Studies

Studies undertaken in a hypertensive emergency fall under two levels of priority. Initial studies should be limited, expedited, and used to confirm the presence of target organ compromise. The tests should be performed simultaneously with initiation of antihypertensive therapy. Subsequent testing, usually at a time when the patient is stabilized, is employed to pursue secondary causes when appropriate.

Discrepant arm/leg pulses or BP
Renal
Flank tenderness
Edema
Bruits in abdomen

Initial studies include a urine examination, CBC with a peripheral smear, chemistry panel, ECG, and imaging when indicated. A urinalysis with microscopic examination of the urinary sediment may reveal significant proteinuria, RBCs, or cellular casts suggestive of renal parenchymal disease. The peripheral blood smear will detect the presence of a microangiopathic hemolytic anemia, which may complicate hypertensive emergency. Electrolyte abnormalities, particularly hypokalemia, reflecting aldosterone activation, occur in up to 50% of patients with hypertensive emergency. The chemistry panel may also provide evidence of renal or hepatic dysfunction, or both. The electrocardiogram identifies evidence of coronary ischemia, infarction, or left ventricular hypertrophy. A chest film may reveal pulmonary edema or a widened mediastinum, raising suspicion for an aortic dissection. When the clinical evaluation suggests cerebrovascular ischemia or hemorrhage, or if the patient is comatose, a CT scan or an MRI of the brain should be obtained immediately. In the best of circumstances, particularly in the era of electronic medical records, comparison of current results with previous findings helps to determine the chronicity of observed abnormalities.

Other testing may be necessary depending on presentations that typify less common scenarios. For example, patients presenting with significant tachycardia and sweating (signs of catecholamine excess) should be considered for plasma catecholamine and metanephrine testing, ideally before drugs with adrenergic mechanisms of action, which may cloud interpretation of plasma catecholamine and metabolite levels, are administered.

MANAGEMENT OF HYPERTENSIVE EMERGENCIES

The initial goal in management of hypertensive emergencies is progressive, controlled reduction of BP with the goal of 20% to 25% reduction in the mean arterial pressure over a period of minutes to an hour. Treatment with parenteral drugs should be administered in an ICU to control target organ damage while minimizing the risk of hypoperfusion in cerebral, coronary, and renovascular beds. The goal is *not* to lower BP to normal levels.[4,12] The asymptomatic patient who presents with severe hypertension (a diastolic BP of 130 to 140 mm Hg; i.e., an "urgency") need not be treated with parenteral drugs. In patients with major stroke, BP should not be lowered unless the etiology is hemorrhagic (see later). Aggressive treatment of BP in ischemic stroke may expand the infarction by reducing perfusion to the area of ischemia. The appropriate management of BP in ischemic stroke is still controversial due to lack of data.

A growing number of antihypertensive medications are available, and choice of drugs and selection of oral versus parenteral drugs depend on the clinical presentation and urgency of the situation. Most patients receiving parenteral therapy should have continuous arterial BP monitoring.[13] The level to which the BP should be lowered varies with the type of hypertensive crisis and other patient characteristics and should be individualized. Dosing of parenteral agents used in hypertensive crisis and the usual indications for their use are outlined in Table 37–4. Because available parenteral drugs have differential effects on the various target organs that may be involved in hypertensive crisis, the approach outlined in Figure 37–4 is recommended.

Extreme BP elevation in many clinical settings (e.g., in acute thrombotic stroke, see later) appears to have a poor outcome whether untreated or treated aggressively with parenteral antihypertensive drugs. Moreover, parenteral drug therapy not uncommonly overshoots the goal, which can worsen the situation by aggravating target organ ischemia. Thus treating hypertensive emergencies is a balancing act, with a true "risk versus benefit" circumstance in each presentation. A generous dose of frequent reappraisal is a healthy adjunct in treatment.

Cardiac Presentations

Several types of hypertensive emergencies involve the heart and aorta directly. These include coronary syndromes, pulmonary edema, and aortic dissection. In the case of suspected thoracic aortic dissection, opinions differ as to whether time-consuming radiologic tests should be completed before treatment is started or whether the clinical signs and symptoms or a noninvasive test, such as an echocardiogram, suffices to make the diagnosis before recommending surgery.[14] It is generally agreed that rapid control of the systolic BP to values <120 mm Hg, with the combined use of a vasodilator (e.g., nitroprusside) along with a β-blocker, such as esmolol, is more critical than the choice of diagnostic procedure.[15]

Nitroglycerin, nitroprusside, and nicardipine are the three drugs most commonly given (sometimes in combination) in the setting of a hypertensive emergency involving cardiac ischemia/infarction or pulmonary edema. For the latter, treatment usually includes furosemide and enalaprilat (which improve hemodynamic outcomes after pulmonary edema), followed by nitroprusside (if the BP has not yet been controlled with the previous two interventions). Intravenous nicardipine has been most commonly used after cardiac bypass or other vascular surgery (see later). Like vasodilators in general, all three drugs can cause reflex tachycardia, but their coronary arterial dilator effects usually offset the increased cardiac oxygen demand. Although nicardipine has not been widely studied in acute myocardial ischemia, there are plausible grounds for its use, along with efforts to preserve the myocardium and open the obstructed coronary artery (by thrombolytics, angioplasty, and surgery). The target BP for hypertensive emergencies involving cardiac ischemia/infarction or pulmonary edema is that which improves cardiac perfusion. A 10% to 15% reduction in BP is generally sufficient to cause a dramatic improvement in symptoms.

Coronary Syndromes

The coronary syndromes involved in hypertensive emergencies include unstable angina and acute myocardial infarction. These are usually managed with a vasodilator, especially nitroglycerin. A β-blocker, such as esmolol or labetalol, is often added for both rate control and additional BP reduction.

Heart Failure/Acute Pulmonary Edema

In acute left ventricular failure, myocardial oxygen requirements rise due to increased left ventricular volume and end-diastolic fiber length. Decreasing the workload of the failing myocardium improves heart function. These patients are treated primarily with sodium nitroprusside, a loop diuretic

such as furosemide and morphine. Vasodilators and nitroglycerin can be used alternatively. Nitroglycerin is effective in patients with acute pulmonary edema due to both ischemic and nonischemic causes.[16] Nitroprusside may be selected for patients not immediately responsive to nitrate therapy.[16] Enalaprilat is the only ACE inhibitor available for parenteral use and may be particularly useful in treating hypertensive emergencies in patients with heart failure. ACE inhibitors rapidly reduce preload and improve myocardial energy balance. Early administration of enalaprilat is effective and

Table 37–4 Parenteral Antihypertensive Agents Used in Hypertensive Emergencies

Agent	Dosing	Onset	Duration of Effect	Caveats*	Usage	Comments
ACE inhibitor						
Enalaprilat	1.25 mg	10-15 min	Up to 6 hr	Angioedema	Renal emergencies	Difficult-to-predict responses; occasional dramatic fall in BP noted
α-Blockers						
Phentolamine	1-5 mg over 1 min, repeat q 5-10 min	1 min	<10 min	Tachycardia; headache; angina	Use with suspected catecholamine excess	
β-Blockers						
Esmolol	0.2-0.5 mg/kg over 1 min; then 0.05 mg/kg for 4 min; then increase dose 0.05 mg/kg at 5 min intervals up to 0.2 mg/kg/min	1-2 min	10 min	Heart block; bronchospasm; heart failure	Postoperative presentations; coronary ischemia; thoracic aorta dissection	
Labetalol	0.5-2 mg/min; alternatively 20-80 mg IV-bolus q 5-10 min; up to 300 mg total dose	5 min	Up to 6 hr	Heart block; bronchospasm; heart failure; scalp tingling; flushing	Postoperative presentations; neurologic presentations; coronary presentations	Avoid in patients with depressed left ventricular function
Calcium-antagonist						
Nicardipine	5 mg/hr; increase by 1-2.5 mg/hr q 15 min max dose 15 mg/hr	5-10 min	1 hr, up to 4 hr	Tachycardia; headache; nausea/vomiting; phlebitis at infusion site if peripheral vein used for >24 hr	Postoperative presentations	Use with care in coronary ischemia (increase in heart rate may worsen ischemia)
Dopamine-agonist						
Fenoldopam	0.1-0.3 mcg/kg/min; increase by 0.05-0.10 mcg/kg/min q 15 min; max dose 1.6 mcg/kg/min	<5 min	30 min	Tachycardia; headache; flushing	Renal presentations (does not impair GFR); used as alternative to nitroprusside, especially postoperatively	Use with caution if glaucoma suspected; may reduce K^+; tends to be less effective after 48 hr

Continued

Table 37–4 Parenteral Antihypertensive Agents Used in Hypertensive Emergencies—cont'd

Agent	Dosing	Onset	Duration of Effect	Caveats*	Usage	Comments
Vasodilators						
Diazoxide	50-150 mg bolus; 15-30 mg/min continuous IV	2-5 min	3-12 hr	Tachycardia; angina; nausea; increased glucose		Used rarely; not used for coronary presentations or with aortic dissection due to heart rate increase
Hydralazine	10-20 mg @ 1 mg/min	10-20 min	3-8 hr	Tachycardia; angina; flushing; rash; headache	Eclampsia	Increased heart rate limits value in cardiac presentations; increased intracranial pressure limits value in neurologic presentations
Nitroglycerin	5-100 mcg/min (titrate q 5 min)	2-5 min	3-5 min	Headache; nausea and vomiting	Acute MI; pulmonary edema; cocaine use with coronary ischemia	Headache may be severe
Nitroprusside	0.3-10 mcg/kg/min	<1min	1-2 min	Headache; nausea and vomiting; thiocyanate toxicity	Encephalopathy; pulmonary edema; most hypertensive emergencies are managed with this drug	Cyanide and thiocyanate toxicity more likely with reduced renal function or rate >2 mcg/kg/min or both
Ganglionic Blocker						
Trimethaphan	0.5 mg/min to 5 mg/min; max dose 6 mg/min	1-5 min	5-10 min	Urine retention; ileus; respiratory arrest	Aortic dissection	Uncommonly used because of frequent instability in BP effect; mostly supplanted by nitroprusside
Miscellaneous						
Magnesium-SO_4	1 g/min up to 4 g (IV)	<1 min	30 min	Sweating, flushing, respiratory and cardiac	Eclampsia	Intramuscular has slower onset and lasts longer; goal serum concentration is 4-6 mEq/L

All agents in this table have "hypotension" as an adverse effect.

well tolerated in acute pulmonary edema.[17] A loop diuretic is usually administered along with these agents. A meta-analysis has shown no significant difference in efficacy of ACE inhibitors versus diuretics or β-blockers in hypertensive patients with heart failure.[18]

Neurologic Presentations

In patients with elevated BP and neurologic abnormalities, examination of the fundus by direct ophthalmoscopy can be helpful in making a proper diagnosis. The finding of

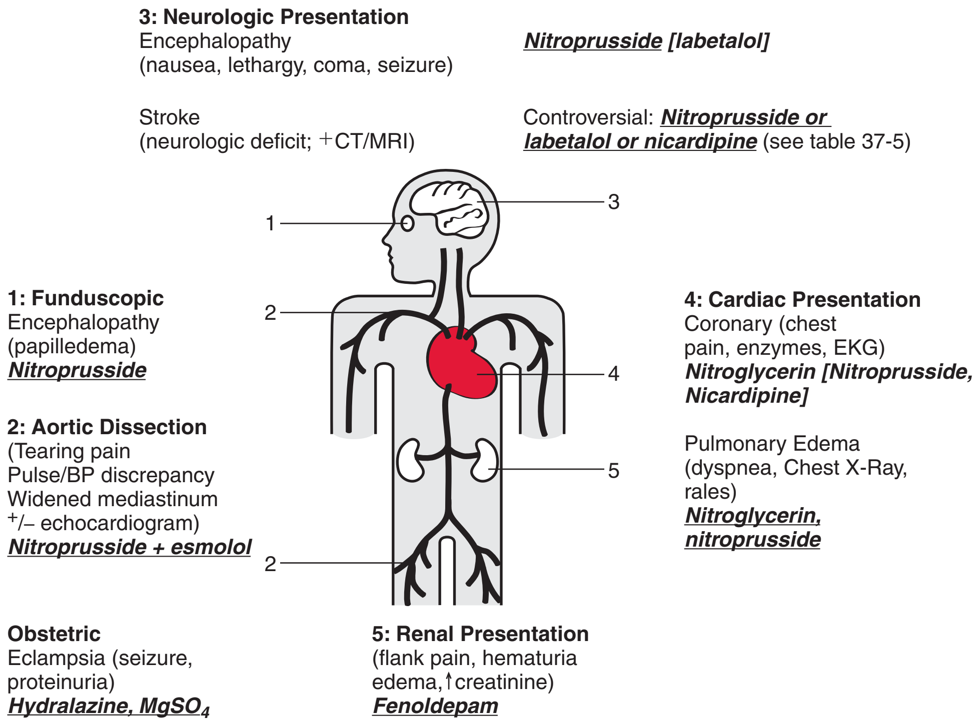

Figure 37–4 Classification of hypertensive emergencies by presentation with key findings in parentheses and initial therapy recommendations in bold, underlined, italic text with secondary agents within brackets.

papilledema or new hemorrhages or exudates is diagnostic of hypertensive emergency, and these patients often manifest hypertensive encephalopathy. The neurologic examination should document the extent and severity of any focal neurological defects because these may change with time or treatment, or both, possibly altering BP management.

The various neurologic emergencies can be difficult to distinguish. Encephalopathy from hypertension is typically a diagnosis of exclusion. Stroke (hemorrhagic and thrombotic) is typically diagnosed by sustained focal neurologic signs on physical examination and a confirmatory CT or MRI scan of the brain. Subarachnoid hemorrhage may be evident on CT or MRI but may also require a lumbar puncture. The patient with BP elevation following head trauma, known as Cushing's reflex, will usually have a trauma history and the physical findings of head trauma to aid the diagnosis. In both acute stroke and the hypertension after head trauma, the BP goal is controversial. Moreover, the management of these sundry conditions is somewhat different. Nitroprusside is still the drug typically chosen for encephalopathy (see later) and is used in many other acute hypertensive conditions. Nimodipine has antihypertensive and anti-ischemic effects and is approved for use in subarachnoid hemorrhage,[18,18a] but it did not show benefit when used early in thrombotic stroke.[19]

Encephalopathy

Hypertensive encephalopathy is a syndrome consisting of a sudden elevation of arterial pressure usually preceded by severe headache and followed by convulsions or coma. Other clinical features include nausea, vomiting, visual disturbances, and a change in mental status. Encephalopathy is accompanied by a severe increase in vascular resistance, and because clinical experience has demonstrated clearing of the sensorium, cessation of convulsions, and release of vasoconstriction following reduction of BP, BP should be lowered promptly.[20]

Drugs that have few or no central nervous system side effects should be used, and agents such as clonidine, guanfacine, methyldopa, and reserpine should be avoided. Diazoxide can decrease cerebral blood flow, so it should also be avoided. Nitroprusside, which may actually increase intracranial pressure, continues to be the agent of choice for treatment of hypertensive encephalopathy.[4] Goal BP reduction is approximately 25% below starting values, achieved over about an hour while maintaining a diastolic BP above 100 mm Hg.

Stroke

Stroke is especially difficult to manage with parenteral antihypertensive therapy, in part because lowering BP in acute *nonhemorrhagic* stroke patients without either hypertensive encephalopathy or a cardiovascular indication that requires immediate reduction of BP may cause harm[21] and is not recommended by guidelines.[22] Lowering the BP in patients with cerebral ischemia may reduce cerebral blood flow. Because cerebral autoregulation is often impaired in these patients, this may result in further ischemic injury. The common practice of "normalizing" BP is thus potentially dangerous. Some experts advise that unless systolic BP exceeds 220 mm Hg or diastolic exceeds 120 mm Hg, it should not be lowered, except if thrombolytic therapy is planned (Table 37–5). Parenteral agents, such as labetalol, that are easily titrated and that have minimal vasodilator effects on cerebral blood vessels are preferred. Sublingual use of a calcium antagonist, such as nifedipine, should be avoided because of rapid absorption and a secondary precipitous decline in BP.[22] As noted earlier, centrally acting agents should be avoided because of their potential to interfere with mental status.

Table 37–5 Approach to Elevated Blood Pressure in Acute Ischemic Stroke

Clinical Situation	Recommendation
A. Not eligible for thrombolytic therapy Systolic BP <220 mm Hg; diastolic BP <120 mm Hg	Observe BP unless there is other end organ involvement, such as aortic dissection, renal failure, or acute myocardial infarction, which would mandate emergency treatment
Systolic BP >220 mm Hg or diastolic BP 121-140 mm Hg	Labetalol 10-20 mg IV over 1-2 min; may repeat or double every 10 min to a maximum dose of 300 mg **OR** nicardipine 5 mg/hr IV infusion as initial dose; titrate to desired effect by increasing by 2.5 mg/hr every 5 min to maximum of 15 mg/hr (target 10-15% reduction)
Diastolic BP >140 mm Hg	Sodium nitroprusside 0.5 mcg/kg/min IV with continuous BP monitoring (target 10-15% reduction)
B. Patient eligible for intravenous rt-PA	If systolic BP >185 mm Hg or diastolic BP >110 mm Hg, intravenous labetalol, 10-20 mg over 1-2 min; may repeat × 1 or 1-2 inches of nitropaste; if BP is not reduced and maintained at desired levels (<185 mm Hg systolic BP and <110 mm Hg diastolic BP), do not administer rt-PA

From Adams HP Jr, Adams RJ, Brott T, et al: Guidelines for the early management of patients with ischemic stroke: A scientific statement from the Stroke Council of the American Stroke Association. Stroke 2003;34:1056-83.

Intracerebral Hemorrhage

Patients with hypertensive intracerebral hemorrhage who present with marked elevation of BP (defined as a mean arterial pressure of >145 mm Hg) have been shown to have higher mortality and more severe morbidity than those with lesser degrees of BP elevation.[23] With radiologic evidence of a major intracerebral bleed, *cautious* lowering of BP, if systolic BP >200 mm Hg or diastolic BP >120 mm Hg, is generally suggested and supported by studies that showed that a *rapid* decline in BP within the first 24 hours after an intracerebral hemorrhage was associated with an increased mortality.[24] Further, in patients with intracerebral hemorrhage, the value of early antihypertensive therapy in preventing rebleeding or reducing vasogenic edema has not been demonstrated.

Subarachnoid Hemorrhage

As with stroke, BP lowering here is controversial. Nimodipine (orally) has been approved with the goal of preventing reflex vasospasm (not blood pressure lowering per se) in the period following the initial bleeding episode. It is considered reasonable to lower blood pressure in subarachnoid hemorrhage, particularly when the systolic blood pressure is substantially elevated (i.e., >160 mm Hg) and thus the risk of bleeding and mortality is increased,[25] However, there is no consensus as to a goal level or recommended rapidity of reduction.

Renal Presentations

Microscopic hematuria or a worsening of renal function, or both, characterize kidney involvement in hypertensive emergency. Gross hematuria is less common than microscopic hematuria, but its presence should trigger a urologic evaluation once blood pressure is stabilized. Acute renal failure can both cause and result from elevated blood pressure, and severe hypertension often accompanies acute renal failure. Consequently, a urinalysis should be performed and serum creatinine measured in the initial evaluation of patients with extreme blood pressure increases.

Not uncommonly, and in our experience more often in African-American patients, successful treatment of hypertensive emergencies with reduced renal function results in further renal function impairment. This (usually) temporary worsening of renal function can occur even when the blood pressure is correctly titrated downward in a controlled gradual fashion and can occasionally result in the need for acute dialysis. When this happens, most patients can usually stop dialysis during long-term follow-up if blood pressure remains well-controlled.[26,27] Therapy in renal presentations should reduce systemic vascular resistance without diminishing renal blood flow. The dopamine-agonist fenoldopam and the calcium channel blocker nicardipine are effective in this situation. Although nitroprusside is also effective, it carries a risk of cyanide and thiocyanate toxicity. When compared with nitroprusside, fenoldopam improves natriuresis and creatinine clearance in patients with elevated blood pressure and impaired renal function.[28]

Catecholaminergic Presentations

Hypertensive emergencies from an excess of catecholamines are associated with pheochromocytoma; monoamine oxidase (MAO) inhibitor therapy; abrupt withdrawal of chronic anti-adrenergic antihypertensive therapy; and the use of drugs, such as cocaine, phencyclidine hydrochloride (PCP), lysergic acid diethylamide (LSD), and amphetamines. The typical triad of headache, sweating, and rapid heart rate along with severe hypertension are the classic characteristics of pheochromocytoma. Physical examination of the skin may provide additional clues (e.g., neurofibromas, port wine stains, café-au-lait spots) to the diagnosis. In some patients the presentation is overwhelmingly cardiac, with severe hypertension, heart failure, and lactic acidosis dominating the picture. Patients receiving MAO inhibitors have generally

been warned that taking these drugs and ingesting tyramine-containing foods can prompt a hypertensive emergency. However, incomplete or inaccurate food labels and dietary or pharmacologic indiscretions (e.g., tricyclic antidepressant use) still occur. A thorough medication history is the only way to make a diagnosis.

Abrupt withdrawal of anti-adrenergic antihypertensive agents, such as clonidine, is more likely to result in a true hypertensive emergency when coronary disease is also present. When clonidine is abruptly discontinued (especially at high dosages) or rapidly tapered, a syndrome consisting of nausea, palpitation, anxiety, sweating, nervousness, and headache, along with marked elevation of the blood pressure, has been noted. Symptoms of clonidine withdrawal can be relieved by reinstituting the clonidine regimen. Abrupt withdrawal from β-blocker therapy may also lead to a syndrome suggestive of sympathetic overactivity. Importantly, the possibility of precipitating angina, myocardial infarction, or sudden death in patients with coronary disease is the major reason to treat this situation with parenteral, as well as oral, therapy. Cocaine may be inhaled, injected, or snorted intranasally. It elevates blood pressure by preventing synaptic catecholamine reuptake with spillover.[29] Cocaine and its metabolites are detectable on a drug screen for up to 36 hours after administration. A syndrome of catecholamine excess can result from spinal cord injury or severe head injury.

In general, catecholaminergic presentations are managed using a direct vasodilator (e.g., phentolamine, nitroprusside) or a combination α-blocker and β-blocker agent (e.g., labetalol). β-Blockers can potentially exacerbate hypertension in patients with catecholamine excess and are better used when adequate vasodilation or α-receptor blockade, or both, are achieved.[12] Treatment of hypertensive emergencies due to pheochromocytoma usually begins with an intravenous α-blocker (phentolamine). A β-blocker is added only if necessary. In the case of MAO inhibitor ingestion, there is a paucity of literature to guide treatment, but the mechanism of hypertension argues that an α-blocker, such as phentolamine, is reasonable to use.[30] Severely elevated BPs due to abrupt withdrawal of anti-adrenergic antihypertensive agents, such as clonidine or β-blockers, are managed by restarting therapy; often a single dose is adequate to produce significant improvement. Treatment of hypertensive emergencies due to cocaine abuse is based on the presence or absence of overt coronary ischemia (about 1 in 20 subjects presenting with cocaine toxicity has acute coronary ischemia[29]). Oxygen, nitrates, verapamil, aspirin, and benzodiazepines are preferred in coronary presentations of cocaine intoxication. Either labetalol or phentolamine is useful when the main issue is blood pressure control.

Thoracic Aortic Dissection Presentations

The most common presenting symptom in thoracic aortic dissection is a severe sharp, tearing, or ripping type of pain (>95%). Most patients say that pain is abrupt in onset and either located in the chest and back (with aortic arch dissections 70%) or the back and abdomen (with dissections of the descending aorta 50% to 65%). Significant differences in brachial artery pressure (right vs. left arm; arm vs. leg); new pulse deficits; a new aortic regurgitation murmur; and Marfan appearance (tall, long limbs, scoliosis, eye findings) are features suggestive of aortic dissection.

Whether or not surgery is undertaken, each acute thoracic aorta dissection patient is a candidate for medical therapy. Surgery is typically undertaken for type A dissections, which involve the aortic arch.[31] Dissections involving only the aorta distal to the left subclavian artery are typically managed medically unless a critical ischemic complication (e.g., a bowel infarction) intervenes.

BP control to a target systolic pressure of 110 mm Hg can be achieved with an intravenous β-blocker, and the short-acting agent esmolol is often used[32] in combination with vasodilating drugs, such as sodium nitroprusside or ACE inhibitors. Intravenous verapamil or diltiazem may also be used, especially if β-blockers are contraindicated. Nitroprusside is usually initiated to reduce the blood pressure quickly and uniformly, with upward titration to achieve the systolic blood pressure goal of <110 mm Hg. Because nitroprusside does not reduce (and may increase) the shearing force of the blood, it should be accompanied by β-blockade.

Obstetric Presentations (Eclampsia)

Obstetric hypertensive emergencies are usually diagnosed at lower BP levels than in nonpregnant patients. Preeclampsia presents with elevated BP (systolic BP of ≥140 mm Hg and diastolic BP of ≥90 mm Hg), typically occurring after the 20th week of gestation in a woman whose blood pressure has previously been normal, and proteinuria, with excretion of 0.3 g or more in a 24-hour period. A woman with preeclampsia who has new-onset grand mal seizures is considered to have eclampsia. Risk factors for the development of eclampsia include preexisting hypertension and renal disease.[33]

Many antihypertensive drugs are contraindicated in pregnancy. Nitroprusside is metabolized to cyanide, which is toxic to the fetus. ACE inhibitors (and angiotensin receptor blockers) carry black-box warnings indicating that they are contraindicated in the second and third trimesters of pregnancy because of adverse effects on the fetus. The ganglion-blocking drug trimethaphan should be avoided because of the risk of meconium ileus. Although definitive therapy is delivery of the fetus, the BP should also be reduced to prevent neurologic, cardiac, and renal damage in the mother. Magnesium sulfate is the standard of therapy for prophylaxis and treatment of seizure activity, with a loading dose of 4 to 6 g in 100 mL dextrose 0.25 saline solution over 15 to 20 min.[34] Because magnesium sulfate has a cerebral vasodilator effect, one explanation for its antieclamptic action is that it decreases ischemia by reducing cerebral vasospasm.[35] Although other antihypertensive drugs may be equally effective in reducing blood pressure, the agent of choice is hydralazine, which has a long record of safety. Nifedipine and β-blockers (particularly labetalol) can be added later if necessary. Delivery of the infant typically lowers the mother's BP. Please see Chapter 39 for a more comprehensive discussion of the management of hypertension in pregnancy.

Hemorrhage and Post-Vascular-Surgery Presentations

Bleeding that does not respond to local measures, such as direct pressure, occurring in association with severe blood pressure elevation, can be a hypertensive emergency. Common bleeding sites are the nose, urinary tract, and surgical sites,

especially in the post-vascular-surgery period. The bleeding is usually witnessed by the patient, often inducing substantial anxiety, thus contributing to the blood pressure elevation. Consequently, it may be wise to both lower the blood pressure acutely and provide judicious anxiolytic therapy.

In postoperative situations, particularly after coronary artery bypass graft (CABG) surgery or carotid endarterectomy, bleeding from suture lines is a significant concern. In the post-CABG patient nitroglycerin is an effective and rational way to manage blood pressure. Post–carotid endarterectomy patients frequently suffer from labile blood pressures that can last for days. One possible cause is disruption of the baroreceptor reflex from trauma or damage to the carotid sinus or vagus nerve during surgery. Hypertension in this period can lead to the "hyperperfusion syndrome" and neck hematoma, particularly in patients undergoing percutaneous stenting procedures. This hyperperfusion syndrome is seen in patients with high-grade carotid artery stenosis, especially with bilateral disease, presumably because of a maximal dilation of the arteries distal to the stenosis to maintain perfusion in a situation where autoregulatory mechanisms are lost. After the stenosis is relieved by surgery or stenting, there is hyperperfusion of that hemisphere, with increased risk of intracranial hemorrhage and seizures.[36]

CAVEATS TO THERAPY IN HYPERTENSIVE EMERGENCY CARE

- When undertaking parenteral therapy in a hypertensive emergency, establish how quickly and by how much you want to see the blood pressure reduced. Be prepared to back off when the clinical situation worsens, particularly from a cognition standpoint.
- Patients with a hypertensive emergency (other than acute pulmonary edema) tend to be volume depleted; thus there is no role for "routine" administration of diuretics. On the other hand, with effective BP reduction, after a day or two there is often evidence of salt and water retention, which jeopardizes continued BP control. At that point diuretic therapy tends to be more rational and effective.
- In patients presenting with presumed catecholamine excess, the recommended approaches are usually effective in lowering BP within minutes. Thus, if a poor response is noted, other diagnoses (and treatment) should be considered.
- One key element in prevention of future episodes is adequate care and follow-up after hospitalization.

CONCLUSION

Hypertensive emergency is a relatively uncommon complication, usually occurring in the setting of long-standing hypertension. Patients with hypertensive emergency typically require immediate reduction in BP to interrupt ongoing or prevent impending target-organ damage. A variety of antihypertensive medications are available for hypertensive emergencies; the choice of drug depends on the type of emergency and the individual patient. Parenteral agents should be used initially. When BP has been stabilized for 24 hours, parenteral antihypertensive medications can be gradually changed over to oral medications. Consideration of secondary causes of hypertension is recommended, particularly in patients without a clear precipitating cause of the hypertensive emergency (e.g., medication nonadherence, an intervening comorbidity, or intercurrent sympathomimetic drug use).

Chapter 38

The Metabolic Syndrome

Michael A. Weber

CHAPTER CONTENTS

The metabolic syndrome is linked primarily to the excess body weight and obesity that are affecting a major proportion of the American population and creating substantial health, social, and economic burdens. At least part of this problem stems from an increasing consumption of high-calorie foods and a reduction in physical activity, particularly in children. Typically, excess weight leads to a cardiovascular metabolic syndrome that is characterized by insulin resistance, lipid abnormalities, high blood pressure (BP), and increased abdominal girth. This syndrome directly increases the risks of cardiovascular and renal events; moreover, it often leads to type 2 diabetes, which sharply amplifies the probability of adverse outcomes. It is now recognized that increased fat mass itself can be a major driver of these events. Fat cells produce adipokines, factors that have inflammatory, proliferative, and prothrombotic effects. The renin-angiotensin-aldosterone system is also stimulated by these cells. The importance of free fatty acids—independent of the state of obesity—is now recognized. Their metabolites within skeletal muscle and liver cells appear to inhibit glucose transport and thereby create insulin resistance. Obesity, however, cannot be blamed for all cardiovascular disease. Interesting data show strong familial trends in the development of the cardiovascular metabolic syndrome. This suggests the possibility of genetic causes, but environmental factors cannot be ruled out. Dealing with obesity will require public policies that will affect dietary and physical activity measures in schools, community institutions, and the workplace. Innovative drugs and minimally invasive surgeries may be partial answers for people with more severe forms of obesity. In addition, new drugs directed at the individual risk factors that comprise the metabolic syndrome and at preventing progression to clinical diabetes must be considered in patients with this condition.

BACKGROUND

The metabolic syndrome can be considered as an intermediate clinical stage, having its origins in excessive calorie intake and its consequences in cardiovascular disease. Many people who are obese or overweight experience metabolic changes that increase their risk of adverse cardiovascular and renal outcomes. In particular, there is evidence for such findings as insulin resistance, lipid abnormalities, increased BP, and microalbuminuria. These are part of a series of abnormalities that constitute what is now usually referred to as the *metabolic* or the *cardiovascular-metabolic syndrome.*

This syndrome, in turn, often leads to cardiovascular events and type 2 diabetes mellitus. Still, despite our preoccupation with obesity as the major factor in this sequence of events, we should not forget that many patients with cardiovascular and renal disease are not overweight. If we are to take a constructive view of the problem of cardiovascular disease that is linked to excess body weight, we can make the argument that this situation potentially can be remedied by a concerted effort of patients, clinicians, and society. An excellent review of the public health implications of this problem was published by senior scientists at the U.S. Centers for Disease Control.[1]

The Breadth of the Problem

Clinicians are understandably both intrigued and frustrated by the current epidemic of obesity. Although many health care practitioners work hard to support and advise their patients in efforts to counter this problem, many external forces work against them. The lay public is already fully aware of the problem of excess body weight and its serious consequences. The print and broadcast media, elected officials, and policy makers have all clearly recognized the medical and economic threats that are posed by this phenomenon. This chapter does not discuss these social and political issues. Clearly, though, they are deeply embedded into our contemporary lifestyle. We live in a world where physical activity for all ages, but particularly for children, has been largely replaced by virtual activity. For the present generation, the computer and other electronic devices have become the main focus of attention. The ready availability of high-calorie and high-fat foods, cleverly and aggressively promoted by their manufacturers, provides seemingly irresistible temptations, again especially affecting children. The health care professions alone clearly cannot solve these problems. Solutions will depend as much on changes in public policy and educational activities as on the efforts of clinicians.

DEFINING AND EXPLAINING OBESITY

The National Institutes of Health has based its classification of body weight on the concept of body mass index (BMI), which is derived by dividing body weight by the square of height.[2] A classification based on a measurement such as this inevitably is somewhat arbitrary and is designed simply to provide an approximate guide for identifying people at differing levels of risk for cardiovascular events. A normal or acceptable BMI is lower than 25 kg/m^2, overweight is between 25 and 29.9 kg/m^2, and obesity is 30 kg/m^2 or higher. Some critics have actually argued that these definitions are too generous, particularly as an optimal cardiovascular prognosis appears to be associated with a BMI of approximately 21 kg/m^2.[3] Realistically, however, if such a low value were to be set as a desirable target, only a small fraction of present-day Americans could meet it.

Another shortcoming of using BMI for classification purposes is that it does not adequately address the physical distribution of excess fat tissue in the body. For the same BMI, a person with predominantly abdominal obesity is at greater risk of serious cardiovascular events than a person whose obesity is chiefly found below the hips. For that reason, clinicians have also directed their attention to measurements of the hips, the waist (the greatest circumference around the central abdomen), and the ratio of the waist-to-hip measurements. In fact, this approach has been used (in preference to BMI) as a criterion for establishing the metabolic syndrome (see later). But whatever methods are used, the prevalence of health-threatening excess body weight and obesity is remarkably high.[4]

Table 38–1 Factors Contributing to Obesity

Dietary
Excess consumption
Calorie-dense foods
High-fat foods
Relatively higher price of healthier, fresh produce
Exposure to advertising for fast foods, beer, and high-calorie products
Eating disorders
Behavioral
Inadequate regular exercise
Low physical activity at work
Low recreational physical activity, lack of facilities
Childcare or domestic arrangements that limit opportunities for spontaneous play by children
Excessive time with computers and television
Medical
Disabilities that impair physical activity
Pregnancy
Certain antidepressant or antipsychotic drugs
Rare endocrine and genetic disorders
Children of mothers who were diabetic or ate excessively during pregnancy

Looking at Causes

Factors that contribute to excess weight are listed in Table 38–1. In essence, the explanation for obesity in most people is that they consume more calories than they expend. It is also easy to see that two ongoing trends in our society can so readily explain the overall problem: (1) We are eating progressively larger portions of the fast foods and beverages (especially beer) that are so attractively and relentlessly advertised on television or in popular magazines; and (2), progressively more time is being spent with computers and televisions, as compared with planned or spontaneous pursuits involving physical activity—particularly as far as children are concerned. It is clear throughout our society what these issues are, but we have been ineffective at dealing with them.

Committees of experts asked to give advice on this matter have recommended that people spend at least 30 minutes involved in energy-consuming physical activities on a daily basis.[5] But there is little, if any, evidence that such recommendations on exercise and dietary changes have had any impact on the body weight of Americans. Clearly, a more thoughtful plan of education, backed up by detailed assessments of the many components that comprise the organization of life in our communities, would be more effective overall than general exhortations to exercise more and eat less. That is not to say that we do not already have a number of organized programs targeted at after-school and recreational activities for children,[6-8] as well as programs targeted at adults with major weight problems.[9,10] Some of these innovative programs have shown promising results, but clearly a major impact across the population will require public policies that comprehensively affect schools, public facilities, places of employment, and—hopefully in a voluntary fashion—the participation of the commercial food industry.

Impact of Excess Body Weight: A Changing Pattern

Obesity in the United States causes a substantial number of excess deaths each year.[11] It can be noted, though, that obesity-related mortality rates are now lower than they were about 30 years ago.[12] Presumably this change reflects an improvement in medical management of the risk factors associated with obesity. Even so, one assessment of this situation concluded that unless the obesity problem can be dealt with decisively, today's young adults and children are destined to live shorter and less healthy lives than their parents,[13] thus overturning previous trends to greater longevity.

An unexpected observation of weight-related secular trends is that overweight people (BMIs between 25 and 29.9) have mortality rates that are not only lower than in the obese, but are also lower than in lean individuals.[12] This finding has not gone unnoticed, and the lay press has even wondered whether the antiobesity establishment, which includes commercial weight-loss centers, dietary food makers, pharmaceutical companies, diet book publishers, and physicians, have been guilty of self-interest in drawing excessive attention to this issue.[14] However, changes in medical practice, particularly in dealing with cardiovascular risk factors, could at least partly explain this apparent paradox. Indeed, with the exception of type 2 diabetes, there has been a marked reduction in the prevalence of clinically manifest risk factors including high BP and hypercholesterolemia during the past 40 years.[15] This trend has been linked to increased prescribing of antihypertensive and lipid-lowering medications,[15] which, beyond their

intended therapeutic effects in countering what otherwise would have been a worsening of these findings, could additionally have pleiotropic actions that might further enhance prognosis. It is also possible that other mechanisms, discussed later in the context of obesity and hypertension, could further explain better-than-expected mortality outcomes in obese individuals.

Further Consequences

Problems of high body weight are associated with a wide range of morbidities. These include not only cardiovascular risk factors like hypertension or lipid abnormalities, but also such conditions as osteoarthritis and cholelithiasis.[16,17] Clearly, the metabolic syndrome, which so often results from obesity and predisposes to the high-risk condition of type 2 diabetes, is a serious concern. A list of common conditions that are at least partly related to obesity is given in Table 38–2.

Obesity-related problems are not always confined to patients who are seen in cardiovascular or other specialty practices. Nor are problems of weight confined to adults. Indeed, obese children are very much at risk of developing the metabolic syndrome,[18] and type 2 diabetes has now become commonly diagnosed in adolescents. In a study of youngsters ages 4 to 20, it was shown that increasing levels of obesity were associated with increases in blood concentrations of glucose, insulin, and triglycerides, together with reduced blood concentrations of high-density lipoprotein (HDL) cholesterol.[18] Along with evidence for glucose intolerance and insulin resistance, there was also an increase in systolic blood pressure. Remarkably, this study showed that whereas 50% of severely obese children and 39% of moderately obese children satisfied diagnostic criteria for the metabolic syndrome, there was no evidence for this syndrome in children with normal or only moderately increased body weight.[18]

Beyond its clinical and societal impact, obesity also produces strong adverse economic consequences. Experts in outcomes research, using data from the National Health and Nutrition Examination Survey III, have noted that during the decade running from approximately 1990 to 2000 there was a 44% increase in obesity in the United States and that this problem affected almost 30% of all people in regular employment.[19] Not surprisingly, obese workers were found to have work limitations at least twice as commonly as normal weight workers, to be four times as likely to have hypertension, three times as likely to have type 2 diabetes, and several-fold more likely to have the metabolic syndrome.[19] Again, quite apart from the human burden of these problems, it is easy to see the disruptive and costly effect of obesity on the economy.

It has been estimated that the cost of lost productivity and the direct cost of caring for the morbidities and limitations of obese and overweight persons total approximately $100 billion each year.[20] If we consider some of the noncardiovascular medical consequences of obesity (see Table 38–2), it could be argued that the true costs of this condition are even greater.

Table 38–2 Conditions That Can Result from Obesity

Type 2 diabetes mellitus
Dyslipidemia
Coronary heart disease
Hypertension
Atrial fibrillation
Stroke
Obstructive sleep apnea
Cholelithiasis
Postmenopausal breast cancer
Endometrial carcinoma
Prostate cancer
Osteoarthritis

How Common Is Excess Weight?

The worsening picture regarding the prevalence of obesity is shown in Figure 38–1. These data show an inexorable increase in obesity from the early 1960s to 2000, rising from approximately 14% to 31% of the adult population during that time. Worse, the rate of rise during that 40-year period actually accelerated from the mid 1970s until about 1990 and appeared to increase even faster after that. The curve for Americans who are considered overweight (BMIs between 25 and 29.9) follows a similar contour; however, because this number had already reached 45% in 1960, the relative increase to 65% by 2000 does not seem quite so dramatic. These findings indicate that barely one third of Americans currently has an acceptable body weight. More detailed information from the same source[1] suggests that, in general, obesity is more of a problem in the Eastern than in the Western states and that it is somewhat more prevalent among African Americans, particularly women, than whites. As discussed earlier, school children are also increasingly overweight or obese: This is true not only in the United States[21,22] but also in Great Britain[23] and Asia,[24,25] where presumably similar behavioral factors are at work.

THE LINK BETWEEN EXCESS BODY WEIGHT AND THE CARDIOVASCULAR METABOLIC SYNDROME

The presence of obesity, even in relatively young adults with no history of previous cardiovascular events, is predictive of metabolic, cardiovascular, and renal abnormalities.[26] Clinical

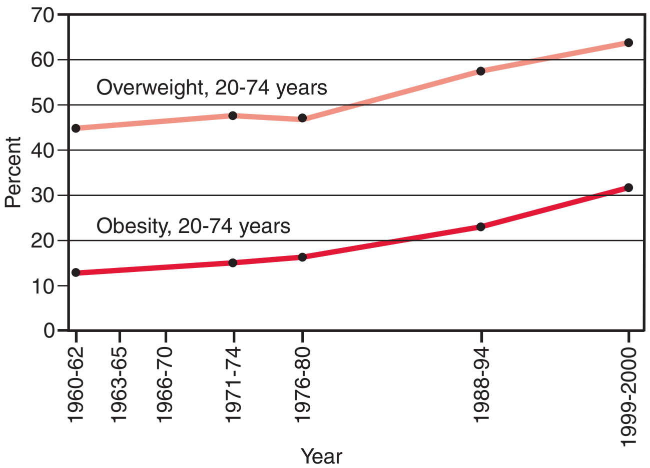

Figure 38–1 Overweight and obesity by age: United States, 1960-2000. (From Trends in Health of Americans. Hyattsville, Md, National Center for Health Statistics, 2003.)

findings in a cohort of individuals we identified by community screening, divided into those who were either obese or nonobese, and either hypertensive or normotensive, are shown in Table 38–3. Clearly, LDL-cholesterol levels are higher and HDL-cholesterol levels are lower in obese individuals, regardless of whether or not they are hypertensive. Triglyceride levels are higher in obese hypertensives (though not in obese normotensives) when compared with nonobese individuals. Interestingly, insulin concentrations are significantly higher in obese persons, either hypertensive or normotensive, than in lean individuals; in fact, insulin levels in lean hypertensives are lower than in normotensive obese individuals, indicating the clear importance of obesity per se as a determinant of early insulin resistance. Therefore, key findings associated with the metabolic syndrome (see later for definitions) are found readily during routine observations in the community.[26]

In the same cohort of subjects (see Table 38–3), obesity and hypertension were associated with a relative increase in echocardiographically measured left ventricular muscle mass index.[26] Because this measurement was factored by body size, the increase in left ventricular mass in obese persons is a real and potentially important finding. One piece of good news for obese people, as shown in Table 38–3, is that their total arterial compliance (as shown by the SV/PP measurement) is actually higher than in lean hypertensives, indicating that increased arterial stiffness—at least as measured by this technique—is not a major issue in obesity.

Renal Effects

Two findings regarding renal function in obese persons are interesting: (1) Creatinine clearance is higher in obese persons, regardless of whether they are hypertensive or not; and (2) the albumin excretion rate is also higher in obese people, again independent of blood pressure status. Obesity is known to affect renal function, in particular increasing sodium reabsorption,[27,28] an action probably mediated by increased renal sympathetic activity.[29] Whether these sympathetic mechanisms also cause the hyperfiltration we observed in obese patients is unknown,[26] although this phenomenon has also been observed by other investigators.[30] This finding may help explain the microalbuminuria found in obese subjects, one of the important diagnostic criteria for the metabolic syndrome as defined by the World Health Organization. Finally, the increased sodium reabsorption[27,28] found in obesity could also contribute to the increased plasma volume and cardiac output—probably important factors in increasing systolic blood pressure—that are typical of these individuals.[31]

Evidence for similar changes in children exists. A study performed in children with an average age of 13 showed that urinary albumin excretion was significantly higher in obese youngsters than in those with normal weight, and that in the obese children the albuminuria correlated with measurements of fasting blood insulin and cholesterol concentrations.[32] The authors of that study concluded that even at a young age, the presence of obesity might lead to early dysfunction of the renal glomerulus and tubule.

Early in the process of obesity, either in children or in younger adults who have not yet experienced cardiovascular or renal events, there are already important clinical manifestations associated with obesity. These include metabolic findings indicative of insulin resistance and lipid abnormalities, as well as early changes in cardiovascular and renal structure and function. Moreover, increased plasma volume and possibly some regional changes in sympathetic activity make these patients more vulnerable to adverse outcomes. How obesity leads to these findings is not clear, but there is growing interest in the possibility that the adipose cell itself may be an important mediator of some of these major clinical attributes of obesity.

The Fat Cell: A Key Biologic Contributor

A variety of mechanisms link obesity and adiposity to insulin resistance, diabetes, and cardiovascular risk. Traditionally, fat cells were seen primarily as storehouses for energy, chiefly in the form of triglycerides, but it is now apparent that adipose tissue can function as an endocrine organ, releasing a variety of peptides, cytokines, complement factors, and even components of the renin-angiotensin system into the circulation.[33] These substances collectively are referred to as adipokines. A report in which investigators studied the gene expression of cytokines obtained from subcutaneous fat in middle-aged obese women, specifically leptin, tumor necrosis factor-alpha

Table 38–3 Metabolic, Cardiovascular, and Renal Measurements

	Obese HTN (n = 55)	Lean HTN (n = 66)	Obese Norm (n = 21)	Lean Norm (n = 55)	P Value (ANOVA)
Total cholesterol (mg/dL)	225 ± 6	208 ± 6	203 ± 9	195 ± 4	0.009*

(TNF-α), IL-6, PAI-1, and adiponectin, provides an interesting insight into these factors.[34] In general, levels of leptin and adiponectin (which likely are protective substances) were lowest in women who had the greatest visceral fat volume. Fasting insulin concentrations correlated directly with adipose tissue TNF-α and IL-6 gene expression. Adiponectin gene expression was significantly lower in women with the metabolic syndrome than in those without it. These findings of a greater prominence of potentially harmful cytokines and a relative reduction of potentially protective factors like leptin and adiponectin help explain some of the adverse consequences of obesity.[34]

A study using the euglycemic hyperinsulinemic clamp in clinically healthy middle-aged men has further clarified these relationships.[35] Adiponectin concentrations correlated directly with glucose clearance rates, whereas TNF-α had a significant but inverse correlation with glucose clearance. In the same patients, total body fat (measured by dual energy x-ray absorptiometry) correlated inversely with adiponectin but directly with TNF-α. Thus, these two adipokines, adiponectin and TNF-α, have opposing effects on insulin resistance and have reverse relationships to body fat. This study also confirmed the relationship of CRP to TNF-α and obesity.[35]

The Renin-Angiotensin System

Adipose tissue expresses components of the renin-angiotensin system, especially angiotensinogen.[36,37] This effect is more pronounced in visceral than in subcutaneous fat.[36,37] If, indeed, this source of activity of the renin axis promotes meaningful systemic effects, it could help explain some of the renal and cardiovascular findings described earlier. It is by no means certain, however, that angiotensin mediates these changes to a marked extent in obesity. Our own findings have indicated, at least in hypertensive persons, that left ventricular muscle mass, for example, is more dependent on the renin-angiotensin system in lean persons than in the obese (for whom BMI was the only consistent predictor of LV muscle mass); and, as far as arterial stiffness is concerned, fasting plasma insulin, but not renin, is predictive of vascular properties in obese patients.[38] It is entirely possible, however, that regional expression of activity of the renin-angiotensin system—not measured in plasma—may play a role in mediating cardiovascular pathology in obesity.

The role of the renin-angiotensin system in insulin resistance and the genesis of diabetes may be particularly important. It is well established that blockers of the renin-angiotensin system including angiotensin receptor blockers and ACE inhibitors are effective in delaying or preventing new-onset diabetes in susceptible patients (see later). Mechanisms by which angiotensin II can promote insulin resistance and accelerate the appearance of diabetes include its effects on the microcirculation (particularly in skeletal muscle), insulin signaling within the pancreas, fibrotic changes in the islets and inhibitory actions—possibly including apoptosis—on β-cells (see reference 39 for review).

Other Factors Linking Obesity to Clinical Effects

The sympathetic nervous system has also been implicated as a mediator of the effects of obesity on cardiovascular and renal function.[36,40] Sympathetic hyperactivity, which can be stimulated by insulin resistance, is not uniform. In particular, renal sympathetic activity is enhanced in obesity[36,41] and may contribute to the sodium and volume retention that underlie the hypertension in such persons.

The role of leptin in the metabolic syndrome is not clear. Researchers know that it works in the hypothalamus, where it has appetite-suppressing activity and can influence sympathetic outflow. Levels of leptin are often increased in obesity, perhaps due to resistance to its effects. It has been speculated that obesity is associated with suppression of cytokine signaling proteins in the hypothalamus.[42] Interestingly, leptin has also been linked to findings such as increased left ventricular mass in obese patients,[43] although it is not clear whether this is a direct effect or is one mediated through such mechanisms as increased sympathetic drive that result from central effects of leptin.

An Additional Hypothesis

Generally, we have assumed that obesity is the main driver of insulin resistance and the metabolic syndrome, and there is little doubt that circulating adipokines released from fatty tissue play an important role in this. But it is also possible that intrinsic abnormalities within skeletal muscle cells and the liver could play a key role. There is compelling evidence from studies that use magnetic resonance spectroscopy that fatty acids are responsible for inhibiting insulin-stimulated glucose from being transported into skeletal muscle cells.[44] It appears that insulin resistance in humans results from defects in mitochondrial fatty acid oxidation in these cells. This causes accumulation of intracellular fatty acyl CoA and diacylglycerol, which, in turn, activate signal transduction pathways that inhibit insulin signaling.[45]

Underlying mitochondrial deficiency may have several causes including genetic abnormalities; aging; or, commonly, increased fat delivery due directly to high-caloric intake.[45] This mechanism could help explain why nonobese people can also develop insulin resistance and also why a reduction in caloric intake—even while previous obesity still exists—can provide immediate clinical improvement in the metabolic syndrome.

Finally, before considering the clinical details of the metabolic syndrome, it should be noted that obesity may have cardiovascular effects that are independent of the traditional risk factors associated with this syndrome. For instance, epidemiological evidence has suggested that increased body weight per se can increase the incidence of heart failure independently of other risk factors.[46] Indeed, a current report has described a linkage between impaired left ventricular diastolic function, as well as altered contractile reserve, with obesity and insulin resistance, again in subjects without any other features of the metabolic syndrome.[47] Further, all obvious risk factors associated with obesity can produce endothelial dysfunction, thus hastening adverse cardiovascular outcomes.[48]

Major Features of the Cardiovascular Metabolic Syndrome

Indicative of the protean features of this syndrome is that at times it has been given a variety of names: syndrome X,[49] the metabolic syndrome, the cardiovascular-metabolic syndrome,

Table 38–4 Clinical Findings Associated with the Cardiovascular Metabolic Syndrome

Metabolic
Central obesity
Hyperinsulinemia
High fasting glucose or impaired tolerance
Low HDL cholesterol
High triglycerides
Small, dense LDL cholesterol particles
Hyperuricemia
Cardiovascular
Hypertension
Endothelial dysfunction
Left ventricular hypertrophy or diastolic dysfunction
Increased arterial stiffness
Increased sympathetic activity
Renal
Microalbuminuria
Salt sensitivity
Hyperfiltration (high creatinine clearance)
Thrombotic
Increased fibrinogen levels
Increased plasminogen activator inhibitor-1
Inflammatory
Increased C-reactive protein, tumor necrosis factor, interleukin-6, and other inflammatory factors

and the hypertension syndrome.[50,51] None of these terms is entirely appropriate, for they do not include the renal, inflammatory, and thrombotic components of the full picture.

Major components of the syndrome are listed in Table 38–4. The manifestations of the syndrome can be divided roughly into five headings: metabolic, cardiovascular, renal, thrombotic, and inflammatory. Given the large number of items listed in Table 38–4 and bearing in mind that there are probably other associated findings that could be included, it becomes difficult and even arbitrary to propose a workable clinical definition of the syndrome. The current recommendations follow.

Current Definitions for the Syndrome

- Adult Treatment Panel III (ATP III): This recommendation, provided by the National Cholesterol Education Program (NCEP), bases the diagnosis on having any three of the following five clinical criteria:
  - Abdominal Obesity: waist measurement ≥40 inches (102 cm) in men or ≥35 inches (88 cm) in women
  - Hypertriglyceridemia: ≥150 mg/dL (1.7 mmol/L)
  - Low HDL Cholesterol: <40 mg/dL (1.04 mmol/L) in men and <50 mg/dL (1.3 mmol/L) in women.
  - High Blood Pressure : ≥130/85 mm Hg
  - High Fasting Glucose Level: ≥100 mg/dL (5.5 mmol/L) (This was set originally at 110 mg/dL but was reduced to 100 mg/dL in recommendations of the American Diabetes Association.)
- World Health Organization (WHO): This definition of the metabolic syndrome requires fundamental evidence for insulin resistance (manifested by type 2 diabetes, impaired glucose tolerance, or high fasting glucose levels) together with two or more of the following abnormalities:
  - High Blood Pressure: ≥160/90 mm Hg
  - Hyperlipidemia: Triglycerides ≥150 mg/dL (1.7 mmol/L); or HDL cholesterol ≤35 mg/dL (0.9 mmol/L) in men and ≤39 mg/dL (1.0 mmol/L) in women
  - Central Obesity: Waist/hip ratio ≥0.90 in men or 0.85 in women; or a BMI ≥30 kg/m^2
  - Microalbuminuria: Urinary albumin excretion rate ≥20 mg/day or an albumin-to-creatinine ratio ≥20 mg/g

Broadly, the two definitions are similar in that they both depend on evidence for central obesity; insulin resistance (though, strictly speaking, the ATP III definition allows for a positive diagnosis if three of the findings are present, even in the presence of a normal fasting glucose level); lipid abnormalities; and high BP. Differences are interesting, however, with respect to BP. The WHO definition requires stage 2 hypertension, whereas the BP criterion for ATP III can be satisfied by a BP that is still in what is called the *prehypertensive range.* Also interesting is that the ATP III definition for obesity can only be satisfied by an increased waist circumference (reflecting the importance of visceral fat), whereas the WHO criterion can be satisfied, if the waist-hip criterion is not met, simply by a high BMI. WHO, but not ATP III, also accepts the presence of microalbuminuria as a criterion. There is little doubt that this particular finding is highly predictive of both cardiovascular and renal events. The choice of criteria and even the differences between the two definitions highlight the difficulty of completely defining this clinical picture; almost certainly these definitions will continue to evolve.

How Common Is the Metabolic Syndrome and What Are its Major Implications?

Approximately 24% of people in the United States have the metabolic syndrome.[52] The prevalence rates are similar for men and women except among African Americans, where women are 50% more likely than men to have the syndrome, and among people of Mexican origin, who are about 25% more likely than other ethnic groups to have the syndrome. Advancing age, at least from the 20s to the 60s, also appears to be linked to an increase in prevalence.

Among high-risk subpopulations, the metabolic syndrome is particularly common. For example, among people with diagnosed coronary heart disease, the prevalence of the metabolic syndrome (as defined by the ATP III criteria) was reported to be approximately 50%. Not surprisingly, coronary patients with evidence for the syndrome are more likely to have severe disease and a poorer prognosis than those who do not have it.[53]

In general, the metabolic syndrome predicts serious health consequences. A longitudinal follow-up of middle-aged men, without cardiovascular or other major disease at the onset of the study, found that those with evidence for metabolic syndrome were three times as likely to have a fatal event of any cause than those who did not have the syndrome.[54] In a similar observational study, not only mortality but also the

incidence of stroke and cardiovascular events was shown to be sharply increased by the presence of the metabolic syndrome.[55]

Antecedents of the Cardiovascular Metabolic Syndrome

On the basis of the previous discussion, it is easy to make the argument that obesity is the primary cause of metabolic syndrome. But just as not all obese people manifest the metabolic syndrome, it is also possible to develop the syndrome without being clinically obese. In fact, both the ATP III and WHO guidelines can be satisfied by criteria other than enlargement of waist circumference or increased BMI.

Although it has been persuasively argued that insulin resistance is a major mediator of the cardiovascular metabolic syndrome,[56] the possibility of a genetic predisposition has been raised by a familial pattern noted in some patients. Certainly, in the context of what has been called the *hypertension syndrome*—which, in essence, is a common form of the metabolic syndrome that includes unequivocally raised BP—there is evidence that cardiovascular and renal changes can appear at an early stage of life.

Familial Trends

It is difficult to ascribe specific causes for clinical findings that appear in successive generations of a family. A genetic basis could very well exist, but at the same time, because family members often adopt similar eating and lifestyle habits, the resemblance could simply reflect a commonality of the living environment. Still, abnormal findings in the relatively young normotensive offspring of hypertensive parents suggest that there may be antecedents for the metabolic syndrome in some individuals that are independent of later obesity.

In a cohort of young adults identified by screening, those with normal BPs who had a positive family history of hypertension (either through one or both parents or siblings) were matched by age and body weight with young adults who did not have such a family history.[50,51] By comparison with the group without a family history, those with a positive history had significantly higher values for LDL cholesterol, triglycerides, and insulin levels. Plasma renin activity and norepinephrine measurements also tended to be higher. Moreover, left ventricular muscle mass was greater, and there was a lower E/A ratio on echo-Doppler measurement,[57] indicating a greater dependency of diastolic filling on late atrial contraction, perhaps due to early left ventricular stiffening. Arterial compliance, particularly that measured in the microcirculation, was also lower (indicating greater arterial stiffness) in those with a positive family history.[58]

Evidence indicates that a positive family history of hypertension is predictive of increased creatinine clearance (hyperfiltration) in normotensive offspring.[50] Normotensive children of hypertensive parents have also been shown to have increased sympathetic activity.[59] These findings appear to be independent of obesity, although it has been separately reported that obese children (in their early teens) are more likely than normal-weight children to have microalbuminuria.[60] These findings support the claim that genetic factors—and not just acquired obesity—could play an important role in the genesis of the cardiovascular metabolic syndrome.[61]

The Issue of Hypertension

Earlier on, in discussing the "hypertension syndrome," it was pointed out that some of the mediators of the cardiovascular and renal aspects of this form of the cardiovascular metabolic syndrome appeared to differ between obese and lean hypertensives. In obese individuals, body weight and insulin levels appeared to be most predictive of clinical abnormalities, whereas in lean patients there appeared to be a greater participation of the renin-angiotensin and sympathetic systems. In addition, lipid and insulin levels (as summarized in Table 38–3) differed between the obese and lean hypertension groups.[26]

Other important differences between obese and lean hypertensives exist. The fundamental hemodynamics of the two forms of hypertension depend on separate mechanisms: In obese hypertensives, presumably reflecting their tendency to sodium and volume retention, the hypertension is characterized principally by an increase in stroke volume (cardiac output) but with a normal peripheral resistance; in lean hypertensives, perhaps reflecting their dependency on heightened neurohumoral activity, cardiac output is normal but peripheral resistance is increased.[62-64]

Perhaps the most meaningful difference between obese and lean hypertensives is the apparently paradoxical finding that obese hypertensive patients actually have a better long-term prognosis regarding cardiovascular mortality and morbidity.[65,66] Interestingly, this finding does not apply only to people with hypertension: Similar findings have been shown for patients with established coronary disease, among whom—somewhat in contradiction to some epidemiologic reports (see earlier)—the lean patients appear to have a poorer prognosis.[67] In the hypertension setting, obese patients have an apparent advantage even when all other risk factors are taken into account.[66] It should be emphasized, however, that even though obese hypertensive patients appear to have better outcomes than lean hypertensives, they still have a poorer prognosis than normotensive controls.[65,66]

Explanations for these disparate outcomes are not immediately obvious. Even though lean patients may be more dependent on renin and sympathetic mechanisms for some of their cardiovascular and renal lesions, a detailed review of studies in which such neuroendocrine measurements were provided showed no consistent trends indicating that these systems were activated in either type of hypertension.[68] Our own observations indicated that plasma renin activity and catecholamine measurements were similar in obese and lean hypertensive patients and similar to such measurements in obese and lean controls with normal BP.[26]

A more promising line of inquiry has focused, not on the resting values of the systems, but on their reactivity to stress. As shown in Figure 38–2, during standardized treadmill testing, there were significantly greater increases in plasma renin activity in lean hypertensives than in obese hypertensives; likewise, there were significantly greater increases in plasma epinephrine in the lean than in the obese groups. Particularly noteworthy is that findings in the normotensive obese and lean patients are virtually identical to those in the corresponding hypertensive groups (see Fig. 38–2). If we make the reasonable assumption that the findings in lean people with normal BP represent the appropriate physiologic response to stress testing, then it can be concluded that obese

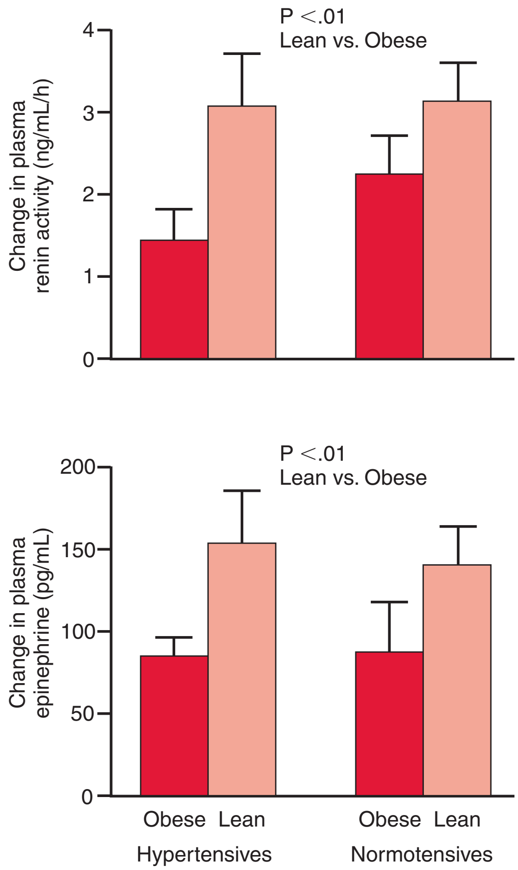

Figure 38–2 Changes in plasma renin activity and in plasma epinephrine concentrations during treadmill testing in obese and lean hypertensive patients and normotensive volunteers. By two-way ANOVA, the differences between the obese and lean subjects were significant, but not the differences between hypertensives and normotensives. (From Melnik TA, Rhoades SJ, Wales KR, et al: Overweight school children in New York City: Prevalence estimates and characteristics. Int J Obes Relat Metab Disord 1998:22: 7-13.)

individuals—either hypertensive or normotensive—exhibit an inhibited neuroendocrine response to this type of stimulation.[26] This finding could either explain a possible protective mechanism in obese hypertensive individuals or the unexpectedly poorer outcomes in lean hypertensive patients. Other data also support the concept of greater neuroendocrine reactivity in lean hypertensive patients.[69] Taken together with the full array of clinical differences between the two hypertensive groups, it can be hypothesized that they represent two distinct clinical entities.

Even though we have no direct mechanistic evidence that volume-dependent hypertension may be more benign than vasoconstrictor-dependent hypertension, there is one clear clinical consequence. An interesting subgroup analysis derived from the Systolic Hypertension in the Elderly Program (SHEP) demonstrated that the diuretic agent chlorthalidone was particularly effective in improving cardiovascular disease outcomes in overweight and obese elderly hypertensive patients but actually appeared to worsen morbidity and mortality in lean patients.[70] More studies of this type would be helpful in further characterizing optimal therapeutic approaches to these different types of hypertension. Studies of genetic characteristics would also be of interest: Do patients with obese and lean hypertension have two separate genetic forms of hypertension? Or, in the particular case of obese people, can hypertension be attributed partly or even entirely to environmental factors?

PREVENTION AND TREATMENT OF OBESITY AND THE METABOLIC SYNDROME

Lay people, as well as health professionals, obviously know that the primary therapeutic approach to obesity is a reduction in energy consumption and an increase in physical activity. In a society that is highly conscious of personal appearance, few, if any, obese people are not aware of their condition and have not made numerous attempts to deal with it. But this problem, which, in the minds of those fortunate enough to be lean, reflects the self-indulgence or lack of willpower of their heavier contemporaries, is obviously more complex.

An innovative study has compared activity levels during the routine daily lives of mildly obese and lean volunteers.[71] Body sensors were used to carefully measure changes in posture and movement (called *nonexercise activity thermogenesis*) on a continuous basis during 10 days of observation. It was found that obese people were seated for 2 hours longer each day than their lean counterparts. Interestingly, when as part of the study the obese people lost weight and the lean people gained weight—thus largely eliminating the weight differential between the groups—their patterns of activity still remained constant. The investigators concluded that this type of activity appears to be biologically determined rather than governed by body weight, and so creates the possibility that genetic differences may play an important role in the development of obesity. The lean group expended about 350 calories a day more than the obese group due to their heightened daily movements. This could potentially be of great importance because this type of activity, which generally cannot be measured in the standard clinical setting, could account for a difference of as much as 30 lb in body weight during the course of a year. Thus, our traditional assumptions about diet and exercise may be oversimplifying the issue of obesity.

Practical Approaches

Strategies for dealing with this problem can broadly be divided into three groups. First are those strategies targeted at preventing or reversing obesity. Then, there are those targeted at people who already have evidence for the metabolic syndrome, which are focused both on preventing or reversing obesity and on preventing progression of insulin resistance into clinical type 2 diabetes. Finally, in addition to the first two strategies, there are treatments aimed at the risk factors associated with the metabolic syndrome and at protecting against cardiovascular and renal events.

The obesity problem has no simple solutions. Public policy remains a cornerstone of preventing and dealing with this issue. Certainly, the traditional health care setting can only be a small part of such a campaign. There must be a strong focus

in schools and other places of education including colleges. Starting this education at a young age is clearly important, and even nursery and kindergarten facilities, as well as after-school and day-care facilities, must focus on teaching good eating habits to young children and providing them with appropriate diets.[6,7] Educating parents, as well as children, about good food choices is essential, as is providing proper exercise facilities. Churches and other places of worship, work sites, and clubs are other places in the community where this pervasive problem can be addressed.

The American College of Physicians has published guidelines for the management of obesity.[72] As shown in Figure 38–3, the recommended algorithm depends chiefly on weight loss, diet, exercise, and other appropriate lifestyle changes. Drug therapy is regarded as an adjunct to a structured lifestyle regimen that is tailored to individual patients.

Uncertainty exists regarding the optimal diets to be recommended for the management of obesity. Traditionally, we have employed low-fat diets and have attempted to reduce caloric intake as much as possible. This approach, given enough time, can undoubtedly effectively reduce body weight, particularly if accompanied by an appropriate aerobic exercise regimen. Apart from contributing to weight loss, exercise also has a beneficial effect on insulin sensitivity, although it has inconsistent effects on inflammatory biomarkers, as measured by levels of C-reactive protein and adiponectin.[73]

There is great current interest in the use of very low carbohydrate diets (sometimes referred to as *ketogenic diets*). This approach has been popular with the lay public because not only are results, in terms of reduced body weight, relatively prompt, but there is no compelling need to practice denial in terms of the quantities of food consumed. Strictly speaking, as long as carbohydrates are avoided, there are no real limitations on other types of foods. There is no evidence that this approach will adequately reverse the cardiovascular metabolic syndrome; beyond that, there is no real evidence regarding the effects of these diets on long-term cardiovascular prognosis. A report of the short-term effects of a low-carbohydrate diet, which interestingly resulted in a meaningful reduction in calorie intake, has demonstrated significant improvement in glucose and insulin metabolism and lipid levels.[74] A thoughtful review of these issues, together with the possible benefits of differing exercise strategies, has been published.[75]

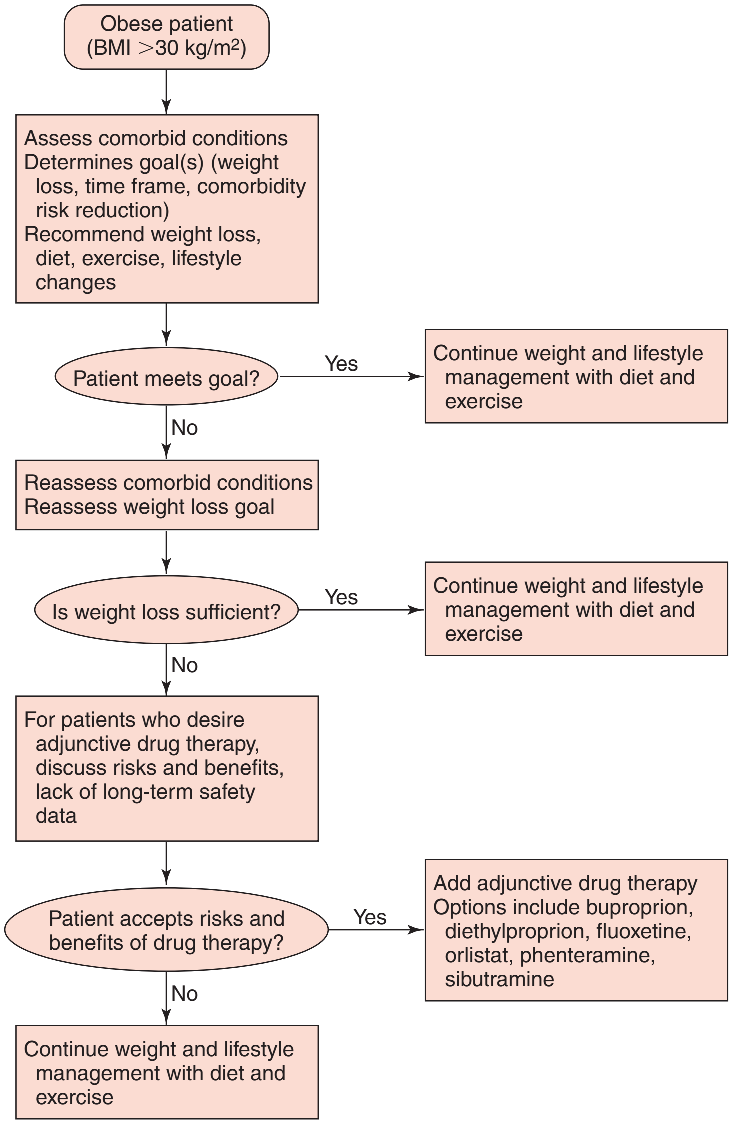

Figure 38–3 Algorithm for managing obesity in clinical practice. This clinical practice guideline was sponsored by the American College of Physicians. (From Snow V, Barry P, Fitterman N, et al: Pharmacologic and surgical management of obesity in primary care: A clinical practice guideline from the American College of Physicians. Ann Intern Med 2005;142:525-31.)

Drug Therapy

The two main agents that are currently prescribed are sibutramine, a serotonin and norepinephrine reuptake inhibitor, and orlistat, an inhibitor of pancreatic lipase. Sibutramine produces decreased appetite and early satiety.[76] This drug is effective in producing weight loss for as long as it is actively taken. The main safety concerns are the increases in BP and pulse rate that occur in some patients; for individuals with more severe forms of hypertension, the use of this agent may be questionable. A meta-analysis of trials using sibutramine in overweight or obese patients has demonstrated a mean weight loss of 4.5 kg compared with placebo after 12 months.[77]

The main effect of orlistat is to impair digestion of about one third of the fat in the diet. Because this results in a reduction in absorption of dietary fat, there is a reduction in caloric intake. At least one study has claimed that, together with appropriate nonpharmacologic therapy, this agent can reduce the incidence of new-onset diabetes in obese people.[78] Because this drug works by inducing a form of malabsorption, not surprisingly most of its symptomatic side effects are linked to steatorrhea. A meta-analysis of clinical trials with orlistat in obese patients showed a mean weight loss of 2.9 kg after 12 months of treatment.[79]

The two other drugs approved by the Food and Drug Administration for appetite suppression are phentermine and diethylpropion. They are both sympathomimetic amines, with side effects of tachycardia and palpitations, as well as gastrointestinal symptoms. A meta-analysis[80] revealed modest efficacy: for phentermine, there was a mean weight loss of 3.6 kg and for diethylpropion, 3.0 kg. Some evidence indicates that selective serotonin re-uptake inhibitor-type antidepressants like fluoxetine and sertraline can have appetite-suppressant effects.

Rimonabant is a new compound that works in the central nervous system as an antagonist of the cannabinoid-1 receptor. Apart from its efficacy in inducing meaningful weight loss, this agent has also undergone successful clinical trials for cessation of smoking and alcohol use. There is also reason to believe that this agent, apart from inducing weight loss, improves the lipid profile.[81] Experience with rimonabant is still relatively limited because it has not yet been registered for general use, but early indications are that it is well tolerated. If this proves to be the case, it may become a valuable tool for managing obese patients who, despite efforts to adopt lifestyle changes, remain at unacceptably high body weights.

Surgical Therapy

In addition to drug therapy, surgical procedures are also now being commonly undertaken for severely obese patients including adolescents who have been unsuccessful in losing weight by other means. Because some of these surgeries can be performed laparoscopically, they are becoming progressively more popular, though they are certainly not free of complications. Procedures such as vertical banded gastroplasty or gastric bypass are unquestionably efficacious in assisting weight loss. It has also been reported that, together with their substantial weight loss, these patients experience significant improvements in components of the metabolic syndrome including systolic blood pressure, total cholesterol, triglycerides, and glucose.[82] Moreover, the benefits of surgical procedures appear to persist over long time periods. A 10-year follow-up of Swedish patients has shown that meaningful weight loss was maintained throughout this period and was associated with a reduced incidence of diabetes and hypertension when compared with patients not having surgery.[83]

Prevention

On a positive note, data from diabetes prevention studies indicate that even moderate lifestyle interventions by diet and exercise in people with impaired glucose tolerance and other aspects of the metabolic syndrome can decrease significantly the incidence of type 2 diabetes.[84] In particular, the Diabetes Prevention Program demonstrated that a weight loss of at least 5% together with at least 2 to 2 1/2 hours of structured physical activity a week produced a better than 50% reduction in new-onset diabetes compared with undertaking no lifestyle modification. The use of the antidiabetes drug metformin was about half as effective in preventing incident diabetes as lifestyle modification alone.[85] Figure 38–4 summarizes the main findings of this important 4-year trial.

Preventing Diabetes

In addition to weight-loss strategies, other important aspects of the cardiovascular metabolic syndrome can also be addressed. A primary objective in managing these patients is to prevent progression of the metabolic syndrome into the full clinical picture of type 2 diabetes. The best success so far has been with blockers of the renin-angiotensin system. For example, in the Heart Outcomes Prevention Evaluation (HOPE) study, carried out in patients at high risk of cardiovascular events, many of whom had characteristics of the metabolic syndrome, an ACE inhibitor reduced new-onset diabetes by 30% when compared with placebo.[86] Of particular note, in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), it was reported that in patients with impaired fasting glucose levels at baseline

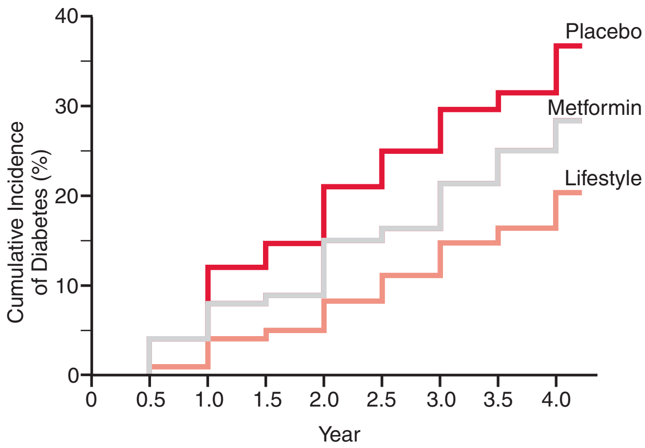

Figure 38–4 New-onset diabetes during 4 years of observation. The rates in the three arms are significantly different from each other ($P < 0.001$). (From Diabetes Prevention Program Research Group: Reduction in the incidence of type 2 diabetes with lifestyle intervention or metformin. N Engl J Med 2002;346:393-403.)

(110 to 125 mg/dL), the use of diuretic-based therapy was associated with a greater than 50% conversion to frank diabetes by the end of the 4-year study. This conversion was significantly lower with an ACE inhibitor than with a diuretic, though still troublingly high (36%) in these very susceptible patients.[87]

In high-risk hypertensive patients in the LIFE study, the angiotensin receptor blocker losartan reduced new-onset diabetes by 25% when compared with the β-blocker atenolol.[88] In the VALUE trial, also carried out in high-risk hypertensive patients, valsartan was 23% more effective than amlodipine in preventing diabetes. This was a meaningful finding because calcium channel blockers—unlike diuretics or β-blockers—may have some slightly beneficial effects on glucose metabolism, thus making the finding with valsartan particularly important.[89]

The oral anti-diabetic agent metformin has also been shown to be effective in preventing diabetes.[85] Also of great interest are the peroxisomal proliferator-activated receptor (PPAR) drugs, which affect the nuclear transcriptional regulators that govern insulin resistance as well as lipid profiles and probably other factors influencing the genesis of vascular disease. Cardiac function may also be improved: A trial with pioglitazone in hypertensive patients demonstrated an enhancement of left ventricular diastolic function that was most evident in those whose measures of insulin sensitivity were improved, most likely reflecting increases in adiponectin and matrix metalloproteinase (MMP-2) produced by this agent.[90] Clinical trials are now examining whether the PPAR agents, generally referred to as thiazolidinediones, already known to be effective in treating type 2 diabetes, can also be shown to prevent or delay diabetes.[91] Similarly, a major clinical trial with the antidiabetes agent nateglinide is currently under way in susceptible patients to measure its potential ability to prevent or delay type 2 diabetes.[92]

Other Approaches

From the viewpoint of the practicing clinician, the goal of managing patients with obesity and its associated abnormalities is to protect them from cardiovascular events. Rigorous control of hypertension and lipid abnormalities are cornerstones of therapy. Blockers of the renin-angiotensin system have much to offer because, in addition to diminishing the rate of new-onset diabetes, they reduce microalbuminuria and prevent its progression to diabetic nephropathy.[93] Further, in patients already manifesting nephropathy, they can significantly reduce progression to end-stage renal disease.[94,95] Moreover, preliminary evidence suggests that angiotensin receptor blockers reduce the cytokines and inflammatory agents that may mediate cardiovascular disease in obese patients. For instance, olmesartan was shown to reduce CRP, TNF, and interleukin-6 during 3 months of treatment in high-risk hypertensive patients.[96]

Some angiotensin receptor blockers appear to have relevant effects, independent of their blockade of angiotensin II, that rely on their partial PPAR-γ against actions. In vitro studies have demonstrated that both telmisartan and irbesartan stimulate adiponectin expression, and studies in an obese rat model showed attenuation of adiponectin depletion together with improved insulin sensitivity when irbesartan was administered.[97]

The clinical and research communities now recognize obesity and the cardiovascular metabolic syndrome as precursors of diabetes and major cardiovascular and renal events. Our growing use of the modern drugs already discussed, along with new types of PPAR agents, more powerful statins, and antiplatelet therapies, which, together with effective antihypertensive therapy could reduce the clinical consequences that arise from the metabolic syndrome, indicates a broad awareness of these problems. These innovative therapies have potential for complementing the results of effective lifestyle strategies.

A Final Caveat

Despite the wide acceptance of the metabolic syndrome as an important clinical entity, some significant observers have raised a cautionary note. A joint statement of the American Diabetes Association and the European Association for the Study of Diabetes points out that while some key cardiovascular risk factors tend to cluster together, and perhaps are linked to obesity and insulin resistance in many cases, the term "syndrome" is not fully justified.[98] They note that the definition of the syndrome is arbitrary and includes people with a potentially wide range of clinical phenotypes that could reflect differing pathophysiologic mechanisms. These experts recommend dealing with all cardiovascular risk factors in an appropriate fashion, regardless of whether or not individuals meet the current criteria for diagnosing the metabolic syndrome. From a pragmatic point of view, this advice confirms what responsible clinicians are already doing.

Chapter 39

Hypertension in Pregnancy

Jason G. Umans

CHAPTER CONTENTS

Hypertension is the most common medical complication of pregnancy, affecting 10% to 15% of all pregnancies in the developed world. It is the second leading cause of maternal death and increases the incidence of preterm birth, intrauterine growth restriction, placental abruption, and perinatal mortality. Hypertension in pregnancy may be due to underlying chronic essential or secondary hypertension, gestational hypertension, or preeclampsia; the latter two disorders are unique to human pregnancy. Importantly, each of these etiologies has a distinct hemodynamic profile, apparent mechanism, risk to mother and fetus, and long-term sequelae. Differential diagnosis of hypertension during pregnancy can be surprisingly difficult. Furthermore, normal physiological adaptations to pregnancy often mask evidence of underlying (preconceptual) hypertension.

Although clinical trial and outcomes data guide treatment goals or blood pressure (BP) targets in nonpregnant hypertensive patients, we are without evidence-based BP targets for hypertensive gravidas. Defining BP targets is even more difficult because guidelines were developed using mercury sphygmomanometry, while practice has largely shifted to use of automated oscillometric BP devices, despite their often erroneous results in hypertensive pregnant women. Tight BP control appears not to benefit women without target organ damage. However, the risk of cerebrovascular catastrophe when BP exceeds either 170 systolic or 110 diastolic should focus our efforts both on avoiding these high levels and on early recognition of preeclampsia, which may evolve rapidly and unpredictably toward multisystem failure and life-threatening complications. Antihypertensive therapy is limited by contraindications to the use of angiotensin-converting enzyme (ACE) inhibitors and AT_1 receptor blockers late in pregnancy and by a paucity of well-designed and adequately powered studies to assess risks and benefits of other antihypertensive agents. This lack of data has not stemmed the profusion of meta-analyses and consensus treatment guidelines.

BLOOD PRESSURE MEASUREMENT AND NORMS DURING PREGNANCY

Hypertension in pregnancy is defined as a BP >140 mm Hg systolic or > 90 mm Hg diastolic, occurring at any time during pregnancy.[1] BP measurement during pregnancy is best performed in the sitting position, with the arm supported, using an appropriately sized cuff, a mercury sphygmomanometer, and defining diastolic BP as the fifth Korotkoff sound.[2] Supine BP may be elevated late in pregnancy in some women due to mass effect of the gravid uterus. This has led many clinicians erroneously to favor BP measurement in the left lateral decubitus position. When BP is then recorded from the right arm (inadvertently elevated relative to the heart), it can be falsely reassuring. By contrast, when it is impractical for the patient to sit for BP measurement, a reasonable and conservative strategy would be to record BP from the left (inferior) arm. Most of the oscillometric devices now used routinely for BP measurement in hospital clinics, on labor and delivery units, and even those that are integral to fetal monitoring devices have not been validated in hypertensive pregnant women; nearly all provide erroneous calculations of diastolic BP. Because many guidelines for treatment of severe hypertension focus on diastolic values, all automated readings should be confirmed by auscultation when they might affect therapy.

Even though oscillometric devices may be inaccurate in hypertensive gravidas, home BP monitoring by women at high risk for preeclampsia or with more severe underlying hypertension can be extraordinarily useful by detecting significant changes in systolic pressure, leading to early diagnosis of preeclampsia or to more careful titration of antihypertensive medications.[3] Similarly, there may be promise in the use of ambulatory BP monitoring for risk assessment in pregnancy, though confirmatory and outcomes data remain lacking.[4]

RISKS OF HYPERTENSION IN PREGNANCY AND GUIDELINES FOR EVALUATION AND MANAGEMENT

Chronic hypertension increases risks of several morbid pregnancy outcomes including superimposed preeclampsia, preterm birth, intrauterine growth restriction, placental abruption, perinatal death, and accelerated hypertension threatening the mother.[5-7] Antihypertensive treatment fails to prevent these outcomes, except for the occurrence of more severe hypertension later in pregnancy. This remains important because adverse perinatal outcomes seem closely related to severity of maternal hypertension and because severe hypertension may be a major cause of both hospitalization and early delivery. Recognition of these risks and of clinical uncertainty regarding evaluation and treatment of hypertensive gravidas has led to updated guidelines by consensus groups in the United States, Canada, and Australia.[2,8,9]

All of the consensus groups agree, even without clear outcomes data, that BPs as low as 170/110 mm Hg can lead to cerebrovascular hemorrhage during pregnancy, making treatment of such pressures a medical emergency. At the opposite extreme, it has been suggested, but not proven, that tight BP control may impair fetal growth.[10] The Australasian Society for the Study of Hypertension in Pregnancy suggests maintaining BPs < 140/90 mm Hg.[8] The Canadian Hypertension Society suggests similarly tight control only for some groups of women.[9] By contrast, the National High Blood Pressure Education Program (NHBPEP) Working Group on Hypertension in Pregnancy suggests (re)instituting drug therapy at pressures of 150 to 160/100 to 110, targeting lower pressures in selected patients with target organ damage or underlying renal disease.[2] Not only is there disagreement among national groups, but disagreement occurs even within one system: a survey of Canadian practitioners with experience in the care of hypertensive pregnant women revealed no consensus regarding appropriate BP targets.[11] These uncertainties should provide the equipoise and impetus for adequately powered prospective trials to guide therapy instead of continued appeal to well-meaning guidelines.

HEMODYNAMICS IN NORMAL AND HYPERTENSIVE PREGNANCY

Normal pregnancy leads to significant hemodynamic and renal adaptations that affect our approach to hypertension. Gestational systemic vasodilation is so prominent that, despite an increase in cardiac output (CO) of nearly 50%, BP falls early in the first trimester.[12,13] Paradoxically, this gestational hypotension is even more prominent in women with underlying chronic hypertension, so BP may fall by 30/15 mm Hg, masking the recognition of pregestational hypertension when the patient is examined at her first prenatal visit.[14] Thus a thorough history, review of records, funduscopic examination, and evidence of target organ damage may be the only good clues to chronic hypertension in the early phase of pregnancy; BP values of 120/80 during the first trimester may be abnormal and should lead to suspicion of underlying hypertension. The mechanisms of gestational vasodilation remain uncertain but appear not to depend on either vasodilator prostaglandins or nitric oxide (NO).

Pregnancy leads to major changes in the renin-angiotensin-aldosterone system, with markedly increased levels of angiotensinogen, plasma renin activity, angiotensin II, Ang 1-7, and aldosterone.[15,16] However, there is a specific refractoriness to the vascular AT_1 receptor-mediated effects of angiotensin, manifest as decreased pressor response to infused angiotensin II and to blunted constriction of human resistance arteries in vitro.

Pregnancy leads to generalized systemic vasodilation, and specifically to renal vasodilation and hyperfiltration, with balanced afferent and efferent arteriolar vasodilation and parallel increments of renal plasma flow and glomerular filtration rate (GFR).[13] In the same way that pregnancy may obscure the recognition of underlying essential hypertension, this gestational hyperfiltration may mask underlying renal insufficiency (chronic kidney disease, CKD). A serum creatinine concentration of > 0.8 mg/dL early in pregnancy should be viewed with suspicion. The mechanisms leading to gestational renal vasodilation have been elucidated in the rat and appear to depend on a cascade in which the ovarian hormone relaxin acts via gelatinase to cleave big endothelin (ET), resulting in ET_B receptor-mediated activation of NO synthase.[17] Whether similar mechanisms occur in women is yet to be determined.

DIAGNOSIS AND CLASSIFICATION OF HYPERTENSION IN PREGNANCY

We now recognize four diagnostic categories for hypertensive disorders of pregnancy, using a nomenclature endorsed by the International Society for the Study of Hypertension in Pregnancy (ISSHP), several national and international obstetrics groups, and by the NHBPEP Working Group on Hypertension in Pregnancy.[1,2] Chronic hypertension (antedating pregnancy) may be either essential or secondary. Two hypertensive disorders occur only in pregnancy: gestational hypertension and preeclampsia. Finally, preeclampsia may be superimposed on underlying chronic hypertension. Obsolete terms, such as pregnancy-induced hypertension (PIH), usually include a mix of disorders, with differing pathophysiology and risks. The literature, ongoing research, and our patients are ill served by their continued use.

Chronic Hypertension

With postponement of childbearing to more advanced age and the epidemic of essential hypertension, often coupled with obesity and insulin-resistance, this is the most rapidly growing cause of hypertension in pregnancy. Though less common than essential hypertension, three forms of secondary hypertension that affect young women are worth specific mention: pheochromocytoma, renovascular hypertension, and primary hyperaldosteronism.[14] Despite its rarity, physicians should have a low threshold for suspecting pheochromocytoma when hypertension is associated with classic symptoms and signs because it may lead to hypertensive crisis during labor. Suspicion of pheochromocytoma should lead to α-adrenoreceptor blockade and confirmatory measurements of catecholamines and their metabolites. Several cases of life-saving surgical management with proper pharmacologic blockade of pheochromocytoma during pregnancy have been

reported.[18] Renovascular hypertension, most likely due to fibromuscular dysplasia or arteritis in women of childbearing age, carries such a high risk of superimposed preeclampsia and poor outcome that it should be corrected before or even during pregnancy if diagnosed. Diagnosis is difficult because usual measurements of circulating elements of the renin-angiotensin system are of little to no diagnostic utility during pregnancy; Doppler ultrasound measurements are often misleading, and radionuclide renal scans are avoided in pregnancy. Further, radiology colleagues often hesitate to perform MRI or interventional procedures, even when indicated. Notwithstanding these obstacles, there are case reports of diagnosis by magnetic resonance angiography and of correction by angioplasty during pregnancy with good outcome.[19] Finally, hypertension due to primary hyperaldosteronism may have a variable and often surprisingly benign course during pregnancy because high levels of progesterone during pregnancy can antagonize mineralocorticoid effects at the aldosterone receptor.[15,20] In these cases, severe hypertension and hypokalemia may be unmasked postpartum.

Importantly, many apparently healthy young women have never had BP measurement or routine medical care. This then conspires with normal gestational vasodilation and relative hypotension to obscure the diagnosis of underlying chronic hypertension, which may then only be recognized later in pregnancy and mistaken for either gestational hypertension or preeclampsia.

Gestational Hypertension

Gestational hypertension is hypertension occurring de novo, usually during the latter half of pregnancy in the absence of proteinuria and other signs or symptoms of preeclampsia and resolving postpartum. Although it may result in severe hypertension requiring treatment, its course is usually more benign than that of preeclampsia. It may recur in subsequent pregnancies and often predicts essential hypertension or, like preeclampsia, increased cardiovascular risk later in life.

Preeclampsia

Preeclampsia is characterized by de novo hypertension, usually during the latter half of pregnancy, though well-characterized cases have been reported as early as 16 weeks. However, it is a multisystem disorder, usually defined by proteinuria (> 300 mg/day) and resolving postpartum. It occurs in approximately 6% of (usually primigravid) pregnancies. Risk factors, listed in Table 39–1, include a family history of preeclampsia, multifetal gestation, diabetes mellitus, renal or autoimmune diseases, and obesity with insulin resistance. In addition, a variety of unrelated genetic abnormalities including mutations of angiotensinogen or nitric oxide synthase genes seem to increase the risk of preeclampsia in some populations. Whereas clinically evident target organ damage characterizes more severe disease, subtle symptoms or laboratory evidence of target organ damage including hyperuricemia, thrombocytopenia, and abnormalities of liver function or coagulation tests are common. Because preeclampsia can have a variable course and explosive clinical evolution,[21] with real risks of maternal morbidity and mortality, one should err toward diagnosing preeclampsia, even in the absence of proteinuria (which can occur later in the evolution of the disorder), when hypertension is accompanied by abdominal pain, neurological symptoms, such as headache or blurred vision, or any evidence of thrombocytopenia or liver function or coagulation abnormalities.[2] Preeclampsia can evolve rapidly to a convulsive and life-threatening phase termed eclampsia. An especially threatening variant of preeclampsia is the HELLP (Hemolysis, Elevated Liver enzymes, Low Platelets) syndrome, which may seem mild in its initial presentation, then evolve over hours to microangiopathic hemolysis, severe thrombocytopenia, and hepatic necrosis with rupture.

Distinguishing preeclampsia from gestational hypertension by the detection of proteinuria and by hemodynamic assessment may be difficult. Obstetricians in the United States typically screen for proteinuria using urine dipsticks, confirming positive (1+) results by 24-hour urine collection (using unspecified methods for quantitation of 24-hour urine protein and a cutoff value of 300 mg). This "gold standard" case definition is based on historical studies of clearly defined cases, before the availability of sensitive and specific methods for assessment of albuminuria or excretion of other specific urine proteins. Many gravidas with proteinuria exceeding this threshold will prove to have no glomerular protein leak; 500 mg/day proteinuria, or some new definition of pathological albuminuria, may better predict morbid maternal and fetal outcomes.[22] Further, the sensitivity of urine dipsticks and their prediction of 24-hour urine protein are poor, due in large part to variations in urine concentration. This limitation may be overcome by efforts to standardize screening techniques on the basis of measurement of albumin-to-creatinine ratios, correction for urine specific gravity, or use of automated point-of-care devices.[23,24] Although proteinuria may occur in synchrony with hypertension in proteinuria, it may be delayed, in some cases by many weeks.[25] This explains why the diagnosis of preeclampsia can only be made with any certainty in retrospect and may also explain the common misconception that gestational hypertension may evolve into preeclampsia. In the future, markers such as sFlt-1 or AT_1 receptor autoantibodies (see later) or convenient, noninvasive hemodynamic measurements may likely allow for a more certain differential diagnosis during pregnancy. We await adequately powered prospective studies that link these

Table 39–1 Risk Factors for Preeclampsia

Primigravida
First pregnancy with this partner
Family history of preeclampsia
Multifetal pregnancy
Preeclampsia in prior pregnancy
IUGR, placental abruption, or fetal demise in prior pregnancy
Obesity
Renal disease of any cause or severity (including microhematuria or microproteinuria without specific etiological diagnosis)
Diabetes mellitus
Chronic hypertension
Connective tissue disease

IUGR, intrauterine growth restriction.

markers to outcomes in women at normal and elevated risk for preeclampsia or superimposed preeclampsia.[26]

Superimposed Preeclampsia

"Pure" preeclampsia complicates approximately 6% of (usually primigravid) pregnancies. It can, in addition, be superimposed on 20% to 40% of pregnancies in women with underlying chronic hypertension or other predisposing medical diseases including even minor renal disease of any cause, such as early diabetic nephropathy, autoimmune disease, or even microscopical hematuria.[27,28] Superimposed preeclampsia is apt to be more severe, with greater risks to mother and fetus, than preeclampsia without predisposing medical disorders, and it is more apt to recur in subsequent pregnancies. Superimposed preeclampsia and progression to more severe hypertension represent the two major risks of chronic hypertension in pregnancy. Often it is difficult to decide when an already-hypertensive or already-proteinuric woman's course has worsened due to the onset of superimposed preeclampsia. Indeed, in a classic study using renal biopsies to verify diagnosis, a nephrologist and obstetrician correctly diagnosed preeclampsia and distinguished it from competing disorders in parous women in only 58% of cases.[29] Because we now believe that sFlt-1 accounts for the typical renal lesion of "glomerular endotheliosis,"[30] we might presume that a study assessing its diagnostic accuracy would demonstrate similar discordance in parous women or in those with underlying disease, though this remains to be determined. Proteinuria in women with pregestational glomerular disease will usually worsen during pregnancy, often to nephrotic levels. We advocate a strategy of close monitoring, repeatedly re-establishing baseline data in order to detect interval changes in BP, proteinuria or albuminuria, symptoms, or blood test results, which might suggest superimposed preeclampsia.

PATHOPHYSIOLOGY OF PREECLAMPSIA AND ECLAMPSIA

Elegant invasive hemodynamic studies of untreated preeclamptic women demonstrate that hypertension in this disorder is due to systemic vasoconstriction associated with decreased cardiac output (CO) and left ventricular filling pressures.[31] Paradoxically, early in pregnancy, CO is increased more in women who subsequently develop either gestational hypertension or preeclampsia than in those who go on to uneventful normotensive pregnancies, although not so reliably as to allow prediction of these disorders. Hemodynamics diverge when hypertension becomes manifest, with further increments of CO (and low systemic vascular resistance, SVR) in women with gestational hypertension and a switch to systemic vasoconstriction and low CO in women with preeclampsia.[32] Preeclampsia is characterized not only by vasoconstrictor hypertension but also by widespread endothelial dysfunction and by evidence of increased oxidative stress. Contemporary literature has focused on larger artery dynamics and on measures of aortic stiffness, revealing marked increments of systolic augmentation index, determined by applanation tonometry, in women with preeclampsia. By contrast, augmentation index is usually negative in normal gravidas and only modestly elevated in gravidas with chronic or gestational hypertension.[33-35]

Preeclampsia decreases glomerular filtration rate (GFR) more than effective renal plasma flow (ERPF), consistent with selective afferent arteriolar renal vasoconstriction, and usually decreases renal uric acid clearance, elevating serum levels above the norms for pregnancy (2.8 to 3.2 mg/dL).[13] The older literature demonstrated striking parallels between the severity of hyperuricemia and either renal biopsy or clinical manifestations of preeclampsia,[36] and more recent studies have revisited the diagnostic and prognostic value of hyperuricemia, demonstrating that uric acid increases progressively before the onset of hypertension in women with preeclampsia and that hyperuricemia predicts fetal morbidity even in the absence of preeclampsia.[37,38] The proteinuria that characterizes preeclampsia is nonselective, with increased excretion of both albumin and nonalbumin proteins. Preeclampsia is the major cause of nephrotic-range proteinuria during pregnancy. The occurrence of edema (which is common even in normal pregnancy) is quite variable in preeclampsia; indeed, many women who present with eclamptic seizures may be free of edema.

Experts have had a longstanding controversy regarding the mechanisms that lead to eclamptic seizures and CNS complications in preeclampsia. Some have viewed these as a form of hypertensive encephalopathy, whereas others have suggested that brain injury is caused by ischemia resulting from local vasoconstriction. The latter view seems best supported by the classic autopsy series of Sheehan and Lynch,[39] which noted hemorrhage and petechiae that are likely the result of focal ischemia. By contrast, more recent studies have used noninvasive Doppler techniques to suggest a role for increased cerebral perfusion pressure in most, but not all, cases.[40] This construct leads to specific therapeutic strategies regarding selection of antihypertensive agents in preeclamptic women because labetalol and magnesium (but not vasodilators) appear to decrease elevated cerebral perfusion pressure in these patients.[41,42]

Because preeclampsia may occur in molar pregnancy (i.e., without a fetus), tends to resolve following delivery of the placenta, and seems uniformly associated with typical defects in placentation when it occurs in primigravid women without underlying risk factors, much attention has been focused on a pathophysiological role of the placenta. The currently held belief is that early abnormalities in trophoblastic invasion and remodeling of spiral arteries may fail to decrease placental resistance appropriately, leading to focal ischemia in the placenta and elaboration of factors that may act on the maternal vasculature to result in preeclampsia. A large body of literature seems to support this construct by demonstrating that experimental uteroplacental hypoperfusion leads to hypertension in pregnant laboratory animals.[43] In preeclamptic women, the placenta elaborates soluble fomesin-like tyrosine kinase-1 (sFlt-1), a soluble receptor for (and functional antagonist of) the growth factors VEGF and PlGF.[17,31] Decreased availability of these growth factors may increase BP and almost certainly leads to proteinuria and the renal biopsy lesion of glomerular endotheliosis, which is typical of preeclampsia. The preeclamptic placenta may also shed soluble endoglin, a TGF-β receptor, which may act in concert with sFlt-1.[44]

Sympathetic outflow is increased in women with preeclampsia, perhaps contributing to hypertension,[45] and preceding the onset of clinically evident disease.[46] Several

studies have also demonstrated changes in angiotensin receptor expression and activity[47] or the occurrence of autoantibodies that activate AT_1 receptors in women with preeclampsia.[17,48] The former report noted the occurrence of (bradykinin) B_2-AT_1 receptor heterodimers in maternal resistance arteries from preeclamptic women; it is conceivable that these abnormal receptors might reveal epitopes, which then lead to agonistic autoantibodies. These autoantibodies, which clear after delivery, may underlie not only vasoconstriction and hypertension, but also oxidative stress (via AT_1 receptor activation of superoxide synthesis by NAD(P)H oxidase) and endothelial dysfunction. The effect of these autoantibodies is inhibited in vitro by angiotensin receptor blockers (ARBs), but use of these agents, along with use of ACE inhibitors, is contraindicated in late pregnancy due to fetal toxicity.[49]

STRATEGIES TO PREVENT PREECLAMPSIA

Meta-analyses of antihypertensive treatment in pregnant women with chronic hypertension agree that BP control per se fails to prevent preeclampsia.[50,51] Likewise, neither salt restriction nor prophylactic diuretics prevents preeclampsia, despite earlier claims to the contrary.[52] Likewise, despite observations of hypocalciuria in preeclamptic women, several large studies of calcium supplementation failed to demonstrate significant prevention of proteinuric hypertension.[53] By contrast, although there was still no effect on the occurrence of preeclampsia, a contemporary randomized trial in 8325 nulliparous women in developing countries showed benefit to women with extremely low dietary calcium by decreasing eclampsia, severe gestational hypertension, and several composite measures of maternal morbidity.[53a]

Among many studies of circulating vasoconstrictor factors in women with preeclampsia, several suggested an imbalance in arachidonic acid metabolism, favoring vasoconstrictor thromboxanes over prostacyclin and leading to many studies of low-dose (60 to 100 mg/day) aspirin. Promising results of many early, small studies have not been confirmed in subsequent well-designed large trials that included > 25,000 women and showed only trivial effects on maternal or fetal outcome or on the occurrence of preeclampsia.[54,55] Additional studies of women at high risk for recurrent or superimposed preeclampsia (see later) also failed to demonstrate meaningful prevention of proteinuric hypertension with aspirin. Although meta-analyses of trials that included > 36,000 women have suggested some benefit (RR 0.81 [0.75 to 0.88]) of aspirin prophylaxis, this conclusion is not supported by any of the larger, well-designed trials included within the meta-analysis and have failed to identify any aspirin-sensitive subgroups of women at risk.[56] For example, in women at moderate risk for preeclampsia, aspirin was without significant effect in any of the 8 trials with > 400 women/study arm. Similarly, a single negative study accounted for 2503 of the 4222 women in the 19 trials included in the meta-analysis of aspirin trials in women at high risk for preeclampsia. It is possible that increased doses or an altered dosing schedule might reveal benefits of antiplatelet therapy, though further large studies seem unlikely.[57]

An extremely controversial literature has suggested that genetic thrombophilias including the factor V Leiden and prothrombin gene mutations may increase the risk of preeclampsia, with studies appearing to either support or refute this association.[58,59] Interestingly, a preliminary report of a large, nonrandomized case series suggested that low-molecular-weight heparin could prevent recurrent preeclampsia, especially early severe disease, in women with these thrombophilias and a history of prior preeclampsia.[60] If confirmed by a properly designed randomized controlled trial, this finding would change practice with regard to screening and secondary prophylaxis of preeclampsia.

On the basis of the increased oxidative stress that characterizes preeclampsia and could account for its vascular abnormalities, several large studies of prophylactic vitamins C and E supplementation have been completed. The first to be reported showed no benefit in 2395 women at high risk for preeclampsia.[61] Of concern, vitamin supplementation appeared to result in more severe and earlier-onset preeclampsia, more severe hypertension, lower birthweight, and increased neonatal morbidity.[61,62] A similarly large and well-designed trial has been completed in Australian nulliparas, again showing no benefit, and an even larger trial is ongoing in the United States.[62]

EVALUATION AND MANAGEMENT OF HYPERTENSION IN PREGNANCY

Evaluation of women with chronic hypertension or with a history of hypertension in a previous pregnancy should begin before conception. Evaluation should focus on the possibility of secondary hypertension, assessment of renal function and hypertensive target organ damage, detecting underlying diabetes or renal disease, and family history of pregnancy complications (Fig. 39–1). Proteinuria, per se, appears to increase pregnancy risk in hypertensive women. In addition, the obstetric history should focus on both maternal and neonatal outcome that includes premature birth, intrauterine growth restriction (IUGR) leading to small-for-gestational-age (SGA) infants, placental abruption, fetal demise, neonatal morbidity and mortality, and the severity and timing of superimposed preeclampsia.

Gestational vasodilation will allow discontinuation of all antihypertensive drugs in most women whose hypertension was well controlled using two or fewer agents before conception. Often, no antihypertensives will be required until later in pregnancy, obviating any concerns regarding drug safety in the first trimester. Women should have a baseline laboratory evaluation that includes urinalysis and urine culture, 24-hour urine for evaluation of creatinine clearance, protein and albumin excretion, comprehensive chemistry panel including measurement of transaminases, uric acid and electrolytes, and CBC with platelets. Most clinicians would repeat these studies each trimester in order to establish a new baseline to aid in the recognition of superimposed preeclampsia, although no prospective studies demonstrate benefit from this strategy. Women should then be seen every 2 to 3 weeks for measurement of BP and urine protein and for fetal assessment as indicated.

Higher-risk, chronic, hypertensive women include those with advanced maternal age, longstanding hypertension or any evidence of target organ damage, diabetes mellitus, renal disease of any cause or severity, any connective tissue disease,

Evaluation prior to conception

Rule out secondary HTN if any clinical suspicion
Screen for target organ damage (TOD)
Determine if absolute need for ACEI/ARB
- change to other med if no compelling indication,
- otherwise continue and stop as soon as pregnancy confirmed

Assess renal function and proteinuria/albuminuria
- Risk increased if pre-pregnancy Screat >1.4 m/dL

Determine if other medical comorbidities or FH that increase pregnancy risk

⇩

Pregnancy confirmed

Stop ACEI/ARB
Routine antenatal care
Evaluation by High-Risk OB specialist if not done already
If no TOD and BP<140/90, taper or D/C antihypertensives
- Consider home BP monitoring, recheck accuracy of home BP device against auscultated BP at each visit

Baseline labs (electrolytes, BUN, Creat, transaminases, uric acid, LDH, 24h urine for CrCl, protein and microalbumin, CBC, platelets)

⇩

After mid-pregnancy

Office visits at least every 2-3 wk
- Measure BP, urine prot/creat or albumin/creat ratio

Repeat baseline labs each trimester
Fetal assessment as indicated

⇩

Recurrent or worsened hypertension (>140/90)

Inpatient evaluation for signs, symptoms or lab evidence of preeclampsia
Assess fetal well-being
(Re-) start antihypertensives for BP>150/100 (lower if underlying target organ damage or nephropathy)
Parenteral antihypertensives as needed to keep BP<160/105 (see Table 39–3)

Figure 39–1 Outline of scheme for evaluation, counseling, and management of women with chronic hypertension who contemplate pregnancy and for management of superimposed preeclampsia (*next page*) should it develop in these women. ACEI, ACE inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; GA, gestational age; GFR, glomerular filtration rate; TOD, target organ damage.

cardiomyopathy, vascular malformation, previous history of fetal or perinatal loss, or worsened hypertension early in pregnancy. These women require closer observation, collaborative care with appropriate subspecialists, and probably tighter BP control to avoid progressive target organ damage during pregnancy. Despite general agreement, no studies have shown benefit of tighter BP control in hypertensive gravidas with renal disease or other underlying medical disorders. Worsened hypertension or suspicion of superimposed preeclampsia will commonly lead to inpatient evaluation in order to assure maternal and fetal well-being, titrate antihypertensive therapy, and decide whether pregnancy may be prolonged safely with close monitoring.

Antihypertensive Therapy Remote from Delivery

With some small differences, the American, Canadian, and Australia–New Zealand consensus statements recognize methyldopa as a preferred antihypertensive with the greatest experience in pregnancy.[2,8,9] It is well tolerated by pregnant women, does not alter uteroplacental or fetal hemodynamics, and has the best long-term follow-up of childhood development following exposure in utero, albeit in an underpowered study.[63] Methyldopa-induced hepatitis is a rare adverse effect, and Coombs-positive hemolytic anemia is rare with short-term treatment, though many women cannot tolerate its common adverse effects of drowsiness or dry mouth. Some concern followed a meta-analysis along with a large retrospective single center report suggesting that other antihypertensive drugs might be superior to methyldopa in limiting perinatal morbidity and mortality.[51,64] However, adequately powered prospective comparative trials are lacking and should be required before abandoning the long clinical experience and consensus support for use of methyldopa in pregnancy.

β-Blockers are also widely used in pregnancy, have been assessed in several randomized trials, and are the subject of a Cochrane meta-analysis.[50] Early preclinical and clinical observations raised concerns of impaired uteroplacental perfusion, fetal growth restriction, and harmful cardiovascular effects on the fetus. Early use of atenolol in one trial led to striking fetal growth restriction, a conclusion supported by several reviews, retrospective series, and meta-analyses.[65-67] However, most prospective studies, focusing on β-blocker use in the third trimester, have shown effective BP control, prevention of more severe hypertension, and an absence of significant adverse effects including bradycardia on the fetus. A large single-center case series has noted superior perinatal outcome with β-blockers (primarily atenolol) compared with other agents (primarily nifedipine or methyldopa).[64] Further, a meta-analysis of several small trials suggested that β-blockers might decrease (and calcium channel blockers increase) the

Clinical diagnosis of preeclampsia
Parenteral antihypertensives as needed to keep BP<160/105 (see Table 39–3)
Magnesium sulfate for eclampsia, or for initial care of severe PE, especially when delivery is imminent
(Adjust dosing when GFR is low)

If GA≥38 wk: Deliver

Deliver if GA<23 wk or ≥34 wk AND any of the following:
- Severe preeclampsia (see Table 39–4)
- Labor or ruptured membranes
- Suspected placental abruption
- Non-reassuring fetal testing
- Severe oligohydramnios or fetal growth restriction

If severe PE at GA 23-32 wk:
- Steroids for fetal lung maturation
- Inpatient care with >daily evaluation of mother and fetus
- Oral antihypertensives (see Table 39–2)
- Plan to deliver at 34 wk

If severe PE at GA 33-34 wk:
- Steroids for fetal lung maturation
- Inpatient evaluation and antihypertensives as above
- Delivery after 48-72 hr

Mild PE at GA <38 wk:
- Inpatient or office management
- Oral antihypertensives for BP >150/100
- Daily BP measurement and assessment for ominous symptoms
- Physical exam, lab evaluation, fetal assessment 2x/wk
- Deliver if worsening maternal or fetal condition, onset of labor, or when GA ≤38 wk

Figure 39–1, cont'd

incidence of proteinuria or superimposed preeclampsia, perhaps by limiting abnormal elevations in cardiac output.[68] The latter preliminary observation should provoke further study rather than a change in practice.[51] Although many older studies focused on agents such as atenolol, the NHBPEP Working Group advocates labetalol (a combined α- and β-blocker) as an alternative to methyldopa, and the Australasian group advocates use of β-blockers with intrinsic sympathomimetic activity, such as oxprenolol (not available in the United States) or pindolol.[8]

Calcium channel blockers, principally extended-release nifedipine, are widely used, apparently safe, and effective in pregnancy.[2] Although data are limited, nifedipine is widely viewed as an acceptable alternative to methyldopa or β-blockers for chronic use during pregnancy.

Hydralazine has been the most commonly used second-line agent (following combinations of those discussed earlier). It is used in combination with either a β-blocker or methyldopa to limit reflex tachycardia. Use of α-adrenergic blockers other than in the setting of suspected pheochromocytoma seems to have little basis. Diuretic use during pregnancy is controversial. Diuretics limit normal gestational volume expansion and can decrease amniotic fluid volume and lead to electrolyte abnormalities. However, they do not seem to impair fetal outcome. Diuretics may be continued if they were crucial to BP control before conception and may be combined with other agents, especially in patients with renal insufficiency, heart disease, or when clinical volume overload is a problem. Diuretics are not used when preeclampsia is suspected because its hemodynamics are characterized by decreased cardiac output and primary systemic vasoconstriction.[12,32]

Increased circulating elements of the renin-angiotensin system during pregnancy and evidence for AT_1 receptor activation in preeclampsia might seem to support use of ACE inhibitors or AT_1 receptor blockers in hypertensive gravidas. These drugs are now widely used for renal protection in young women of childbearing age who have underlying diabetic nephropathy or proteinuric renal disease. They are, however, contraindicated during the latter half of pregnancy due to a specific fetopathy (including renal dysgenesis and calvarial hypoplasia) and the risk of (fatal) neonatal acute renal failure.[49,69,70] ACE inhibitors and AT_1 receptor blockers are often discontinued when pregnancy is planned. However, because they are not teratogenic and all adverse outcomes appear caused by fetal exposure in the second or third trimester, reliable patients who are followed closely can continue these drugs through conception, discontinuing them in the first trimester if pregnancy is detected early. Table 39–2 summarizes those agents most commonly used for chronic BP control in pregnancy.

Antihypertensive Therapy of More Severe Hypertension

Table 39–3 lists the antihypertensives most commonly used for urgent control of severe hypertension late in pregnancy. Hydralazine is used either in small (5- to 10-mg) repeated doses or as a continuous infusion because larger doses or

Table 39–2 Oral Antihypertensives Used Commonly in Pregnancy

Drug (FDA Risk*,†)	Dose	Concerns or Comments
Most Commonly Used First-Line Agents		
Methyldopa (B)	0.5-3.0 g/d in 2-3 divided doses	Preferred agent of the NHBPEP working group; maternal side effects sometimes limit use.
Labetalol (C) or other β-receptor antagonists	200-2400 mg/d in 2-3 divided doses	Labetalol is preferred by the NHBPEP working group as an alternative to methyldopa. Atenolol most commonly used in Canada and β-blockers with intrinsic sympathomimetic activity are preferred by some in Australia. May cause fetal growth restriction when started early.
Nifedipine (C)	30-120 mg/d of a slow-release preparation	Less experience with other calcium entry blockers.
Adjunctive Agents		
Hydralazine (C)	50-300 mg/d in 2-4 divided doses	Few controlled trials, long experience; used only in combination with sympatholytic agent (e.g., methyldopa or a β-blocker) to prevent reflex tachycardia.
Thiazide diuretics (C)	Depends on specific agent	Most studies in normotensive gravidas.
Contraindicated		
ACE inhibitors and AT1 receptor antagonists (D[4])		Use after first trimester can lead to fetopathy; oligohydramnios; growth retardation; and neonatal anuric renal failure, which may be fatal.

*No antihypertensive has been proven safe for use during the first trimester (i.e., FDA Category A).
†U.S. Food and Drug Administration classifies the risk for most agents as C: Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal effects or other) and there are no controlled studies in women, or studies in women and animals are not available. Drugs should only be given if the potential benefit justifies the potential risk to the fetus. This classification is of limited clinical utility since it unfortunately still applies to most drugs used during pregnancy.
NHBPEP, National High Blood Pressure Coordinating Committee.

Table 39–3 Antihypertensives Commonly Used for Urgent BP Control

Drug (FDA Risk*)	Dose and Route	Concerns or Comments†
Hydralazine (C)	5 mg, IV or IM, then 5-10 mg every 20-40 min; or constant infusion of 0.5-10 mg/hr	Preferred by NHBPEP working group. Higher doses or more frequent administration often precipitate maternal or fetal distress, which appear more common than with other agents.
Labetalol (C)	20 mg IV, then 20-80 mg every 20-30 min, up to maximum of 300 mg; or constant infusion of 1-2 mg/min	Probably less risk of tachycardia and arrhythmia than with other vasodilators; likely less BP control than hydralazine.
Nifedipine (C)	5-10 mg PO, repeat in 30 min if necessary, then 10-20 mg every 2-6 hr	Parenteral calcium channel blockers (e.g., nicardipine is a reasonable alternative, but fewer data are available).

*U.S. Food and Drug Administration Class C, as noted in footnote to Table 39–1.
†Adverse effects for all agents, except as noted, may include headache, flushing, nausea, and tachycardia (primarily due to precipitous hypotension and reflex sympathetic activation).

frequent dosing may lead to precipitous maternal hypotension and fetal distress. Parenteral labetalol, by continuous IV infusion or in repeated boluses, has replaced hydralazine at many centers and appears to have similar safety and efficacy, although comparative studies are few and parenteral labetalol may result in less effective BP control.[71,72] Despite its lack of approval by the U.S. Food and Drug Administration for the treatment of hypertension, the NHBPEP Working Group advocates oral (or sublingual) nifedipine as an acceptable alternative to hydralazine or labetalol for urgent BP control during pregnancy.[2] Its efficacy and safety appear similar to the other agents, whereas diazoxide and ketanserin seem inferior.[71] Although most studies have suggested little difference in outcome among patients treated with these three agents, a meta-analysis suggests that hydralazine may be inferior to labetalol or calcium channel blockers because it more often leads to adverse effects including excessive hypotension, fetal distress, oliguria or renal dysfunction, placental abruption, and cesarean delivery due to toxicity.[72] Sodium nitroprusside remains a relatively contraindicated agent of last resort, usually reserved for urgent BP control in the minutes leading up to delivery.[73] Finally, although there have been reports of ACE inhibitor use as salvage therapy during pregnancy,[74] there seems to be no justification for use of these agents or of

angiotensin receptor blockers during the second or third trimester.

Clinical and Adjunctive Management of Preeclampsia

Suspicion of preeclampsia should lead to hospitalization and inpatient evaluation (see Fig. 39–1). Despite common practice, we still do not know if hypertensive gravidas benefit from bedrest.[75] Near to term (>34 weeks), if fetal maturity can be assured, delivery is the preferred and definitive treatment for preeclampsia. Earlier in pregnancy, it may seem desirable to temporize, attempting to control BP; administer glucocorticoids to hasten fetal lung maturation; and monitor laboratory and clinical status closely so as to prolong pregnancy. The obstetric literature on such temporizing strategies often appears confusing and contradictory. Expectant management may result in a few days to, rarely, several weeks of additional fetal maturation; however, such strategies are best reserved to tertiary centers. Regardless of gestational age, any of the ominous signs or symptoms noted in Table 39–4 should lead to immediate delivery. As noted earlier, accelerated hypertension should be treated at systolic levels of > 160 mm Hg or diastolic of > 105 mm Hg (Korotkoff 5) to avoid the cerebrovascular catastrophes that can occur at pressures of ≥170/110. We advocate treatment at these somewhat lower pressures due to increased BP lability and uncertainty in BP measurement in women with preeclampsia. Central nervous system signs or symptoms including even headache or blurred vision should provoke treatment at even lower pressures. Despite findings from invasive hemodynamic studies, there appears to be no benefit from therapeutic volume expansion in addition to BP control.[76]

Parenteral magnesium sulfate has long been favored by North American clinicians for prevention or treatment of eclamptic seizures, which can occur antepartum (38% to 53% of cases), intrapartum (18% to 36% of cases), or postpartum (11% to 36% of cases).[77] Magnesium is more effective than either phenytoin or diazepam in preventing recurrent seizures in women with eclampsia.[78,79] Several primary prevention trials in women with preeclampsia including a placebo-controlled, double-blind study in more than 10,000 women, demonstrated the efficacy of magnesium, without significant short-term adverse effects to mother or baby.[77,80] It remains unclear, however, which women with preeclampsia should be offered magnesium and for how long. In most centers, treatment usually entails a loading dose of 4 to 6 g $MgSO_4$ (infused over 10 minutes, never as a bolus), followed by continuous infusion of 1 to 2 g/hour to achieve plasma levels of 5 to 9 mg/dL. Magnesium is then usually continued until the patient stabilizes or for 24 hours following delivery. Lower doses should be used, without continuous infusion, guided by serum levels, in women with any degree of renal insufficiency because magnesium is excreted renally. Finally, a vial of calcium gluconate should always be kept at the bedside in case of magnesium toxicity.

Table 39–4 Ominous Signs and Symptoms in Preeclampsia Suggesting Prompt Delivery

Inability to control BP (systolic < 160 mm Hg or diastolic < 105)
Any evidence of acute renal failure or progressive oliguria
Falling platelets or thrombocytopenia < 10^5/mm^3
Any evidence of microangiopathic hemolysis or coagulopathy
Upper abdominal (epigastric or right upper quadrant) pain
Headache, visual disturbance, or any CNS signs
Retinal hemorrhage or papilledema
Acute congestive heart failure or pulmonary edema

Overall, our clinical approach to evaluation, management, and treatment of pregnant women with underlying hypertension is in accord with recommendations made by the NHBPEP Working Group (see Fig. 39–1).[2] Our key objectives, to be carried out in close coordination with experienced high-risk obstetric colleagues, are to achieve BP control adequate to assure maternal safety; carefully and serially monitor maternal BP, well-being, and laboratory data in order to assist early recognition of superimposed preeclampsia; and proceed to expeditious delivery (±magnesium prophylaxis) in the face of preeclampsia or accelerated hypertension when it presents a threat to maternal safety.

Postpartum Antihypertensive Therapy in Nursing Mothers

Despite a clear understanding of the pharmacokinetic principles governing drug distribution to milk and delivery to the infant,[81] there are few well-designed studies assessing neonatal effects of administered antihypertensive drugs in nursing mothers. However, this field has been summarized thoughtfully in a current review.[82] Factors that favor drug passage into milk are a small maternal volume of distribution, low plasma protein binding, high lipid solubility, and lack of charge at physiological pH. Even when drugs are ingested by nursing infants, effective infant exposure depends on the volume of milk ingested, intervals between drug administration and nursing, oral bioavailability (in the infant), and the capacity of the infant to clear the drug.

Neonatal exposure to methyldopa, propranolol, or labetalol appears low and is considered safe. Similarly, calcium channel blockers, although transferred into milk, appear to be safe for nursing infants. By contrast, atenolol and metoprolol are concentrated in breast milk. Diuretics are believed to decrease milk production so as to interfere with nursing, though convincing studies are lacking. Due to concerns regarding effects of ACE inhibitors and AT_1 receptor antagonists on neonatal renal function, these drugs are usually avoided, especially in very premature infants. However, milk concentrations of captopril are undetectable, suggesting use of this agent when an ACE inhibitor is required.[83]

Management of Hypertension in Children and Adolescents

Bonita Falkner

CHAPTER CONTENTS

INTRODUCTION

Hypertension can occur at any phase of childhood, from the newborn period through adolescence. Hypertension in childhood is defined differently than in adulthood and occurs less frequently than in adults. The underlying causes of hypertension are identified more frequently in children than in adults. Childhood hypertension also has some striking similarities to hypertension in adults. Severe, untreated hypertension in children has as poor an outcome as it does in adults.[1] Children with essential hypertension can have the same risk factors for cardiovascular disease as adults; and children with hypertension can benefit from interventions to control the blood pressure (BP). The diagnosis of hypertension requires BP measurements, systolic or diastolic, or both, that are consistently equal to or above the 95th percentile for age, sex, and height.[2] With this statistical definition, the prevalence of hypertension is expected to be 1% to 5%. As more attention is given to evaluating BP in children during routine health care visits, and as a result of the rising rates of childhood obesity, more cases of hypertension in the young are being identified. An important aspect in the management of high BP in the young is to determine when elevated BP is a sign of an underlying disease, as with secondary hypertension; and when elevated BP in childhood is an early expression of primary (essential) hypertension.

DEFINITION OF HYPERTENSION IN CHILDHOOD

- Normotension: Systolic and diastolic BP <90th percentile.
- Prehypertension: Systolic or diastolic BP >90th percentile and <95th percentile (for adolescents >120/80 mm Hg and <95 percentile).
- Stage 1 hypertension: Systolic or diastolic BP, or both, between the 95th percentile and 5 mm Hg above the 99th percentile.
- Stage 2 hypertension: Systolic or diastolic BP, or both, >5 mm Hg above the 99th percentile.

The definition of hypertension in adults is based on the level of BP that is linked with an increase in risk for cardiovascular events. Although the risk for cardiovascular events in adults increases as BP rises above 115/75 mm Hg,[3] hypertension continues to be defined as BP that exceeds 140/90 mm Hg, regardless of age or gender. However, in children, with the exception of extreme hypertension as noted earlier, no data have linked a level of BP with subsequent cardiovascular events. In the absence of such data, hypertension is defined statistically. The results of several large epidemiologic studies that measured BP in healthy children[2,4-6] provide data from which the normal distribution of BP in healthy children and adolescents in the United States has been established.[2] An analysis of BP data on healthy children in Europe describes a similar BP distribution pattern.[7,8]

A progressive rise in BP occurs with increasing age throughout childhood concurrent with the normal age-related increase in height and weight. Thus, there is a consistent relationship of BP with body size in childhood; and there is a normal upward shift in BP with growth. A gender difference in BP distribution emerges in adolescence that is concurrent with a gender difference in height.

The definition of hypertension in children delineates the top segment of the normal BP distribution at each childhood age.[2,4] With the expansion of the epidemiologic data and with further analysis of the growth-related determinants of BP in childhood, the 95th percentile is further adjusted for height.[2,6] The present definition of hypertension in children and adolescents is systolic or diastolic BP that, on repeated measurement, is equal to or greater than the 95th percentile for age, sex, and height. The severity of hypertension is also defined according to the degree of BP elevation. Table 40–1 provides the level of BP for the 90th, 95th, and 99th percentiles for age, sex, and height percentile for boys, and Table 40–2 provides the same percentile levels for girls.[2] In each table the 50th percentile for systolic and diastolic BP is also provided to denote the midpoint of the BP distribution.

Table 40–1 Blood Pressure Levels for Boys by Age and Height Percentiles

BP, blood pressure.

MEASUREMENT OF BLOOD PRESSURE IN THE YOUNG

Measurement of BP in children and adolescents should be performed in a standardized manner that is similar to the methods used in developing BP tables. In the ambulatory clinic setting the preferred method for BP measurement in children is by auscultation with a standard sphygmomanometer. Detailed guidelines for BP measurement in the young have been published.[2,9] Correct BP measurement in children requires the use of a cuff that is appropriate for the size of the child's upper arm. A cuff that has a bladder width approximately 40% of the arm circumference midway between the olecranon and the acromion should be selected because it usually covers 80% to 100% of the arm's circumference. Most manufacturers of BP cuffs provide lines on the cuff that are useful in choosing the correct cuff size for a given child. The equipment necessary to measure BP in children 3 years of age through adolescence includes three pediatric cuffs of different size, as well as a standard adult cuff, an oversized cuff, and a thigh cuff for leg BP measurement. The latter two cuffs may be necessary for use in obese adolescents.

BP measurement in children should be conducted in a quiet and comfortable environment after 3 to 5 minutes of rest according to a procedure similar to that described for adults.[9] With the exception of acute illness, the BP should be measured with the child in the seated position with the cubital fossa supported at heart level. The child should have his or her feet on the floor while the BP is measured, rather than dangling the feet from an examination table. Overinflation of the cuff should be avoided due to discomfort, particularly in younger children. The BP should be measured and recorded at least twice on each occasion. The disappearance of Korotkoff sounds or fifth Korotkoff sound (K5) is the definition of diastolic pressure in adults. In children, particularly preadolescents, a difference of several mm Hg is frequently present between the fourth Korotkoff sound, the muffling of Korotkoff sounds, and K5.[10] Normative BP data in children indicate that K5 can be used as the measure of diastolic BP in children, as well as adults. When there is a large gap between K4 and K5, both numbers should be recorded.

The BP level in a child is interpreted by comparing the child's measured BP with the BP tables. Precise interpretation requires plotting the BP according to the child's height percentile, as well as age and sex. The child's height is measured and plotted on the standard child growth curves. The height percentile is used in the tables, wherein the BP level for the 90th and 95th percentiles at the child's age, sex, and height percentile are compared with the child's measured BP. Tables 40–1 and 40–2, which contain the BP levels for the 50th, 90th, 95th, and 99th percentiles according to sex, age, and height, are from the Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents,[2] (*www.nhlbi.nih.gov/guidelines/hypertension/child_tbl.htm*). A program can be downloaded from this site to provide a classification of a child's BP status when his or her sex, age, height, and BP are entered.

Elevated BP measurements in a child or adolescent must be confirmed on repeated visits before making the diagnosis of hypertension. An average of multiple BP measurements taken over weeks or months provides a more accurate characterization of an individual's BP level. Population standards for ambulatory BP monitoring (ABPM) over a 24-hour period in children and adolescents are now available,[11] and ABPM BP data can be helpful in making clinical decisions in these patients.[12] ABPM can be used to detect "white coat hypertension," determine the need for pharmacologic therapy, and assess the effectiveness of therapeutic interventions. When ABPM is used in children or adolescents, the appropriate cuff size should be used and the appropriate childhood BP cutpoints should be used for interpretation of the results.

CAUSES OF HYPERTENSION IN THE YOUNG

The management strategies for hypertension in a child or adolescent are determined by the underlying cause of the hypertension—that is, whether the hypertension is primary (or essential) or whether the hypertension is secondary to some other cause. If the hypertension is secondary, the management will be determined by the underlying disorder that is causing high BP. For example, the management of a child with hypertension secondary to chronic glomerulonephritis would be antihypertensive medication that would lower BP and also possibly confer renal protection. Alternatively, the management for a child with hypertension secondary to hyperthyroidism would be to correct the hyperthyroidism, as well as control the BP with antihypertensive medication until the child is euthyroid.

Secondary Hypertension

Although hypertension is, overall, less prevalent in children than adults, hypertension that is secondary to an underlying renal or endocrine disorder is more frequently found in hypertensive children than in hypertensive adults. The prevalence of secondary hypertension in the young varies according to the age and severity of hypertension. Hanna et al.[13] identified a secondary cause of hypertension in 90% of children younger than 10 years of age; only 10% of these young children were considered to have essential hypertension. A report on a series that included both children and adolescents with hypertension describes secondary hypertension in 65% of the adolescents, with 35% of the adolescents having essential hypertension.[14] With the increase in attention to BP levels in the young, along with the rising rates of childhood obesity, the proportion of children and adolescents with essential hypertension is increasing.

Young children, younger than 12 years of age, with sustained hypertension are more likely to have a secondary cause for the hypertension. The degree of hypertension is also an important clue, as severe BP elevation in a young child is most likely to be due to an underlying abnormality. Children and adolescents with stage 2 hypertension should have a thorough evaluation for possible causes of the hypertension and for evidence of target organ damage. Although the list of conditions that can cause hypertension in the young is long, the majority of the identifiable causes of hypertension in the young are related to renal disorders. Table 40–3 provides a list of underlying causes for chronic hypertension in the young, as well as the conditions associated with acute hypertension in the young.

For children up to 10 years of age, the leading causes of hypertension are renal parenchymal diseases, coarctation of the aorta, and renal artery stenosis. Coarctation of the aorta, a congenital cardiac anomaly that can be missed in infants and toddlers, should be considered in a hypertensive child.[15-17] The disorders that cause acute hypertension include postinfectious glomerulonephritis and hemolytic uremic syndrome. Some conditions, such as hemolytic uremic syndrome, may cause permanent renal scarring that results in chronic hypertension.

The secondary causes of hypertension that are detected most frequently in adolescents are renal parenchymal diseases, such as chronic pyelonephritis, focal segmental glomerulosclerosis (FSGS), and other types of chronic glomerulonephritis. Adolescent behaviors that may contribute to high BP are use of illicit substances, especially cocaine and amphetamine-related compounds.[18,19] Other substances that have been associated with high BP in adolescents include appetite suppressants (both prescription and over the counter), oral contraceptives, excessive alcohol intake, and use of anabolic steroids for body building.[20]

Essential Hypertension

Essential hypertension has traditionally been considered a disorder of older adults. However, the concept that essential hypertension has its roots in childhood can be inferred from BP tracking data, which demonstrate that children with elevated BP will continue to have elevated BP as adults.[6] Evidence of target organ injury is detectable in children and adolescents with essential hypertension, even with mild degrees of BP elevation. Using echocardiography and appropriate childhood reference values for cardiac structure, left ventricular hypertrophy (LVH) has been reported in 30% to 40% of children and adolescents with hypertension.[21,22] Available longitudinal data support a direct link between risk factors in childhood including BP level, with evidence of target organ injury including greater intima-media thickness of carotid arteries.[21,23,24] Therefore, essential hypertension in childhood should be considered an early phase of a chronic disease.

Children and adolescents with essential hypertension generally demonstrate several clinical characteristics or asso-

Table 40–3 Secondary Causes of Hypertension

Chronic Hypertension	
Renal	**Drugs**
Chronic glomerulonephritis	Corticosteroids
Interstitial nephritis	Alcohol
Collagen vascular diseases	Appetite suppressants
Reflux nephropathy	Anabolic steroids
Polycystic kidney disease	Oral contraceptives
Medullary cystic disease	Nicotine
Hydronephrosis	**Syndromes**
Hypoplastic/dysplastic kidney	Alport
Cardiac and Vascular	Williams (renovascular lesions)
Coarctation of aorta	Turner (coarctation or renovascular)
Renal artery stenosis	Tuberous sclerosis (cystic renal)
Takayasu arteritis	Neurofibromatosis (renovascular)
Endocrine	Adrenogenital
Hyperthyroidism	Little
Pheochromocytoma	
Primary aldosteronism	
Acute Hypertension	
Renal	**Drugs**
Postinfectious glomerulonephritis	Cocaine
Schönlein-Henoch purpura	Phencyclidine
Hemolytic uremic syndrome	Amphetamines
Acute tubular necrosis	Jimson weed
Vascular	**Miscellaneous**
Renal or renal vascular trauma	Burns
Neurogenic	Orthopedic surgery
Increased intracranial pressure	Urologic surgery
Guillain-Barré syndrome	

ciated risk factors. The degree of BP elevation is generally mild, approximating the 95th percentile, and there is often considerable variability in BP over time. A consistent clinical observation in children exhibiting mild essential hypertension is a positive history of hypertension in parents or grandparents, or both.[25-27]

In both children and adults, greater body weight and increases in body weight correlate with higher BP.[28] Essential hypertension in children is frequently associated with obesity, which appears to be a contributory factor because even a modest reduction in excess adiposity is often associated with a reduction in BP.[29,30] The cluster of modest BP elevation, positive family history of hypertension, and obesity is a typical pattern in children and adolescents with essential hypertension.[31]

The prevalence of childhood obesity is increasing,[32] having more than doubled in the past 20 years.[33] An analysis of two separate sets of data from the National Health and Nutrition Examination Survey demonstrated a small but statistically significant increase in the childhood BP level that is largely due to the concurrent increase in obesity.[34] Obesity has an adverse effect on risk for cardiovascular disease and warrants attention for disease prevention and health promotion. Marked BP sensitivity to sodium intake has been demonstrated in obese adolescents, with a significant dampening in the BP response to sodium following weight reduction.[29,30] LVH can be detected in up to 40% of obese children with high BP.[35]

The term *metabolic syndrome,* or *insulin-resistance syndrome,* has been applied to the condition in which high BP, non–insulin-dependent diabetes mellitus or prediabetes, atherosclerosis, and obesity coexist (see Chapter 38). The metabolic syndrome is associated with marked increases in risk for cardiovascular events in individuals and in populations.[36] Children and adults may exhibit characteristics of the metabolic syndrome.[37-39] Some investigators have detected the metabolic syndrome in nonobese offspring of hypertensive parents,[40,41] indicating a hereditary component of the syndrome. The characteristics of the metabolic syndrome are also congruent with the overweight child having a strong family history of hypertension or early heart disease and stage 1 hypertension.[42] Although these children are not at risk for immediate adverse effects of the higher than normal BP, they should be considered at high risk for future cardiovascular disease.[43] They can benefit from behavioral changes that improve insulin action including an increase in physical activity, diet modifications, and control of excess adiposity.

EVALUATION OF HYPERTENSION IN CHILDREN AND ADOLESCENTS

- Evaluate for identifiable cause
- Evaluate for comorbidities
- Evaluate for target organ damage

When sustained hypertension is established in a child by repeated BP measurements that are at or above the 95th percentile, additional evaluation is necessary. The extent of the

diagnostic evaluation is determined by the type of hypertension that is suspected. When a secondary cause is considered, more extensive evaluation may be necessary. On the other hand, when the patient's elevated BP is more likely to be an early expression of essential hypertension, a few diagnostic screening studies may be sufficient. Children or adolescents with severe hypertension, particularly young children, generally have an identifiable underlying cause. The recommendations for evaluation of hypertension in children now include (1) evaluation for an identifiable cause; (2) evaluation for comorbidity; and (3) evaluation for target organ damage.[2]

The medical history and physical examination are basic tools in determining whether the characteristics of a patient's presentation indicate essential hypertension or reflect a secondary, and potentially correctable, cause. A particular symptom complex revealed in the history or findings on physical examination may also prompt a thorough investigation. Any pediatric patient who is hypertensive and is not growing normally should undergo an evaluation for secondary causes. A sudden onset of elevated BP in a previously normotensive child should always prompt a search for secondary causes. Absence of a positive family history of hypertension should increase the level of suspicion for an underlying disorder. A general rule is: The younger the child and the higher the BP, the more likely there will be a secondary cause of the hypertension.

Children and adolescents with essential hypertension generally have modest elevations in BP, a strong family history of essential hypertension, elevated resting heart rate, variable BP readings on repeated measurement, and obesity. If no other abnormalities are found on history or physical examination, these children require less extensive evaluation for an underlying disorder than those in whom secondary causes are suspected. However, children with early expression of essential hypertension, particularly those who are obese, may have associated comorbidities including dyslipidemia, sleep apnea, and prediabetes. These comorbidities deserve treatment because they contribute to cardiovascular disease risk.

Medical History

The medical history and physical examination are used to detect clues to determine if the BP elevation is secondary or primary and long-standing or of acute onset. The family history is particularly important. A history of essential hypertension, myocardial infarction, stroke, renal disease, diabetes, and obesity should be sought in both first- and second-degree relatives. Early onset of any of these conditions in relatives is relevant to the diagnostic evaluation of a hypertensive child. Parents should be asked about family history of heritable conditions that have hypertension as a component (e.g., polycystic kidney disease, neurofibromatosis, pheochromocytoma). Another familial type of hypertension is glucocorticoid-remediable aldosteronism, an autosomal dominant condition that should be considered when multiple family members have early-onset hypertension associated with hypokalemia or stroke.[44,45]

Details about previous health problems, such as history of urinary tract infections, is important, because there may be associated reflux nephropathy, renal scarring, and resultant hypertension. A history of medications and over-the-counter products used can be helpful.[46,47] Information should be obtained about health-related behaviors, such as usual diet, amount of physical activity or athletic participation. Use of "street" drugs, smokeless tobacco, oral contraceptive pills, cigarette smoking, diet aids, ethanol, and anabolic steroids should be queried in adolescents.

Physical Examination

The physical examination of a hypertensive child should include an assessment of the child's growth rate and body size. Weight, height, and body mass index (BMI) should be plotted according to age and sex on the child growth charts. Abnormalities in growth associated with hypertension can be seen with chronic renal disease; hyperthyroidism (causing primarily systolic hypertension); pheochromocytoma; adrenal disorders; or certain genetic abnormalities, such as Turner syndrome.

To rule out coarctation of the aorta, the BP should be measured in the leg with an appropriately sized cuff. Normally the BP level measured in the leg is slightly higher than the arm BP. A child with coarctation will have systolic hypertension in an upper extremity, sometimes absent or decreased femoral pulses, and a leg BP that is lower by 10 mm Hg or more than the BP level in the arm.[15,17]

Other physical clues to a secondary etiology for child hypertension include abnormal facies or dysmorphic features, which may suggest a variety of syndromes.[48] For example, both Turner and Williams syndromes are associated with renovascular or cardiac lesions that cause hypertension. Renal vascular lesions may cause audible abdominal bruits. Skin lesions are sometimes the first manifestations of disorders, such as tuberous sclerosis and systemic lupus erythematosus. Acanthosis nigricans in overweight children may be a sign of abnormal glucose tolerance.

Diagnostic Testing

When the history and physical examination provide clues for a specific underlying cause for the hypertension, subsequent testing should be directed to the area of clinical suspicion. In the absence of specific clues, renal parenchymal disease should be considered because it is the most frequent cause of secondary hypertension in the pediatric population. Screening studies for renal abnormalities include urinalysis, electrolytes, creatinine, complete blood count, urine culture, and renal ultrasound. Evaluation for comorbidity includes fasting plasma lipids for dyslipidemia; a sleep history for sleep apnea; and, if there is a positive family history of diabetes, a glucose tolerance test.

The evaluation also includes an assessment of target organ injury. The presence of target organ injury provides a measure of chronicity and severity (characteristics sometimes difficult to ascertain from the history) and will aid in deciding whether pharmacologic therapy should be instituted. Chest x-ray and ECG are not sufficiently sensitive to detect LVH in children and adolescents; echocardiography is a sensitive means of quantifying left ventricular mass (LVM) and detecting interventricular septal and posterior ventricular wall thickening. To adjust for differences in body size, echocardiographic measurements of LVM must be indexed to some body size measurement, such as height, weight, or body mass index. Height in meters ($m^{2.7}$) is the recommended measurement for

adjustment of echo-measured LVM to derive a left ventricular mass index (LVMI). LVMI >51 g/m$^{2.7}$ is the adult criterion for LVH. Using this criterion, one study found that 15.5% of hypertensive children have LVH.[35] However, as with BP level, the adult criteria for categorical classification are not appropriate for children and adolescents. The 95th percentile for LVMI in children and adolescents (based on normative data) is 36.88 g/m$^{2.7}$ for females and 39.36 g/m$^{2.7}$ for males.[49] When the 95th percentile for LVMI was used as the criteria for LVH in a multicenter study of hypertensive children, 41.1% of the children had LVH. In addition, LVH was detected more frequently among those who were obese. For clinical purposes, LVMI above 40 g/m$^{2.7}$ may be considered evidence of target organ damage in a child or adolescent with hypertension.

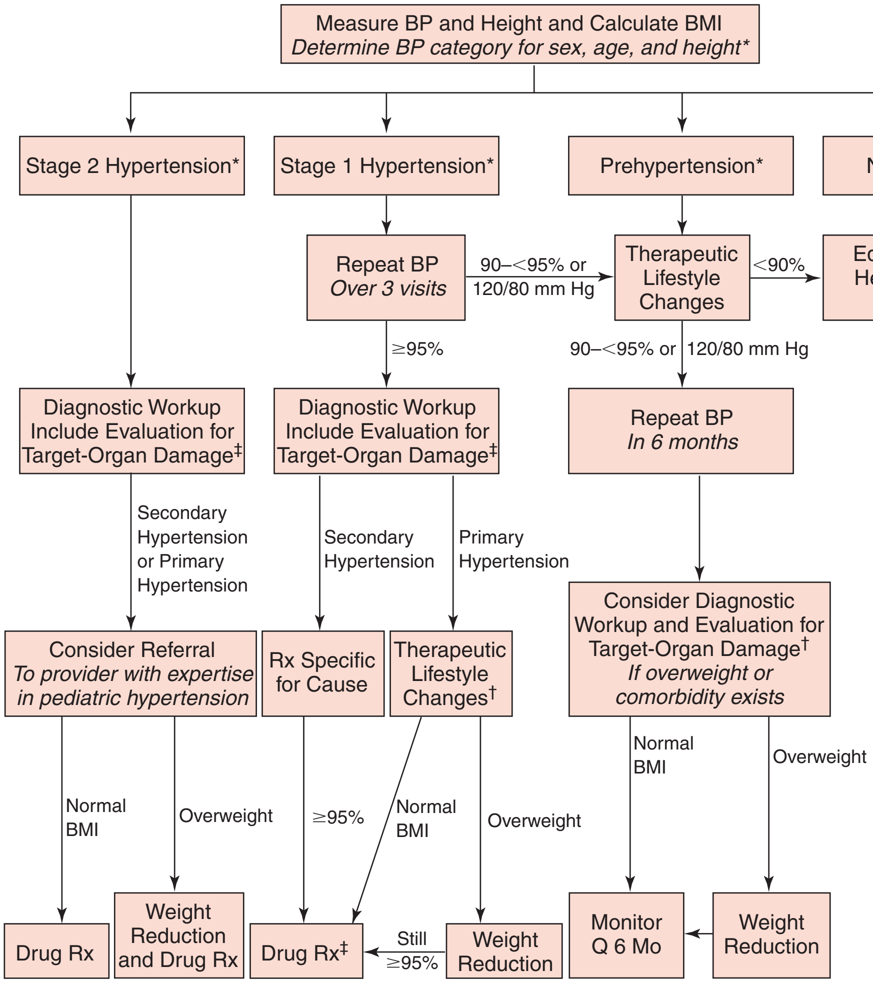
An ophthalmologic examination of retinal vessels may also be helpful in detecting signs of hypertensive vascular injury.[50] The usefulness of microalbuminuria, sometimes used as a marker for renal injury in adults,[51] has not been determined for children. The remainder of the evaluation should be directed by specific findings on history and physical examination, as well as results of initial screening studies. Laboratory or ultrasound abnormalities that suggest underlying renal disease will require more specific diagnostic testing. Electrolyte abnormalities may point to a need for further plasma renin and aldosterone testing and imaging studies.

MANAGEMENT OF HYPERTENSION IN CHILDREN AND ADOLESCENTS

An algorithm for the evaluation and treatment of hypertension in the young is provided in Figure 40–1. The algorithm takes into account the age of the child, severity of the hypertension, and presence or absence of obesity.

Normotensive

No intervention is necessary. The BP should be remeasured at the next scheduled physical examination. The child and his or her parent should be encouraged to maintain or develop healthy lifestyles including appropriate levels of physical activity, heart-healthy diets, and avoidance of excessive weight gain.



BMI, body mass index; BP, blood pressure; Rx, prescription; Q, every.

†Diet modification and physical activity.
‡Especially if younger, very high BP, little or no family history, diabetic, or other risk factors.

Figure 40–1 Evaluation and treatment of hypertension in the young.

Prehypertensive

Pediatric patients with prehypertension should have their BP rechecked in 6 months. Therapeutic lifestyle changes (TLCs) are appropriate and may lower BP or reduce further rise in BP. The major components of TLCs—physical activity, diet modification, and weight control—should be strongly encouraged, particularly when the prehypertensive child is also obese. Further evaluation for comorbidity and target organ damage may be indicated in some children with prehypertension. A pediatric patient with prehypertension and obesity already has two components of the metabolic syndrome and should be evaluated for other comorbidities including abnormal levels of plasma lipids. An obese prehypertensive child with a strong family history of type 2 diabetes or acanthosis nigricans should also have an evaluation of glucose metabolism. When multiple risk factors are detected in an obese prehypertensive child, an echocardiogram can be helpful in determining further management. Children with chronic renal disease or diabetes mellitus, both types 1 and 2, who have BP levels in the prehypertensive range and are not responsive to TLCs should receive pharmacologic therapy sufficient to reduce their BP to below the 90th percentile for renal protection benefits. In the absence of obesity, other risk factors, or chronic disease, children and adolescents with prehypertension should have their BP monitored every 6 months along with TLCs.

Stage 1 Hypertension

BP measurement should be repeated to confirm the diagnosis of hypertension within 1 to 2 months. When stage 1 hypertension is verified, a diagnostic evaluation should be performed. It should include an evaluation for comorbidities and target organ damage, as well as identifiable cause. If the evaluation detects an underlying cause of the hypertension, such as renal disease, coarctation of the aorta, or endocrine disorder, further management involves treatment of the underlying cause and controlling the BP. TLCs are appropriate and should be included in the management of stage 1 secondary hypertension, but most patients will also require pharmacologic treatment to control BP to a level that is below the 90th percentile. When no underlying cause for the hypertension is identified and the hypertension is presumed to be primary, initial therapy should focus on TLCs, particularly if the child is obese. Pharmacologic therapy is indicated in stage 1 primary hypertension if the child is symptomatic, has evidence of target organ damage, or has persistent hypertension despite TLCs.

Stage 2 Hypertension

Evaluation should begin in pediatric patients with stage 2 hypertension within a week of diagnosis (sooner if symptomatic). Children, especially the very young, with this degree of hypertension are likely to have secondary hypertension. Some children with stage 2 hypertension may benefit from referral to consultants with expertise in pediatric hypertension. Pediatric patients with stage 2 hypertension will require pharmacologic therapy for BP control, as well as management of the underlying cause if the hypertension is found to be secondary. Some adolescents with stage 2 hypertension may have primary hypertension, particularly if they are also obese. Although drug therapy is required, efforts to achieve weight reduction are also important for obese adolescents with stage 2 hypertension.

ANTIHYPERTENSIVE TREATMENTS FOR CHILDREN AND ADOLESCENTS

Therapeutic Lifestyle Changes

Health-related behavior changes in diet, physical activity, and weight control improve BP control in children, as well as adults. These TLCs are appropriate as a first step in treatment of children and adolescents with stage 1 hypertension who do not have evidence of target organ damage. TLCs may also provide some benefit in preventing a further rise in BP among children with prehypertension.

Obesity is often associated with stage 1 hypertension in childhood, and weight reduction has benefit in obese children. Using a program of both behavior modification and parental involvement, Brownell et al.[52] showed that weight loss in obese adolescents was associated with a significant decrease in BP. Exercise training also lowers BP in school-aged children and adolescents.[53-55] Rocchini et al.[29] showed that a program including both caloric restriction and exercise produced a decrease in BP, as well as a reversal of structural changes in forearm resistance vessels. Weight reduction can be extremely difficult and generally requires multiple strategies that include the input of a nutritionist, dietary education, emotional support, information about exercise, and family involvement.

Increasing physical activity is an important component of TLC. Reversing sedentary behavior should be strongly encouraged through whatever method is most appealing or acceptable to a given child. The methods may include sports participation, exercise plans or workouts, dance classes, or even nonathletic activities. Particularly among girls, there tends to be a decline in leisure-time activity from preadolescence to late adolescence, and the decline in physical activity is associated with greater weight gain and higher body mass index among those who decrease physical activity compared with adolescents who remain physically active.[56] The only form of exercise that should be discouraged in hypertensive adolescents is power weight lifting, due to its potential to induce marked BP elevation during the lifting of excessively heavy weights. Participation in other sports should be encouraged as long as BP is under reasonable control, regular monitoring of BP occurs, and a thorough examination has been conducted to exclude cardiac conditions.[20]

The guidelines for dietary modification in the pediatric population are less clear than in adults. Information on the effects of salt on BP in children is not as definitive as in adults. There does seem to be a subset of adolescents, particularly those who are obese, who demonstrate BP sensitivity to salt, as well as other risk factors for hypertension.[30] Because the usual dietary intake of sodium for most children and adolescents in the United States exceeds nutrient requirements, it is reasonable to restrict sodium intake to less than 4 g/d by decreasing consumption of processed foods and fast-foods and refraining from adding salt to cooked foods.[57]

Data on the effects of potassium and calcium intake on BP in children are even less definitive. The Dietary Approaches to

Stop Hypertension (DASH) trial, which was conducted in adults with stage 1 hypertension or prehypertension, reported results that could be relevant to diet benefits in children. DASH demonstrated a significant reduction in both systolic and diastolic BP in subjects consuming a diet high in fruits, vegetables, and low-fat dairy products compared with the subjects consuming the usual American diet, indicating that a combination of multiple nutrients from diets that are high in potassium, calcium, magnesium, and other vitamins have a beneficial effect on BP.[58] A similar benefit may occur in children, particularly as secular changes in diet patterns and food sources are trending away from the DASH-style diet. Practical recommendations for diet changes in children and adolescents include (1) increase intake of fruits and vegetables to five servings a day; (2) reduce intake of processed foods; and (3) eliminate sugar-containing drinks including sodas and fruit juices.

Pharmacologic Therapy

Pharmacologic therapy is indicated if nonpharmacologic approaches are unsuccessful or when a child is symptomatic, has severe hypertension, or target organ damage. Children with diabetes mellitus or chronic renal disease may achieve renal protective benefits from BP reduction with medication. For children with these disorders it is reasonable to use pharmacologic therapy to lower BP to a level that is below the 90th percentile for age, sex, and height.

Most of the medications used for adults can be used for children. However, efficacy data, as well as long-term safety data, are limited for the pediatric population. The choice of antihypertensive medication should be individualized and depends on the child's age, etiology of the hypertension, degree of BP elevation, adverse effects, and concomitant medical conditions. In most patients therapy is begun with a single agent. The dose is titrated upward until control of the BP is attained. BP control, in most instances, is defined as maintaining systolic and diastolic pressure below the 90th percentile. If control cannot be achieved using the maximum dose of a single agent, a second medication can be added or, alternatively, another agent from a different class selected. The more commonly used medications for chronic antihypertensive therapy in children are listed in Table 40–4 and those for use in acute, hypertensive emergencies in Table 40–5. The dosing recommendations for children are based largely on practitioner experience, not on large, multicenter trials. Some clinical trial work in children is now being conducted using medications that are approved and commonly prescribed for hypertension in adults. This information will provide more information on efficacy, safety, and dosing in children.

β-Adrenergic blockers are good choices in some nonasthmatic children but may not be well tolerated by athletes in whom exercise capacity could be decreased. More frequently, first-line medications are either angiotensin-converting enzyme (ACE) inhibitors or calcium-channel blockers (CCBs). ACE inhibitors rarely cause side effects (e.g., cough, rash, neutropenia) in children and are usually well tolerated. Many formulations have the advantage of once-a-day dosing. They are effective in controlling BP and may have beneficial effects on renal, cardiac, and peripheral vascular (endothelial) function.[59] Importantly, children with diabetes or chronic kidney disease may be at special risk for progressive deterioration of renal function and may benefit from ACE inhibitors.[60,61] Because of their vasodilator effects on the efferent arteriole, ACE inhibitors can severely reduce glomerular filtration and therefore their use should be accompanied by regular monitoring of renal function in patients with renal artery stenosis, a solitary kidney, or a transplanted kidney.[62] ACE inhibitors are contraindicated during pregnancy because of teratogenic effects on the lungs, kidneys, and brain of the fetus.[63] These agents should be used only after thorough discussion of the risks in adolescent girls who may be sexually active. Angiotensin receptor blockers (ARBs) also interact with the renin-angiotensin system and have benefits similar to the ACEs. Some experience is now being developed with these agents in treatment of children with hypertension.

Several of the CCBs are being used in children as initial therapy or as the second or third medication when more than one drug is necessary to control BP. As with most of the oral antihypertensive preparations, the appropriate dose for small children is often lower than the strength of available tablets, which makes initial dose determinations challenging. When CCBs are necessary for BP control in chronic hypertension, long-acting preparations are preferred, provided that the correct dosage preparation can be used.

Diuretics are generally recommended as initial drug therapy for uncomplicated hypertension in adults on the basis of a vast amount of clinical trial data. No such information is available to guide pharmacologic management of hypertension in children and adolescents. Unless there is clinical evidence of fluid retention in a hypertensive child, such as may occur when the elevated BP is related to chronic steroid use, diuretics are usually not the preferred first step in drug treatment. Most hypertensive children will not achieve adequate BP control with a thiazide diuretic alone, and children receiving thiazide diuretics often develop hypokalemia and require potassium supplements. For children, taking potassium supplements is extremely unpleasant, frequently leading to compliance problems. Despite these caveats, a low-dose diuretic can be useful as a second or third drug in children who require multiple drugs to achieve BP control.

SUMMARY

Essential, or primary, hypertension can occur in childhood. Because of the rising rates of childhood obesity, the prevalence of essential hypertension in childhood will increase. Despite this trend, the possibility of secondary hypertension should be considered in all children with documented hypertension. Children with suspected secondary hypertension require a more extensive evaluation than those with apparent essential hypertension. Whether the hypertension is determined to be secondary or primary, these children require monitoring, interventions to control the BP, and long-term follow-up. Considering the long-term morbidity and mortality associated with hypertension, interventions including preventive interventions that focus on BP control beginning in the young are necessary. Essential hypertension encompasses many distinct pathophysiologic entities, each with its own genetic basis and management approach. As new information develops, improved management strategies can be created for hypertension in the young, as well as in adults.

Table 40–4 Antihypertensive Drugs for Outpatient Management of Hypertension in Children 1 to 17 Years Old*

Class	Drug	Dose†	Dosing Interval	Evidence‡	FDA labeling§	Comments¶
Angiotensin-converting enzyme (ACE) inhibitor	Benazepril	Initial: 0.2 mg/kg/d up to 10 mg/d Maximum: 0.6 mg/kg/d up to 40 mg/d	qd	RCT	Yes	1. All ACE inhibitors are contraindicated in pregnancy—females of childbearing age should use reliable contraception. 2. Check serum potassium and creatinine periodically to monitor for hyperkalemia and azotemia. 3. Cough and angioedema are reportedly less common with newer members of this class than with captopril. 4. Benazepril, enalapril, and lisinopril labels contain information on the preparation of a suspension; captopril may also be compounded into a suspension. 5. FDA approval for ACE inhibitors with pediatric labeling is limited to children 6 years of age and older to children with creatinine clearance ≥30 mL/min/1.73 m^2.
	Captopril	Initial: 0.3-0.5 mg/kg/dose Maximum: 6 mg/kg/d	tid	RCT, CS	No	
	Enalapril	Initial: 0.08 mg/kg/d up to 5 mg/d Maximum: 0.6 mg/kg/d up to 40 mg/d	qd-bid	RCT	Yes	
	Fosinopril	Children >50 kg: Initial: 5-10 mg/d Maximum: 40 mg/d	qd	RCT	Yes	
	Lisinopril	Initial: 0.07 mg/kg/d up to 5 mg/d Maximum: 0.6 mg/kg/d up to 40 mg/d	qd	RCT	Yes	
	Quinapril	Initial: 5-10 mg/d Maximum: 80 mg/d	qd	RCT, EO	No	
Angiotensin receptor blocker	Irbesartan	6-12 yr: 75-150 mg/d ≥13 yr: 150-300 mg/d	qd	CS	Yes	1. All ARBs are contraindicated in pregnancy—females of childbearing age should use reliable contraception. 2. Check serum potassium, creatinine periodically to monitor for hyperkalemia and azotemia. 3. Losartan label contains information on the preparation of a suspension. 4. FDA approval for ARBs is limited to children 6 years of age and older and to children with creatinine clearance ≥30 mL/min/1.73 m^2.
	Losartan	Initial: 0.7 mg/kg/d up to 50 mg/d Maximum: 1.4 mg/kg/d up to 100 mg/d	qd	RCT	Yes	
α- and β-Blocker	Labetalol	Initial: 1-3 mg/kg/d Maximum: 10-12 mg/kg/d up to 1200 mg/d	bid	CS, EO	No	1. Asthma and overt heart failure are contraindications. 2. Heart rate is dose limiting. 3. May impair athletic performance. 4. Should not be used in insulin-dependent diabetics.

Table 40–4 Antihypertensive Drugs for Outpatient Management of Hypertension in Children 1 to 17 Years Old*—cont'd

Class	Drug	Dose[†]	Dosing Interval	Evidence[‡]	FDA labeling[§]	Comments[¶]
β-Blocker	Atenolol	Initial: 0.5-1 mg/kg/d Maximum: 2 mg/kg/d up to 100 mg/d	qd-bid	CS	No	1. Noncardioselective agents (propranolol) are contraindicated in asthma and heart failure. 2. Heart rate is dose limiting. 3. May impair athletic performance. 4. Should not be used in insulin-dependent diabetics. 5. A sustained-release formulation of propranolol is available that is dosed once daily.
	Bisoprolol/ HCTZ	Initial: 2.5/6.25 mg/d Maximum: 10/6.25 mg/d	qd	RCT	No	
	Metoprolol	Initial: 1-2 mg/kg/d Maximum: 6 mg/kg/d up to 200 mg/d	bid	CS	No	
	Propranolol	Initial: 1-2 mg/kg/d Maximum: 4 mg/kg/d up to 640 mg/d	bid-tid	RCT, EO	Yes	
Calcium channel blocker	Amlodipine	Children 6-17 yr: 2.5-5 mg once daily	qd	RCT	Yes	1. Amlodipine and isradipine can be compounded into stable extemporaneous suspensions. 2. Felodipine and extended-release nifedipine tablets must be swallowed whole. 3. Isradipine is available in both immediate-release and sustained-release formulations; sustained release form is dosed qd or bid. 4. May cause tachycardia.
	Felodipine	Initial: 2.5 mg/d Maximum: 10 mg/d	qd	RCT, EO	No	
	Isradipine	Initial: 0.15-0.2 mg/kg/d Maximum: 0.8 mg/kg/d up to 20 mg/d	tid-qid	CS, EO	No	
	Extended-release nifedipine	Initial: 0.25-0.5 mg/kg/d Maximum: 3 mg/kg/d up to 120 mg/d	qd-bid	CS, EO	No	
Central α-agonist	Clonidine	Children ≥12 years: Initial: 0.2 mg/day Maximum: 2.4 mg/day	bid	EO	Yes	1. May cause dry mouth and/or sedation. 2. Transdermal preparation also available. 3. Sudden cessation of therapy can lead to severe rebound hypertension.
Diuretic	HCTZ	Initial: 1 mg/kg/d Maximum: 3 mg/kg/d up to 50 mg/d	qd	EO	Yes	1. All patients treated with diuretics should have electrolytes monitored shortly after initiating therapy and periodically thereafter. 2. Useful as add-on therapy in patients being treated with drugs from other drug classes.
	Chlorthalidone	Initial: 0.3 mg/kg/d Maximum: 2 mg/kg/d up to 50 mg/d	qd	EO	No	

Continued

Table 40–4 Antihypertensive Drugs for Outpatient Management of Hypertension in Children 1 to 17 Years Old*—cont'd

Class	Drug	Dose†	Dosing Interval	Evidence‡	FDA labeling§	Comments¶
Diuretic—cont'd	Furosemide	Initial: 0.5-2.0 mg/kg/dose Maximum: 6 mg/kg/d	qd-bid	EO	No	3. Potassium-sparing diuretics (spironolactone, triamterene, amiloride) may cause severe hyperkalemia, especially if given with ACE inhibitor or ARB. 4. Furosemide is labeled only for treatment of edema but may be useful as add-on therapy in children with resistant hypertension, particularly in children with renal disease. 5. Chlorthalidone may precipitate azotemia in patients with renal diseases and should be used with caution in those with severe renal impairment.
	Spironolactone	Initial: 1 mg/kg/d Maximum: 3.3 mg/kg/d up to 100 mg/d	qd-bid	EO	No	
	Triamterene	Initial: 1-2 mg/kg/d Maximum: 3-4 mg/kg/d up to 300 mg/d	bid	EO	No	
	Amiloride	Initial: 0.4-0.625 mg/kg/d Maximum: 20 mg/d	qd	EO	No	
Peripheral α-antagonist	Doxazosin	Initial: 1 mg/d Maximum: 4 mg/d	qd	EO	No	May cause hypotension and syncope, especially after first dose.
	Prazosin	Initial: 0.05-0.1 mg/kg/d Maximum: 0.5 mg/kg/d	tid	EO	No	
	Terazosin	Initial: 1 mg/d Maximum: 20 mg/d	qd	EO	No	
Vasodilator	Hydralazine	Initial: 0.75 mg/kg/d Maximum: 7.5 mg/kg/d up to 200 mg/d	qid	EO	Yes	1. Tachycardia and fluid retention are common side effects. 2. Hydralazine can cause a lupus-like syndrome in slow acetylators. 3. Prolonged use of minoxidil can cause hypertrichosis. 4. Minoxidil is usually reserved for patients with hypertension resistant to multiple drugs.
	Minoxidil	Children younger than 12 yr: Initial: 0.2 mg/kg/d Maximum: 50 mg/d Children ≥12 yr: Initial: 5 mg/d Maximum: 100 mg/d	qd-tid	CS, EO	Yes	

*Includes drugs with prior pediatric experience or recently completed clinical trials.
†The maximum recommended adult dose should not be exceeded in routine clinical practice.
‡Level of evidence upon which dosing recommendations are based (CS, case series; EO, expert opinion; RCT, randomized controlled trial)
§FDA-approved pediatric labeling information is available. Recommended doses for agents with FDA-approved pediatric labels are the doses contained in the approved labels. Even when pediatric labeling information is not available, the FDA-approved label should be consulted for additional safety information.
¶Comments apply to all members of each drug class except where otherwise stated.
ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; bid, twice-daily; HCTZ, hydrochlorothiazide; qd, once-daily; qid, four times daily; tid, three times daily.

Table 40–5 Antihypertensive Drugs for Management of Severe Hypertension in Children 1 to 17 Years Old

Drug	Class	Dose[†]	Route	Comments
	Most Useful*			
Esmolol	β-blocker	100-500 mcg/kg/min	IV infusion	Very short-acting—constant infusion preferred. May cause profound bradycardia. Produced modest reductions in BP in a pediatric clinical trial.
Hydralazine	Vasodilator	0.2-0.6 mg/kg/dose	IV, IM	Should be given every 4 hr when given IV bolus. Recommended dose is lower than FDA label.
Labetalol	α- and β-blocker	Bolus: 0.2-1.0 mg/kg/dose up to 40 mg/dose infusion: 0.25-3.0 mg/kg/hr	IV bolus or infusion	Asthma and overt heart failure are relative contraindications.
Nicardipine	Calcium channel blocker	1-3 mcg/kg/min	IV infusion	May cause reflex tachycardia.
Sodium nitroprusside	Vasodilator	0.53-10 mcg/kg/min	IV infusion	Monitor cyanide levels with prolonged (>72 hr) use or in renal failure or coadminister with sodium thiosulfate.
	Occasionally Useful[‡]			
Drug	Class	Dose[†]	Route	Comments
Clonidine	Central α-agonist	0.05-0.1 mg/dose, may be repeated up to 0.8 mg total dose	po	Side effects include dry mouth and sedation.
Enalaprilat	ACE inhibitor	0.05-0.1 mg/kg/dose up to 1.25 mg/dose	IV bolus	May cause prolonged hypotension and acute renal failure, especially in neonates.
Fenoldopam	Dopamine receptor agonist	0.2-0.8 mcg/kg/min	IV infusion	Produced modest reductions in BP in a pediatric clinical trial in patients up to 12 yr.
Isradipine	Calcium channel blocker	0.05-0.1 mg/kg/dose	po	Stable suspension can be compounded.
Minoxidil	Vasodilator	0.1-0.2 mg/kg/dose	po	Most potent oral vasodilator; long acting.

*Useful for hypertensive emergencies and some hypertensive urgencies.
†All dosing recommendations are based on expert opinion or case series data except as otherwise noted.
‡Useful for hypertensive urgencies and some hypertensive emergencies.
ACE, angiotensin-converting enzyme; IM, intramuscular; IV, intravenous; po, oral.

Chapter 41

Pharmacologic Options for Treating Cardiovascular Disease During Pregnancy

Sharon C. Reimold and Lisa W. Forbess

CHAPTER CONTENTS

Pregnancy leads to an expansion of blood volume and altered pharmacokinetics of therapeutic agents. In addition, cardiovascular therapies may have effects on the fetus by crossing the blood-placenta barrier and on the newborn by excretion in breast milk. Physicians caring for pregnant and lactating patients with cardiovascular disorders should understand the hemodynamic changes associated with pregnancy, as well as the pharmacokinetics of various drugs, in order to make the most rational and safe decisions regarding pharmacologic therapy during pregnancy, delivery, and the early postpartum period.

Increases in human chorionic somatomammotropin lead to an increase in red cell formation and subsequently to an increase in red blood cell mass in pregnancy. High estrogen levels activate the renin-angiotensin axis, which results in sodium and water retention and an increase in extracellular volume. The combined impact of these two changes is to increase blood volume by 30% to 50% over baseline during pregnancy.[1] This increase in blood volume begins before the end of the first trimester and levels off by the middle of the third trimester. Increases in extracellular volume are proportionally larger than increases in red cell volume, one cause of the "anemia of pregnancy."[1] Iron supplementation, which is recommended, can partially correct this "physiologic anemia" of pregnancy.[2]

Cardiac output increases throughout pregnancy by increasing heart rate as well as stroke volume. Multiple factors contribute to a fall in systemic vascular resistance.[2,3,4] The systolic pressure begins to fall during the first trimester, nadirs in midpregnancy, and returns to normal before term. Diastolic pressure decreases more than systolic pressure, thus causing a widened pulse pressure. Decreased blood pressure may be most pronounced during the second trimester and must be considered when prescribing therapies for cardiovascular disorders.

The pharmacokinetics of drugs is altered because of changes in gastrointestinal and renal function during pregnancy. Decreases in gastrointestinal motility are quite heterogenous but may lead to significantly decreased and delayed gastrointestinal absorption. Increases in fatty tissue, as well as decreased maternal hepatic enzyme activity, may decrease the metabolism of some pharmacologic agents. The distribution of the increased cardiac output is altered in pregnancy with a large amount of flow distributed to the uterus to allow fetal growth and development. Renal blood flow increases during pregnancy, with a 30% to 80% increase in glomerular filtration rate. Metabolic considerations for drug dosing in pregnancy are listed in Table 41–1.

The ability of a pharmacologic agent to cross the placental barrier must be considered. Early in pregnancy, the fetal blood-brain barrier is not developed. Therefore agents crossing the placental barrier may affect general fetal development as well as fetal central nervous system development. Data on the safety of pharmacologic agents in pregnancy are paramount, but for many agents clinical data from patients are limited, and recommendations for safety are often

Table 41–1 Factors Leading to Altered Pharmacokinetics in Pregnancy

Altered Systems	Impact of Changes
Gastrointestinal motility	Decreased motility and absorption caused by elevated estrogens
Hepatic enzyme activity	May be decreased in pregnancy, leading to slower metabolism
Increased volume of distribution and increased levels of fatty tissue	Results in altered protein binding and volume of distribution of some agents (e.g., digoxin)
Increased renal blood flow	Increased glomerular filtration rate may lead to increased drug clearance
Altered distribution of cardiac output	Increased proportion of cardiac output dedicated to uterus; impact on fetal-placental unit dependent on ability of agent to cross placental barrier and through fetal tissues

extrapolated from animal data. The text *Drugs in Pregnancy and Lactation: A Reference Guide to Fetal and Neonatal Risk* is a useful reference for physicians caring for pregnant patients.[5] Table 41–2 lists the classification of and most common risks associated with the use of cardioactive drugs during pregnancy and lactation.[5]

HYPERTENSION

The treatment of hypertension in pregnancy is covered in Chapter 39.

EDEMA

Peripheral edema is common in pregnancy and may be seen in patients with or without underlying cardiovascular disorders. Routine treatment of edema with diuretics is not recommended. Compression stockings may be useful for women with bothersome edema. These stockings also decrease venous stasis and may be helpful in patients who have a history of venous thromboembolism. Diuretics should be used sparingly in pregnancy because they may interfere with the normal physiologic volume expansion of pregnancy. Loop diuretics are indicated in the management of edema associated with congestive heart failure, nephrosis, cirrhosis, or preeclampsia. Furosemide is generally the diuretic of choice. Furosemide crosses the placenta and may result in increased fetal urine production.[5] Thiazide diuretics cross the placenta and can cause fetal or neonatal jaundice, thrombocytopenia, hypoglycemia, hemolytic anemia, hyponatremia, and fetal bradycardia.[6] Data on the use of potassium-sparing diuretics in pregnancy are inadequate. Spironolactone can adversely affect sexual differentiation in males and is contraindicated in pregnancy.[6] The American Academy of Pediatrics classifies furosemide, thiazides, and spironolactone as compatible with breast-feeding.[5,6]

VALVULAR HEART DISEASE

As the heart enlarges with pregnancy, most women develop a small amount of mitral and tricuspid regurgitation. This amount of regurgitation is only slightly more than physiologic and generally does not produce any symptoms and does not require therapy. Women with preexisting aortic or mitral regurgitation related to structural heart disease tend to tolerate pregnancy well because of the decreased systemic vascular resistance of pregnancy, which serves as a “natural vasodilator.” However, patients with severe aortic or mitral regurgitation may experience difficulty in handling the increased volume load imposed on the heart by pregnancy. In these patients, optimal therapy may include valve repair or replacement before pregnancy. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) are commonly used in nonpregnant patients with severe mitral or aortic regurgitation to decrease the volume load on the left ventricle. Both ACE inhibitors and ARBs cross the placenta and appear to rise to toxic levels in the fetus, mainly affecting the developing urogenital tract but also causing a number of other abnormalities (see Table 41–2). Although limited data suggest that ACE inhibitor exposure in the first trimester may not be harmful,[7,8] without definitive proof of safety early in pregnancy, both ACE inhibitors and ARBs should be avoided throughout pregnancy and discontinued before conception whenever possible. During pregnancy, hydralazine and nitrates can be used as a substitute for ACE inhibitors and ARBs. In symptomatic patients, medical therapies include bed rest, nitrates, digoxin, salt restriction, and loop diuretics. Symptomatic patients may benefit from invasive hemodynamic monitoring during labor and delivery. Epidural anesthesia can be administered safely.[9]

Patients with mild-to-moderate aortic stenosis suffer few cardiovascular complications with pregnancy. However, severe aortic stenosis is poorly tolerated in pregnancy and may lead to increases in medication, hospitalizations, atrial arrhythmias, congestive heart failure, and premature delivery. Fetal outcome is also affected with a higher incidence of preterm birth, intrauterine growth retardation (IUGR), and neonatal respiratory distress syndrome.[10,11] Medical therapy for symptomatic aortic stenosis is limited to diuretics and bedrest. Those patients who are refractory to medical therapy must be treated surgically or with palliative balloon valvuloplasty, a procedure that seems to be associated with a lower risk of fetal loss and is the preferred treatment.[12] Many surgeons have reported successful aortic valve replacement during pregnancy, and surgical valve replacement is associated with a fetal mortality rate up to 30%.[13] During labor, when epidural anesthesia is used, invasive hemodynamic monitoring is recommended to avoid hypotension and reflex tachycardia during labor and delivery. Vaginal delivery is preferred with assisted second stage of labor. General anesthesia is the preferred technique for cesarean section.[14] Postpartum hemorrhage can be catastrophic for women with severe aortic stenosis and must be managed aggressively.

Patients with rheumatic mitral stenosis may first develop symptoms during pregnancy. As heart rate and cardiac output

Table 41–2 Risk of Cardiac Drugs to Fetus and Newborn—cont'd

Drug	Placental Transfer	Risk Factor*	Fetal Effects	Breast-Feeding Risk
Mexiletine	Yes	C_M	No adverse effects reported	Limited data—probably compatible; excreted into milk
Nesiritide	Unknown	C	No data	No data
Nifedipine	Yes	C_M	No teratogenic effect reported; important interaction with IV magnesium	Limited data—probably compatible
Nitroglycerin	Unknown	B/C_M	No adequate human studies	No data—probably compatible
Procainamide	Yes	C_M	None	Limited data—probably compatible
Propafenone	Unknown	C_M	No adequate human data	No data—probably compatible
Propranolol	Yes	C_M	Growth retardation, prematurity, hypoglycemia, bradycardia, respiratory depression	Limited data—potential toxicity
Quinidine	Yes	C_M	Thrombocytopenia	Limited data—probably compatible
Sodium nitroprusside	Yes	C	Potentially toxic; no adequate human studies	No data; potential toxicity
Sotalol	Yes	B_M/D if used in 2nd or 3rd trimester	Bradycardia; used to treat fetal tachycardia; IUGR, decreased placental weight	Limited data—potential toxicity
Spironolactone	Unknown	C_M/D if used in gestational hypertension	No human congenital defects reported; known antiadrogenic effects	Limited data—probably compatible
Streptokinase	Yes (minimal)	C_M	No reports of congenital anomalies	No data—probably compatible
tPA	Probably not	C_M	No teratogenicity observed	Compatible
Unfractionated heparin	No	C_M	Thrombocytopenia, acute distress	Yes
Verapamil	Yes	C_M	No reports of congenital anomalies	Limited data—probably compatible
Warfarin	Yes	D_M/X according to manufacturer DuPont Pharma, 2000	Abortion, hemorrhage, nasal hypoplasia, stippled epiphyses	Compatible

*Risk factors: Category B: Either animal reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women or animal reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters). Category C: Either studies in animals have revealed adverse effects on the fetus and there are no controlled studies in pregnant women or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus. Category D: There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is necessary for a life-threatening situation for which safer drugs cannot be used or are ineffective). The M subscript indicates that the manufacturer has rated the risk. X denotes that the manufacturer designates the drug as contraindicated in pregnancy.
Data mainly from Briggs GG, Freeman RK, Yaffe SJ: Drugs in Pregnancy and Lactation, 7th ed. Philadelphia, Lippincott Williams & Wilkins, 2005.

increase during the second trimester, the diastolic filling period decreases and left atrial pressure increases. These changes may lead to atrial distention, which may be associated with dyspnea and the development of atrial fibrillation. Left atrial filling pressures may be reduced by the use of loop diuretics and β-adrenergic blocking agents. β-Blockers decrease heart rate and increase the diastolic filling period. Use of β-1-selective agents is preferred due to the lack of interference with β-2-mediated uterine relaxation.[15] Restriction of physical activity is also important in controlling heart rate and symptoms. Atrial fibrillation may be poorly tolerated during pregnancy and, in a hemodynamically unstable patient, should be promptly treated with cardioversion. Rapid restoration of sinus rhythm decreases left atrial pressure and congestive symptoms. However, the risk of thromboembolic complications must be considered before cardioversion. To rule out the presence of left atrial thrombus, transesophageal echocardiography (TEE) should be performed before cardioversion. Full-dose anticoagulation is indicated for pregnant patients with mitral stenosis and atrial fibrillation.

Pregnancy is a hypercoagulable state due to the increased levels of factors I, II, VII, VIII, IX, and X and may increase the

risk of thromboembolism in patients with severe mitral stenosis even in the absence of atrial fibrillation. Left atrial thrombus has been reported in three pregnant women with mitral stenosis in sinus rhythm.[16] The first patient suffered a left middle cerebral artery stroke, a second had partial occlusion of the mitral valve orifice, and the third patient had worsening of heart failure.[14,16]

For patients presenting with atrial fibrillation, digoxin and β-blockers can be used safely to control the ventricular response. If a third drug is necessary to control ventricular rates, a calcium channel blocker can be added. Verapamil is not teratogenic and appears relatively safe, although maternal hypotension has been reported after intravenous bolus of verapamil.[5] When used to treat fetal supraventricular arrhythmias, verapamil can cause fetal bradycardia, heart block, depression of contractility, hypotension, and fetal demise.[17] There is less experience with diltiazem during pregnancy, but short-term use of intravenous diltiazem to control ventricular rate may be considered safe and effective. A Michigan Medicaid surveillance study suggests an association between use of diltiazem during pregnancy and congenital cardiovascular defects.[5]

Patients who have symptoms related to mitral stenosis before the end of the first trimester (which is the beginning of volume expansion for these patients) are unlikely to tolerate pregnancy well. Percutaneous valvuloplasty or surgical commissurotomy should be considered for these patients. Percutaneous balloon mitral valvuloplasty during pregnancy has been reported in numerous patients with good outcomes.[9,14] The procedure should be avoided in the first trimester to avoid fetal radiation during organogenesis and should be reserved for those who are refractory to medical therapy. Mitral valve surgery should be considered only for medically refractory patients who are not suitable candidates for percutaneous valvuloplasty because the risks to mother and fetus are significantly greater. With surgery, the maternal mortality rate has been reported as 9% and the fetal or neonatal mortality rate as 29%.[12] Vaginal delivery with assisted second stage of labor can be permitted, with cesarean section reserved for obstetric indications. Invasive hemodynamic monitoring is recommended with use of epidural anesthesia.[18] β-Blocking agents (and occasionally diuretics) may be used to decrease the left atrial filling pressures at the time of delivery. The autotransfusion of blood from the uterus shortly after delivery is associated with an increase in left atrial filling pressures (increases of ≈ 10 mm Hg might be expected) and can precipitate pulmonary edema.

Isolated valvular pulmonic stenosis (PS), even when severe, is typically well tolerated throughout pregnancy. Although the number of reported pregnancies complicated by isolated PS is small, severe PS does not seem to adversely affect maternal or fetal outcome. Balloon valvuloplasty should be considered in symptomatic patients. Pulmonic stenosis is frequently associated with more complex congenital heart disease, which is reviewed in Chapter 42.

THROMBOEMBOLIC DISEASE DURING PREGNANCY

Anticoagulation is indicated during pregnancy for the prevention and treatment of venous thromboembolism, for patients with mechanical heart valves, and for the prevention of complications in women with thrombophilia or recurrent late pregnancy loss. Pregnancy is a hypercoagulable state because of the increased production of clotting factors, an acquired resistance to the endogenous anticoagulant, activated protein C, and a decrease in fibrinolysis.[19] This prothrombotic state, along with lower-extremity venous stasis caused by an enlarging uterus, increases the likelihood of deep venous thrombosis during pregnancy. Venous thromboembolism is 5 to 6 times more common in pregnant women as compared with nonpregnant women, and pulmonary embolism remains a leading cause of maternal mortality throughout the United States.

Acquired or hereditary thrombophilias occur in almost two thirds of women who present with recurrent miscarriages, preeclampsia, IUGR, abruptio placentae, or stillbirths that are associated with microvascular thrombosis in placental blood vessels.[19,20] Because thrombophilic disorders can be seen in up to 20% of normal pregnancies, screening for thrombophilia is recommended only for selected women with unexplained late or recurrent fetal losses of unclear etiology. Anticoagulation strategies are controversial. In general, thromboembolic prophylaxis is recommended for those individuals who are at increased risk and therapeutic anticoagulation is recommended for those individuals who are at highest risk. The Seventh American College of Chest Physicians (ACCP) Conference on Antithrombotics and Thrombolytic Therapy provides evidence-based guidelines on the use of antithrombotic agents during pregnancy.[20a]

ANTICOAGULATION DURING PREGNANCY

The antithrombotics currently available for the prevention and treatment of thromboembolism and valve thrombosis include unfractionated heparin (UFH), low molecular weight heparin (LMWH), heparinoids, coumarin derivatives, and aspirin. The direct thrombin inhibitors, such as hirudin, cross the placenta and have not been evaluated during pregnancy. In evaluating an anticoagulant strategy, there are two potential fetal complications of treatment to consider: teratogenicity and bleeding. Neither UFH, LMWH, nor heparinoids cross the placenta and therefore do not have the potential to cause fetal bleeding or teratogenicity. Numerous studies have shown that UFH and LMWH therapy are safe for the fetus. In contrast, coumarin derivatives cross the placenta and have the potential for fetal bleeding and teratogenicity. Coumarin's effect on the fetus is most marked during the first trimester. The fetal warfarin embryopathy consists of nasal hypoplasia, which can result in nasal bridge depression, upper airway obstruction, and stippled epiphyses.[21] Significant central nervous system abnormalities including microcephaly, optic atrophy, and hydrocephalus have been reported, as well as spontaneous abortions, stillbirths, and neonatal deaths.[21] The exposure period of greatest risk for warfarin embryopathy and spontaneous abortion is between the 6th and 12th weeks of gestation. However, the period of risk for the developing CNS abnormalities is controversial and may extend throughout pregnancy. One cohort study reported a higher incidence of neurodevelopmental problems in children who were exposed to coumarin in the second and third trimesters.[22] Ongoing

exposure to coumarin may result in cerebral microhemorrhages and abnormal brain development.

In a systematic review of the literature on anticoagulation management during pregnancy in women with mechanical heart valves, Chan reported the risk of warfarin embryopathy to be 6.4% in 1234 pregnancies.[23] When warfarin was discontinued and heparin was used prior to 6 weeks' gestation and continued through 12 weeks, the risk of warfarin embryopathy was eliminated entirely. Warfarin use throughout pregnancy was associated with the lowest risk of valve thrombosis, 3.9%, which increased to 9.2% with substitution of heparin from weeks 6 to 12. Warfarin use between 6 and 12 weeks' gestation was associated with a 33.9% spontaneous abortion rate, compared with a rate of 14.7% when heparin was used before week 6. It is noteworthy that 46% of the patients had first-generation valves, typically cage and ball valves or Bjork-Shiley single-tilting disk valves, with only 7.1% having newer bileaflet valves. Chan concludes that use of heparin in the first trimester eliminates the fetal warfarin embryopathy and lowers the spontaneous abortion rate but subjects the woman to an increased risk of valve thrombosis/thromboembolism.

In clinical practice, the use of warfarin during pregnancy varies. Most clinicians avoid warfarin entirely throughout pregnancy. Other clinicians reintroduce warfarin after the first trimester and discontinue its use at approximately 36 weeks, to avoid major maternal and fetal bleeding during late pregnancy and around the time of delivery. If the mother is fully anticoagulated with warfarin at the onset of labor, fresh-frozen plasma should be administered. Warfarin can usually be restarted on the first postpartum day. Overlap therapy with intravenous UFH may be necessary until warfarin becomes effective, depending on the maternal indication for anticoagulation. Warfarin is safe to administer to women who are breast-feeding and does not alter clotting mechanisms in the infant.[24]

UFH has been used extensively for treating thrombotic disorders associated with pregnancy. Potential complications of its use include hemorrhage, thrombocytopenia, and osteopenia. Significant osteopenia may occur in up to one third of women treated with long-term UFH.[25] Thrombocytopenia is a less common adverse effect, but it may affect up to 10% of patients. Approximately 3% of nonpregnant patients treated with UFH acquire immune, IgG-mediated thrombocytopenia, which is frequently complicated by extension of preexisting venous thromboembolism or new arterial thrombosis.[26] This represents a serious complication of heparin therapy and necessitates monitoring the platelet count throughout the course of treatment. Long-term heparin therapy during pregnancy is feasible via subcutaneous injection or continuous intravenous infusion. Dosing of UFH requires adjustment throughout pregnancy. Subcutaneous UFH may have to be administered at doses as high as 10,000 to 20,000 U every 8 to 12 hours in order to maintain midinterval activated partial thromboplastin time (aPTT) of 2 to 3 times control or an anti-Xa level 0.35 to 0.70 IU/mL. Monitoring of a predose (trough) level is useful in determining the need for every-8-hour dosing.[27] For patients in whom subcutaneous UFH therapy is ineffective, continuous infusion of UFH may be used. Placement of a semipermanent indwelling line makes this feasible.[28] Small infusion pumps are available and may be loaded with prefilled heparin cartridges. Subcutaneous UFH should be discontinued 24 hours before elective induction of labor, whereas intravenous UFH should be discontinued 4 to 6 hours before the expected time of delivery.[29]

For many physicians, LMWH has become the preferred agent for the prevention and treatment of venous thromboembolism during pregnancy and for the management of pregnant women with mechanical heart valves. LMWHs have approximately 92% bioavailability compared with 30% of UFH, and they have a longer half-life (4 hours) compared with UFH (3 hours when administered subcutaneously). Moreover, LMWHs have a more predictable anticoagulant response and a lower incidence of heparin-induced thrombocytopenia (HIT), osteopenia, and bleeding complications. Increasing experience has been reported regarding the use of LMWH in pregnancy.[30-34] In one review of 486 pregnancies in which LMWH was administered, symptomatic osteoporosis was observed in only 1 patient, and only 3 patients suffered a thromboembolic event.[34] Allergic reactions and minor bleeding were rare, reported in 2.7%. LMWHs are frequently administered twice daily in high-risk patients. Enoxaparin is most commonly administered subcutaneously at 1 mg/kg twice a day. The dose of enoxaparin may have to be adjusted during pregnancy as maternal weight and drug clearance increases. Dalteparin can be dosed 100 IU/kg every 12 hours. Many have advocated the use of peak or trough anti-Xa levels, or both, to assess adequacy of anticoagulation.[27,29]

Pregnancy in a patient with a mechanical heart valve poses difficult issues with respect to anticoagulation. Pregnant women with prosthetic heart valves are at particularly high risk for thromboembolic complications, with incidence ranging from 7.5% to 23%.[27,35,36] Most events present as valve thrombosis, with an associated mortality rate of 40%.[35-37] The highest-risk patients are those with older, higher-profile mechanical mitral valves, such as the Bjork-Shiley or Starr-Edwards caged ball valve, those in atrial fibrillation, and those with left ventricular dysfunction.[23,27]

There are several case reports and small series on the use of LMWH in pregnant women with prosthetic heart valves, some of which have described treatment failures. Further review has shown that many of the complications were associated with an inadequate dose, lack of monitoring, or subtherapeutic anti-Xa levels.[27] A randomized, open-label trial was designed to compare enoxaparin with warfarin in pregnant women with prosthetic valves. The trial was terminated after enrollment of only 12 patients due to 2 deaths from prosthetic valve thrombosis in the enoxaparin group. Both deaths occurred in high-risk patients who had subtherapeutic anti-Xa levels (less than the recommended 0.3 to 1.0 IU/mL). It is unclear whether the outcomes would have been different with coumarin, and many experts believe the trial should not have been terminated.[38]

For pregnant women with prosthetic heart valves, the ACC/AHA Task Force report in 1998[39] recommended the use of warfarin, especially in high-risk women, through week 35. The Task Force recommended a target INR 2.0 to 3.0 along with administration of low-dose aspirin.[6,39,40] Guidelines from the ACCP outline three possible regimens for women with mechanical heart valves: (1) use of either LMWH or UFH between 6 and 12 weeks and close to term only, with use of vitamin K antagonists (VKAs) at other times; (2) aggressive dose-adjusted UFH throughout pregnancy; or (3) aggressive

Table 41–3 Recommended Approach for Anticoagulation Prophylaxis in Women with PHV During Pregnancy

Higher Risk	Lower Risk
First-generation PHV (e.g., Starr-Edwards, Bjork Shiley) in the mitral position, atrial fibrillation, history of TE on anticoagulation	Second-generation PHV (e.g., St. Jude Medical, Medtronic-Hall) and any mechanical PHV in the aortic position
Warfarin (INR 2.5 to 3.5) for 35 wk, followed by UFH (midinterval aPTT > 2.5) or LMWH (predose anti-Xa ≈0.7) + ASA 80-100 mg q.d. OR UFH (aPTT 2.5 to 3.5) or LMWH (predose anti-Xa ≈0.7) for 12 wk, followed by warfarin (INR 2.5 to 3.5) to 35th week, then UFH (aPTT > 2.5) or LMWH (predose anti-Xa ≈0.7) + ASA 80-100 mg q.d.	SC UFH (midinterval aPTT 2.0 to 3.0) or LMWH (predose anti-Xa ≈0.6) for 12 wk, followed by warfarin (INR 2.5 to 3.0) for 35 wk, then SC UFH (midinterval aPTT 2.0 to 3.0) or LMWH (predose anti-Xa level ≈0.6) OR SC UFH (midinterval aPTT 2.0 to 3.0) or LMWH (predose anti-Xa ≈0.6) throughout pregnancy

aPTT, activated partial thromboplastin time; ASA, acetylsalicylic acid; INR, international normalized ratio; LMWH, low molecular weight heparin; PHV, prosthetic heart valve; SC subcutaneous; TE, thromboembolism; UFH, unfractionated heparin.

adjusted-dose LMWH throughout pregnancy.[29] With use of coumarin, the recommended INR is 3.0 with a range of 2.5 to 3.5 or a range of 2.0 to 3.0 if the patient has a bileaflet aortic valve and does **not** have atrial fibrillation or LV dysfunction. UFH should be initiated at high doses and adjusted to maintain aPTT at least 2x control or anti-Xa level 0.35 to 0.70 U/mL. LMWH should be given every 12 hours in doses adjusted to maintain a 4-hour postinjection anti-Xa level 1.0 to 1.2 U/mL or, suboptimally, according to weight. In a review of the management of prosthetic valves in pregnancy, Elkayam[27,41] and Bitar modified the recommendations of the ACC/AHA and the Seventh ACCP Consensus by differentiating between patients at higher and lower risk and by advocating use of both peak and trough levels of heparin activity (Table 41–3). Peak levels should be checked to prevent toxicity and should be less than 1.5, ideally 1.0 to 1.2. Biweekly monitoring of the aPTT or anti-Xa levels is recommended. Higher-risk patients include those with first-generation mechanical mitral valves, a history of atrial fibrillation, previous thromboembolism, or significant left ventricular dysfunction. Thromboembolic prophylaxis in higher-risk patients seems best achieved with coumarin during the first 35 weeks. A higher level of anticoagulation is recommended with target INR 2.5 to 3.5, aPTT >2.5, or predose anti-Xa level approximately 0.7. For higher-risk patients who want to avoid coumarin during the first trimester, UFH or LMWH can be used from weeks 0 to 12 and then again after 35 weeks. All of the contemporary guidelines recommend adding low-dose aspirin (80 to 100 mg) for high-risk patients because it has been shown to decrease the incidence of valve thrombosis in nonpregnant patients, albeit with a slight increase in bleeding risk.[42,43] For the lower-risk group, Elkayam and Bitar[2,27,41] recommend a lower level of anticoagulation: INR 2.5 to 3.0, aPTT 2.0 to 3.0, or predose anti-Xa level of approximately 0.6 (see Table 41–3).

THROMBOLYSIS

Although pregnancy has been perceived as an absolute contraindication to fibrinolysis, fibrinolytic agents have been used in pregnant patients for a variety of indications including iliac vein thrombosis, acute myocardial infarction, massive pulmonary embolism, stroke, renal vein thrombosis, and prosthetic valve thrombosis.[27,44-47] Fibrinolytic agents, such as streptokinase and tissue plasminogen activator, have been used in pregnancy for ST-elevation myocardial infarction (STEMI) and pulmonary embolism that is complicated by hemodynamic instability or right ventricular dysfunction.[48-50] These agents have been used during the first trimester without overt developmental abnormalities. No congenital defects are known to be associated with the use of fibrinolytic agents. The risks of these agents include significant bleeding, peripheral embolization, premature labor, and death. A few cases of placental abruption and neonatal intracranial hemorrhage have been reported.[51] Depending on the case, however, the benefits may outweigh the risks. Streptokinase does cross the placenta in small amounts but has minimal fibrinolytic effects; streptokinase antibodies do cross the placenta.

ISCHEMIC HEART DISEASE

Unstable angina and acute myocardial infarction (MI) may develop in pregnancy through a variety of mechanisms including spontaneous coronary artery dissection; atherosclerotic coronary artery disease (CAD); or use of a toxin, such as cocaine. Women who present with symptomatic CAD in pregnancy tend to be patients with a high burden of cardiovascular risk (i.e., diabetes, smoking, hypertension, lipid disorders, or family history of premature CAD). Mortality rates from MI appear to be higher in late pregnancy and may be attributable to the increased hemodynamic demands on the heart during

this period. Optimal delivery in the peri-infarct period requires coordination and planning by the cardiologist, obstetrician, pediatrician, and anesthesiologist.[52,53]

In general, treatment of STEMI during pregnancy is unchanged from that of the nonpregnant patient. Both fibrinolytic therapy and percutaneous coronary intervention (PCI) have been used in pregnant patients with acute coronary syndromes.[49,50,54,55] In STEMI, primary PCI may be preferred over fibrinolysis because it may reveal a nonatheromatous etiology of coronary insufficiency and carries a lower bleeding risk. Although concerns about PCI have focused on the risks of contrast agents and radiation to the fetus, radiation shielding can be performed to decrease the radiation exposure. Expected exposure rates for PCI range from less than 0.01 to 0.1 Gy, depending on the complexity of the procedure.[51] Isolated case reports document successful use of antiplatelet agents, such as clopidogrel and platelet GP IIb/IIIa inhibitors in pregnancy.[55] However, these agents should be used only with the understanding that there is an increased risk of maternal and fetal bleeding. The safety of drug-eluting stents in pregnant subjects is unknown. Moreover, the duration and safety of poststent antiplatelet therapy has not been studied. Coronary artery bypass during pregnancy carries high risk to the fetus (estimated death rate 19%), whereas the maternal risk is similar to that in nonpregnant patients.[56]

Antianginal therapy during pregnancy includes β-adrenergic blocking agents, calcium channel blocking agents, heparin, and nitrates.[5,57,58] The risks of β-adrenergic blocking agents have been described previously (see Table 41–2). Reports on the use of nitroglycerin during pregnancy, especially during the first trimester, are limited. Transdermal nitroglycerin patches have been used as tocolytic agents. Hypotension and headaches are common side effects of nitrate use, as they are in nonpregnant individuals (see Chapter 5).

In nonpregnant patients, diltiazem has been used successfully to treat ischemia. As previously reviewed, there are limited human data on the use of diltiazem in pregnancy and verapamil is the preferred calcium channel blocker. Nifedipine has been used successfully for the treatment of severe hypertension in pregnancy; however, severe adverse reactions have been reported when the drug is combined with intravenous magnesium. No reports on the use of amlodipine in human pregnancy or lactation are available.

Previous recommendations suggested avoiding aspirin during pregnancy due to the potential risk of premature closure of the ductus arterious. However, a meta-analysis and a large randomized trial found no increased risk of fetal or maternal side effects with aspirin doses of 60 to 150 mg daily.[29,59] High doses of aspirin (325 to 650 mg daily) should be avoided throughout pregnancy. The drug may affect maternal and fetal hemostasis and may cause cardiovascular septal defects, IUGR, and premature ductal closure, which may lead to persistent pulmonary hypertension of the neonate.[5] We recommend using low-dose aspirin (81 to 162 mg daily) throughout pregnancy and lactation in patients with known CAD. Aspirin is excreted into breast milk in low concentrations, but no adverse effects on platelet function in the nursing infant exposed to aspirin have been reported.[5,6] The American Academy of Pediatrics advises cautious use of aspirin during lactation.[5]

LIPID DISORDERS

Few data are available on the use of statins during pregnancy.[60-62] Some animal data demonstrate developmental abnormalities with high-dose fluvastatin and atorvastatin.[6] Postmarketing surveillance reports of exposure to lovastatin and simvastatin during pregnancy are available and include 134 patients with variable exposure to these agents.[6,60,62] Pregnancy outcomes were not markedly different from those of a normal population; however, the number of patients was adequate only to exclude a threefold to fourfold increase in adverse outcomes. Because the risks of statin drugs during pregnancy are unclear and the benefits of treatment of these disorders during pregnancy are unknown, the current recommendation is to stop statin drugs before conception and avoid them throughout pregnancy and lactation.

Although there are limited data on fetal effects from bile acid sequestrants, such as cholestyramine and colestipol, these drugs are not absorbed and therefore should not be teratogenic. A theoretical risk to the fetus from the reduced maternal absorption of fat-soluble vitamins exists. Given the lack of data, these drugs should be avoided throughout pregnancy. No reports of bile acid sequestrant use in lactation have occurred, but the drugs are considered compatible with breast-feeding.[5] Little information is available on the use of nicotinic acid, gemfibrozil, fenofibrate, or ezetimibe in human pregnancy. Animal studies with high-dose gemfibrozil, fenofibrate, and ezetimibe demonstrate toxic fetal effects.[5]

In general, discontinuation of lipid-lowering drugs is likely to expose the mother to minimal risk. Given the lack of data on fetal effects, cholesterol-lowering drugs should be discontinued before conception and avoided throughout pregnancy and lactation.

HEART FAILURE

Peripartum cardiomyopathy (PPCM) is defined as the development of dilated cardiomyopathy (DCM) from the last month of pregnancy through the first 6 months after delivery, when other causes of heart failure have been excluded.[2] This diagnosis is associated with mortality rates ranging from 9% to 50%, depending on the series.[2,9,63-65] The outcome for PPCM appears to be better than that for idiopathic DCM, with approximately 50% of patients with PPCM demonstrating marked improvement in ventricular function and clinical symptoms compared with 10% in idiopathic DCM.[65]

Treatment of PPCM is similar to that for congestive heart failure of any etiology: preload reduction with sodium and fluid restriction, diuretics and nitrates; afterload reduction; and positive inotropes, such as digoxin. Digoxin is relatively safe for both the fetus and the mother and may be used safely while the mother is breast-feeding.[66,67] Diuretics should be used sparingly to avoid a decrease in placental perfusion. Furosemide is the diuretic of choice. Spironolactone should be avoided. No data are available on the use of eplerenone.

Afterload reduction is advantageous for many patients with heart failure. ACE inhibitors and ARBs should be avoided until after delivery because they are teratogenic. Hydralazine, with or without concomitant use of nitrates, is another treatment option for vasodilation during pregnancy. There is

extensive experience with hydralazine in pregnancy, with no significant adverse maternal or fetal outcomes seen.[68] Use of hydralazine is associated with a higher incidence of development of a lupus-like syndrome in the mother. Although it is excreted in breast milk in low concentrations, hydralazine may be used by the nursing mother. Addition of β-blockers can be considered, especially in the setting of arrhythmia. However, because the use of β-blockers is associated with low birth weight and the benefit of β-blockers in heart failure is a long-term benefit, it is prudent to initiate β-blockade after delivery. No human data on the use of carvedilol or nesiritide in pregnancy are available. Therefore, use of these drugs is best reserved for postpartum medical management.

Patients with PPCM have a high rate of thromboembolism, which may complicate up to 53% of cases.[69] Full-dose anticoagulation is recommended for PPCM patients with ejection fraction less than 35%.[65,70] Because the diagnosis of PPCM is made in the last month of pregnancy, LMWH or UFH is preferred over warfarin. Warfarin can be initiated postpartum.

For the hemodynamically unstable patient with heart failure, the first priority is reestablishing adequate maternal circulation with inotropic or mechanical support as needed. If cardiac output is inadequate to support the fetus or if the supportive therapy for the mother puts the fetus at risk, prompt delivery is recommended. Following delivery, the medical regimen should be altered to include β-blockers and ACE inhibitors, as tolerated. Cardiac transplantation has been performed successfully in the postpartum period.

Subsequent pregnancies in patients with PPCM are associated with adverse outcomes. Elkayam et al.[71] reviewed the outcomes of 60 subsequent pregnancies in 44 women with PPCM. In 16 patients with left ventricular dysfunction before subsequent pregnancy, 44% developed symptoms of heart failure compared with 21% of the 28 patients with normal left ventricular function before the pregnancy. Three deaths (19%) were reported in the group with prepregnancy left ventricular dysfunction. Because of the high rate of maternal morbidity and mortality rates associated with subsequent pregnancy, women with PPCM should consult with a cardiologist before conception. A baseline echocardiogram is recommended, along with follow-up for signs and symptoms of heart failure.

CARDIAC ARRHYTHMIAS

The evaluation of a pregnant woman with an arrhythmia should include assessment of cardiac structure and function; pulmonary status; hematocrit; thyroid function; and extrinsic precipitants, such as caffeine, sympathomimetic amines, and alcohol. An echocardiogram is indicated to rule out congenital defects, ventricular dysfunction, and valvular disease. A diagnosis of inappropriate sinus tachycardia is made in a patient with sinus tachycardia out of proportion to the stage of pregnancy in the absence of thyroid disease, anemia, cardiac dysfunction, extrinsic precipitants, or infection. Inappropriate sinus tachycardia may be associated with maternal anxiety and high sympathetic tone. These patients may experience dyspnea at low workloads. Appropriate volume and salt expansion may limit the symptoms produced by this disorder. Treatment with β-adrenergic blocking agents is effective for this disorder but should be prescribed only for severe cases, given the relatively benign nature of this condition and the potential harmful effects of β-blockers on fetal growth.

With the normal volume expansion of pregnancy, atrial expansion may lead to increased atrial irritability and precipitate atrial fibrillation or supraventricular tachycardia (SVT). Atrial premature contractions may be associated with symptoms but rarely need to be treated in pregnancy. For patients with SVT, vagal maneuvers should be attempted first. If vagal maneuvers are not effective, intravenous adenosine is highly effective for the termination of such arrhythmias.[72-74] Adenosine has a short half-life, making it a safe drug for use in pregnancy. No fetal complications related to adenosine have been reported. β-Adrenergic blocking agents and verapamil have been used successfully to terminate supraventricular arrhythmias.[17,75]

Recurrent episodes of SVT may warrant suppressive antiarrhythmic therapy. In the absence of preexcitation, atrioventricular nodal blocking agents may be used. Extensive use of digoxin in pregnancy has occurred without reported significant side effects. The volume of distribution of digoxin is increased during pregnancy, which may lead to an increased dosage requirement (0.25 to 0.50 mg daily). β-blocking agents and verapamil have been used to suppress SVT.

Atrial fibrillation and atrial flutter may develop in pregnancy. For patients with significant structural heart disease, development of atrial fibrillation or flutter can result in acute hemodynamic decompensation and urgent cardioversion may be required. For patients who need antiarrhythmic therapy to assist conversion, quinidine is a good choice because it has been used in pregnancy for more than 50 years. Quinidine toxicity in the mother can lead to severe nausea, vomiting, diarrhea, light-headedness, and tinnitus. Cardiac effects include hypotension, torsades de pointes, and sudden death. Quinidine crosses the placenta, leading to similar fetal and maternal serum levels. Although neonatal thrombocytopenia has been reported, this agent is classified as relatively safe in pregnancy.[6,76,77] Quinidine also has oxytocic properties at high doses but rarely results in pregnancy loss. It is excreted in breast milk but does not cause major problems for the nursing infant.

Procainamide has also been used for the treatment of atrial and ventricular arrhythmias and is not associated with any developmental abnormalities.[76] Procainamide and its primary metabolite, *N*-acetylprocainamide, are excreted in breast milk but are not associated with adverse short-term effects.[78] Little is known about the long-term impact of this agent on the development of antinuclear antibodies or lupus-like syndromes in the child.

Flecainide and propafenone, both class IC agents, are useful in managing ventricular and supraventricular tachycardias and appear to be relatively safe during pregnancy.[5,17,79] There is more experience with flecainide than with propafenone because it has been used successfully in the treatment of fetal tachycardias. All IC agents should be avoided in patients with prior myocardial infarction or cardiomyopathy due to the increased risk of mortality, as reported in the CAST trial.[80]

Sotalol is a class III agent with noncardiac selective β-receptor antagonist properties and is generally considered safe. Sotalol has become a first- or second-line agent in the treatment of fetal tachycardia.[79] Of greatest concern with

sotalol is the proarrhythmic risk in both the mother and the fetus. Ibutilide and dofetilide are class III antiarrhythmics, which have been released for the acute conversion of atrial flutter and fibrillation in nonpregnant patients. There are no reports of their use in pregnancy, and they should be avoided. Amiodarone is widely used in the conversion of atrial fibrillation/flutter, maintenance of sinus rhythm, and in the treatment of ventricular tachycardia. Amiodarone, however, contains iodine and leads to increased circulating iodine levels.[81] The elevated iodine levels may produce neonatal hypothyroidism. Use of amiodarone in pregnancy is restricted to severe or life-threatening arrhythmias that cannot be effectively treated with other agents.

Although many women experience an increase in ventricular premature beats during pregnancy, few develop nonsustained or sustained ventricular tachycardia. Ventricular tachycardia in patients without structural heart disease generally carries a low risk for mortality and morbidity and can often be treated with β-blocking agents. Patients with long QT syndrome, ischemic heart disease, or cardiomyopathies who have ventricular tachycardia are at higher risk for serious arrhythmias. For hemodynamically tolerated ventricular tachycardia, treatment should begin with lidocaine or procainamide. Lidocaine crosses the placenta and readily appears in the fetal circulation. It has been associated with central nervous system depression in the newborn if high levels are achieved. Nonetheless, it remains appropriate therapy for acute treatment of ventricular tachycardia. Type IC agents, such as flecainide and propafenone, are contraindicated for patients with structural heart disease. Some of these patients may have to be treated with chronic suppressive antiarrhythmic therapy or with implantable devices, depending on the nature of their underlying disorder. Minimal fetal radiation exposure should be required for successful placement of a device during pregnancy.

Cardiopulmonary resuscitation is rarely necessary during pregnancy.[82] Effective delivery of chest compressions may be difficult, and positioning the patient on her left side may optimize blood return from the periphery. If the arrest occurs before fetal viability, efforts should be directed toward maternal resuscitation. If the arrest occurs after this time, the focus of the resuscitation is on both the mother and the fetus, which should be delivered rapidly by cesarean section.

MARFAN'S SYNDROME

The most common cardiovascular manifestations of Marfan's syndrome include myxomatous mitral valve disease with mitral regurgitation, aortic regurgitation, aortic root enlargement, and aortic dissection. Patients with Marfan's syndrome are at increased risk for aortic dissection during pregnancy.[83] Patients at highest risk for this complication are those with significant aortic root enlargement (>4.0 cm) before pregnancy.[83] Even patients without significant aortic root dilatation before pregnancy are at a higher risk for this complication than are patients without Marfan's syndrome.

The use of β-blockers is associated with a decreased rate of aortic root dilatation and a decrease in the progression of aortic regurgitation. These agents also attenuate the risk of aortic dissection during pregnancy. For these reasons, patients with Marfan's syndrome should be treated with a β-blocker throughout pregnancy. Preconception counseling is crucial to examine maternal risk and optimize the medical therapy for women at acceptable risk for pregnancy.

PULMONARY HYPERTENSION

Women with significant pulmonary hypertension are at extremely high risk for maternal morbidity and mortality and fetal demise. Pregnancy in women with Eisenmenger's syndrome is associated with maternal mortality rates from 36% to 39%.[9,84,85] The increased cardiac output and decreased systemic vascular resistance of pregnancy can result in increased right-to-left shunting with worsening cyanosis in patients with Eisenmenger's syndrome (see Chapter 42). Patients with pulmonary hypertension often experience symptomatic deterioration in the second or third trimester and may require hospitalization. Patients can present with fatigue, exertional dyspnea, syncope, chest pain, palpitations, cough, hemoptysis, and leg edema. Premature rupture of membranes is common and should be anticipated.[2,86] Primary pulmonary hypertension is also associated with a high maternal mortality rate, with series reporting rates from 30% to 40%[2,87] and older series reporting rates up to 50%.[85] The increased risk of maternal mortality is seen throughout pregnancy and in the first few weeks following delivery. Death frequently occurs in the early postpartum period and is associated with pulmonary hypertensive crisis, in situ pulmonary artery thrombosis, progressive right ventricular failure, arrhythmias, and sudden death.[2] Recognition of this high maternal mortality rate has led physicians to recommend effective contraception, tubal ligation, and, in the event of pregnancy, early termination.

For patients with pulmonary hypertension who opt to continue a pregnancy, early and prolonged bed rest is recommended.[84] Supplemental oxygen may be helpful. Anticoagulation is recommended throughout gestation (or at least during the third trimester) and in the early postpartum period because in situ thrombosis is a mechanism of maternal demise. Calcium channel blockers, prostacyclins, nitric oxide, and bosentan (an oral endothelin antagonist) are useful therapies for some patients with pulmonary hypertension (see Chapters 42 and 43). Numerous case reports have documented successful use of inhaled nitric oxide and intravenous and inhaled prostacyclins in pregnancy, during labor and delivery, and in the early postpartum period.[86-91]

Avoidance of increases in pulmonary vascular resistance and maintenance of right ventricular preload and contractility are essential in the management of labor and delivery in these patients.[92] Vaginal delivery under epidural anesthesia is recommended. Cesarean section is reserved for obstetric indications because it is associated with greater rates of morbidity and mortality.[93] Oxygen should be administered to minimize hypoxemia, and inhaled nitric oxide or intravenous or inhaled prostaglandins may be used to lower pulmonary vascular resistance. Monitoring in an intensive care unit is recommended for the first several days following delivery.

ENDOCARDITIS PROPHYLAXIS

Antibiotic prophylaxis for bacterial endocarditis is recommended by the American Heart Association for a variety of

dental, respiratory, gastrointestinal, and genitourinary tract procedures if the patient is in a high-risk or moderate-risk category. Patients at high risk for endocarditis include those with prosthetic cardiac valves, a prior history of endocarditis, surgically constructed systemic-pulmonary shunts, and complex cyanotic congenital heart disease. Moderate-risk disease processes include acquired valve dysfunction, such as that associated with rheumatic heart disease; mitral valve prolapse with valvar regurgitation or thickened leaflets, or both; hypertrophic cardiomyopathy; and most other congenital cardiac malformations except for isolated atrial septal defect or repaired atrial septal defect, ventricular septal defect, or patent ductus arteriosus.

Few cases of endocarditis have been associated with delivery. Bacteremia after vaginal delivery was felt to be uncommon, with a reported frequency of 1% to 5%,[14,94,95] compared with rates of 60% to 90% for dental procedures. For this reason, antibiotic prophylaxis is not recommended in the current AHA/ACC practice guidelines for uncomplicated vaginal or abdominal delivery, unless there is suspected bacteremia or active infection.[39] For high-risk patients, prophylaxis during vaginal delivery remains optional. For moderate-risk patients, antibiotics should be administered if complications that increase the likelihood of bacteremia occur during delivery. Many disagree with these guidelines, arguing that complications are usually unexpected and giving antibiotic after a complication occurs exposes a patient unnecessarily. Moreover, reports have documented higher rates of postpartum bacteremia than previous studies, with rates ranging from 14% to 19%.[96-98] Finally, a review of cases of endocarditis complicating pregnancy found significant fetal and maternal mortality rates, 15% and 22%, respectively.[99] Given a higher incidence of bacteremia, the relative low cost of antibiotic prophylaxis, and the major morbidity and mortality of endocarditis, many institutions routinely administer prophylactic antibiotics to moderate- and high-risk patients with valvular and congenital heart disease before delivery.[14] Ampicillin 2.0 g IM or IV plus gentamicin 1.5 mg/kg (not to exceed 120 mg) should be given at initiation of labor or within 30 minutes of a cesarean section, followed by 1 g of ampicillin IM or IV or oral amoxicillin 6 hours later. For penicillin-allergic patients, vancomycin 1.0 g IV is recommended.[39] For moderate-risk patients, a single dose of ampicillin 2 g or vancomycin 1 g is recommended. Practitioners should realize that routine antimicrobial prophylaxis does have its downside. Cost considerations, resultant changes in skin flora with high rates of colonization by resistant staphylococci, and the potential for adverse effects on neonates with resistant bacterial infections must be taken into account when instituting practice guidelines.

Chapter 42

Care for Adults with Congenital Heart Disease

Giuseppe Martucci, Mary Mullen, and Michael J. Landzberg

CHAPTER CONTENTS

Adult patients with congenital heart disease (ACHD) remain a unique and challenging population in need of cardiac follow-up and care. In the United States this rapidly expanding group is estimated to now exceed its pediatric counterparts, with likely more than 1 million adults with congenital heart disease currently surviving.[1] Longevity and improved well-being can be attributed to increased understanding of cardiac and pulmonary vascular physiology, cardiac embryology and anatomic pathology, as well as improved diagnostic studies and advances in medical therapy, pediatric cardiac surgery, and transcatheter management strategies.[2] Included in the ACHD population are young and older adults who remain unrepaired, those who have undergone palliative procedures such as systemic-pulmonary or cavopulmonary shunts, and those patients who have undergone complete surgical and transcatheter repair with or without known residua (Table 42–1).[3]

We continue to observe an increase in ACHD patient complexity. A shift in improved survival of complicated lesions (tetralogy of Fallot, single ventricle, transposition of the great arteries) has led to patients with such diagnoses receiving a greater percentage of attention from ACHD caregivers. Intensity of medical illness has increased as longstanding atrial, ventricular, and pulmonary vascular volume abnormalities have contributed to increased incidence of arrhythmias, ventricular failure, pulmonary vascular disease, and thrombosis. Close interaction between pediatric and adult cardiologists, cardiovascular interventional catheterizers, cardiac surgeons, and primary physicians is necessary for successful care of ACHD patients, within all levels of regional and local care.[4]

ISSUES FOR THE CARE PROVIDER

Endocarditis

Despite improvements in antibiotic therapy and diagnostic strategies, many adults with congenital heart disease remain at lifelong risk from infective endocarditis. Potential for infection occurs in the setting of structural cardiac lesions that generate turbulent blood flow. Transient bacteremia allows colonization of fibrin/platelet meshwork on the endocardial or prosthetic surface, partially sequestering the organisms from host defenses. Unrepaired defects at greatest risk include high-velocity lesions, such as ventricular septal defects (VSDs) and left-sided stenotic or regurgitant valves. Infective endocarditis is rare in low-pressure lesions, such as mild valvar pulmonary stenosis or in secundum atrial septal defect. After complete surgical repair, endocarditis risk may be significantly decreased, unchanged, or increased due to placement of a prosthetic valve or conduit. A 30-year follow-up study addressed the risk of infective endocarditis after surgery for congenital heart defects.[5] The highest incidence was found in patients after repair of aortic valve stenosis with 20.6% experiencing an episode of endocarditis after 30 years. No cases were reported after repair of patent ductus arteriosus, secundum atrial septal defect, or pulmonary valve stenosis.

A high index of suspicion for the presence of infective endocarditis in adults with congenital heart disease should be maintained due to significantly varied clinical presentations. Patients may have definitive microbiologic data or show the classic manifestations of fever, weight loss, night sweats, splinter hemorrhages, Janeway lesions, and Osler nodes. Others may pose diagnostic challenges. Algorithms that combine clinical criteria with echocardiography may assist evaluation.[6,7] Transthoracic echocardiography may demonstrate vegetations, abscesses, new prosthetic valve dehiscence, or valvar regurgitation. Transesophageal echocardiography has a higher sensitivity for the presence of vegetations and may contribute to diagnostic accuracy.[7] Empiric antibiotic therapy is often initiated in the acutely ill patient while microbiologic data are pending.[8] Therapy for active or presumed infection by common bacterial pathogens is discussed elsewhere in the text.

Patients and other medical care providers should be educated about decreasing the risk for infective endocarditis through the use of established guidelines for antibiotic prophylaxis before undergoing dental, gastrointestinal, or genitourinary procedures.[9] In a survey of adult congenital clinic patients, only 68% were able to identify their own heart condition and 79% understood the necessity for antibiotic prophylaxis of dental procedures.[10] Cardiologists are often asked about the necessity of closing a small ventricular septal defect or patent ductus arteriosus to reduce the chance of developing endocarditis. In the modern antibiotic era, surgical or transcatheter correction of a small hemodynamically insignificant

Table 42–1 Palliative Surgical Procedures and Surgical Repairs

Name	Procedure	Indication	Long-term complications
Palliation			
Blalock-Taussig shunt	Anastomosis of divided subclavian artery to right or left pulmonary artery	Tetralogy of Fallot, single ventricle/pulmonary stenosis	Pulmonary vascular disease, pulmonary artery distortion, ventricular volume overload, decreased ventricular function
Waterston shunt	Ascending aorta to right pulmonary artery anastomosis	Tetralogy of Fallot, single ventricle/pulmonary stenosis	Pulmonary vascular disease, pulmonary artery distortion, ventricular volume overload, and decreased ventricular function
Potts shunt	Ascending aorta to right pulmonary artery anastomosis	Tetralogy of Fallot, single ventricle/pulmonary stenosis	Pulmonary vascular disease, pulmonary artery distortion, ventricular volume overload, and decreased ventricular function
Classic Glenn anastomosis	Superior vena cava to right pulmonary artery anastomosis	Single-ventricle physiology	Pulmonary arteriovenous malformations, cyanosis
Bidirectional Glenn	Superior vena cava to right pulmonary artery anastomosis, pulmonary arteries in continuity	Single-ventricle physiology	Cyanosis
Repair			
Mustard procedure	Atrial baffle	D-transposition of the great arteries	Arrhythmias, decreased systemic right ventricular function, baffle leak, baffle obstruction, abnormal atrial volume conduction
Senning operation	Atrial baffle	D-transposition of the great arteries	See Mustard procedure
Rastelli operation	Intraventricular repair and right ventricle-to-pulmonary artery conduit	D-transposition of the great arteries/ventricular septal defect/left ventricular outflow tract obstruction	Conduit obstruction, myocardial dysfunction, arrhythmia
Fontan procedure	Atriopulmonary or total cavopulmonary connection for separation of systemic and pulmonary circulations	Tricuspid atresia, single-ventricle physiology	Arrhythmia, thrombus, protein-losing enteropathy, atrial distortion and abnormal volume conduction, baffle leak
Ross operation	Aortic valve replacement with native pulmonary valve, pulmonary homograft	Aortic stenosis, aortic regurgitation	Pulmonary regurgitation, homograft obstruction, aortic regurgitation
Konno operation	Aortoventriculoplasty	Tunnel subaortic stenosis	Recurrent subaortic stenosis
Arterial switch operation	Anatomic correction with coronary transfer	D-transposition of the great arteries	Supravalvar pulmonary stenosis, supravalvar aotic stenosis, dilation of neoaortic root
Damus-Kaye-Stansel operation	Arterial level repair without coronary transfer	Double-outlet right ventricle (Taussig-Bing type/ subaortic stenosis, D-transposition of the great arteries and coronary pattern not appropriate for transfer)	Native aortic regurgitation, thrombosis in coronary arterial blind pouch
Takeuchi procedure	Intrapulmonary baffle of anomalous coronary artery from the pulmonary artery	Anomalous left coronary artery from the pulmonary artery	Baffle obstruction or leak, supravalvar pulmonary stenosis

ventricular septal defect or patent ductus arteriosus with the primary intent to decrease or eliminate subacute bacterial endocarditis (SBE) risk is not recommended.[11]

Left-to-Right Shunting: General Principles

Patients with the potential for left-to-right intravascular recirculation of arterial blood into the systemic venous circulation pose challenges for health care providers because of the risk of volume overload and the development of congestive heart failure. These shunts depend on both the presence of a physical passage between the arterial and venous circulations, as well as differential resistance to flow within these circuits. Capacitance and resistance to filling in the most proximal downstream chamber or vessel to the existing shunt is the most important determinant of direction and extent of flow. Increased left-to-right shunt flow depends on decreased vascular or ventricular compliance or increased pressure and increased systemic vascular resistance as may occur in the setting of aging, stress, heart failure, and certain hypermetabolic states. Decreased shunting may result from a fall in arterial resistance as occurs in pregnancy, sepsis, and endocrinologic illness. The results of acute volume loss can be mixed on the basis of the effects of decreased blood pressure (BP) versus increased systemic vascular resistance. Assessment of chronic shunting is better performed once such conditions have been corrected. Regardless of the nature and extent of intravascular shunting, and even with predominant left-to-right shunting, the potential for right-to-left passage of even a minute quantity of blood at some phase of the cardiac cycle typically exists. Therefore precautions such as intravenous catheter filtering of particulate or gaseous material should be used.

Cyanosis

Cyanosis is the dark blue discoloration of skin and mucous membranes caused by increased amounts of reduced or abnormal hemoglobin in cutaneous blood vessels. Underlying pathology, extent of skin pigmentation, keratinization, and capillary density may influence the degree of cyanosis. Cyanosis may fluctuate due to alterations in hematologic parameters, as well as changes in cardiovascular, pulmonary, and renal function. Sequelae of long-term cyanosis occur in virtually all organ systems and may have profound consequences.

Generally, clinically evident cyanosis is seen at an arterial saturation of approximately 85%, although in patients with dark skin pigmentation, cyanosis may not be recognized until considerably lower oxygen saturations. Cyanosis most frequently encountered by the physician caring for adults with congenital heart disease is caused by right-to-left intravascular shunting of systemic venous blood into the systemic arterial circulation. This situation depends on either physical obstruction of pulmonary blood flow or elevation of pulmonary vascular resistance. Increased pulmonary vascular resistance may be transient and reactive to secondary stimuli including oxygen, acetylcholine, prostaglandin (PGE1), prostacyclin (PGI2), or nitric oxide or may be more "fixed" with increased arteriolar muscularity, intimal hyperplasia, and decreased numbers of intra-acinar arteries.[12] Major congenital lesions that may present with cyanosis in adulthood include unoperated lesions, such as tetralogy of Fallot and its variants; Ebstein's anomaly; and patients with single ventricle physiology, either repaired or after a palliative procedure. Additionally, patients with unrepaired left-to-right shunt lesions may present with cyanosis secondary to reversed shunting in the presence of elevated resistance or the Eisenmenger syndrome.[13]

Major Cyanotic Organ Complications

Musculoskeletal Changes

The presence of clubbing is a significant accompaniment to central cyanosis. This is a flattening of the nail beds, which causes loss of the normal 160-degree angle between the base of the nail and the adjoining skin.[14] Clubbing is a component of hypertrophic osteoarthropathy, a clinical syndrome that also includes periostosis and joint swelling. The severity of clubbing varies with extent of cyanosis and, in the setting of differential cyanosis, is found only in the cyanotic region. Histologic findings associated with clubbing include dilation and thickening of vascular walls, an increase in blood vessel–associated connective tissue and the development of multiple tiny arteriovenous connections.[14,15] Additionally, increased thickness of the periosteum is observed along with increased bone resorption.

Hematologic Changes

Arterial oxygen content in cyanotic individuals is maintained by compensatory changes in hemoglobin concentration; 2,3,DPG levels; and cardiac output. Increased production of erythropoietin is triggered by tissue hypoxia, which produces an increase in erythrocyte mass and blood volume. This improves oxygen-carrying capacity by increasing hemoglobin; however, extreme elevations in hematocrit may result in symptoms of hyperviscosity.[17] Hyperviscosity syndromes may present as headache, visual changes, mild paresthesias, fatigue, or musculoskeletal symptomatology.[16] Iron deficiency due to reduced deformability of microcytic red blood cells also contributes to increased blood viscosity.[18] Additionally, diminished iron stores affect tissue oxygen delivery as evidenced by a more right-shifted oxyhemoglobin dissociation curve.

Cyanotic patients may be divided into two categories: "compensated" and "decompensated" erythrocytosis.[19] "Compensated" patients are iron replete, have stable volume status and hematocrit, are in multiorgan system balance, and do not experience symptoms of hyperviscosity. "Decompensated" patients are iron deficient and have continually rising hematocrits often due to episodic identifiable and correctable influences (dehydration, acute increase in right-to-left shunting or pulmonary resistance, heart failure, infection, or central nervous system events.) These patients experience symptoms of hyperviscosity requiring phlebotomy that may further increase iron deficiency. Correction of the underlying influence is the primary treatment. Isovolumic phlebotomy is advised only for hyperviscosity symptoms in patients with hematocrit typically greater than 65 gm/dL when adequately hydrated and after correction of potential precipitating factors. Phlebotomy is not advised for an isolated elevation of the hematocrit in "compensated" patients without symptoms. Iron repletion in cyanotic patients should be undertaken with close monitoring to prevent rebound erythrocytosis and hyperviscosity.

An increased tendency for perioperative bleeding has long been recognized in patients with cyanotic congenital heart disease, and numerous abnormalities of hemostasis have been reported in this population. These have included prolonged

prothrombin time, thrombocytopenia, impaired platelet aggregation, and shortened platelet survival. In some individuals, the problem may be compounded by deficiency of vitamin K–dependent clotting factors due to altered hepatic function in the setting of passive congestion secondary to chronic heart failure. The use of anticoagulants and antiplatelet agents in the cyanotic patient has been controversial; however, no data exist to support the increased risk of bleeding associated with long-term anticoagulation. Chronic anticoagulation is typically prescribed if other standard indications, such as atrial fibrillation or a mechanical prosthetic heart valve, are present.

Renal Changes

Abnormalities of renal function are frequently recognized in patients with cyanotic heart disease. Urinalysis results suggesting glomerulopathy have been noted to occur in up to one third of a population of adults with cyanotic congenital heart disease.[20] Associated renal pathology takes the form of altered glomerular architecture including focal glomerular sclerosis, congestion, and mesangial hypercellularity, as well as disorders of renal function. Cyanotic patients have been shown to exhibit decreased glomerular filtration rates, proteinuria, and impaired water handling. Renal dysfunction may be compounded by the use of long-term diuretic therapy or associated decreased ventricular function. Reduction of concomitant risks for acute renal dysfunction, such as ensuring adequate hydration, and dosing medications based on estimates of glomerular filtration rate are advised.

Gout has long been associated with cyanotic heart disease. Cyanotic patients have been found to have increased serum uric acid levels due to decreased fractional urate excretion rather than to increased production. Cornerstones of symptomatic management of acute gouty arthritis in cyanotic patients include the use of colchicine (0.5 to 0.6 mg po Q1 to 2 hours) and corticosteroids (40 to 60 mg PO QD). Nonsteroidal anti-inflammatory agents are generally not preferred as first-line agents due to potential deleterious effects on renal function. Maintenance therapy (allopurinol 100 mg PO QD) may be required for recurrent episodes, although allopurinol may exacerbate decreased renal function as well.

Cardiopulmonary Exercise

Decreased ventricular function has been described in cyanotic patients with persistence after repair in some groups, although causation remains unclear.[22] Contributing factors include age at repair, extent of cyanosis, and the presence of pressure or volume overload. Potential mechanisms for ventricular dysfunction secondary to cyanosis may involve myocardial hypoxia with oxygen demand exceeding supply, as well as altered coronary perfusion due to erythrocytosis, resulting in myocardial necrosis and fibrosis.

Cyanotic patients have been noted to have increased dyspnea on exertion, as well as decreased exercise tolerance. Patients with single-ventricle physiology have been shown to have significant exercise limitations as determined by decreased exercise time, total work performed, peak heart rate, peak oxygen uptake, and arterial oxygen saturation.[23] In normal persons, oxygen demand and CO_2 production are closely matched by circulatory and respiratory changes during exercise. Right-to-left shunting produces changes both in oxygen uptake and ventilation. During exercise, cyanotic patients show decreased oxygen uptake, as well as a delay in establishment of a steady state. In addition, cyanotic patients exhibit higher exercise ventilation than control patients.[24] Presumably, this occurs as a result of increased pCO_2 and hydrogen ion concentration in the systemic arterial system from right-to-left shunting.

Neurologic Effects

A variety of neurologic effects are associated with the presence of chronic cyanosis due to right-to-left shunt lesions. The ability of blood flow to bypass the pulmonary circulation leads to the possibility of embolization to the cerebral circulation of substances that might have been filtered in the lungs. Cyanotic patients are therefore at risk for brain abscesses from septic embolization, as well as for cerebral vascular accidents precipitated by migration of thrombus, air, or foreign particles.[25] The physician should have a low threshold for obtaining brain imaging in the setting of a patient with a fever, headache, or fixed and localizing neurologic signs. Importantly, the differential diagnosis in a cyanotic patient with transient neurologic symptoms includes transient ischemic attacks and infection, as well as hyperviscosity.

Longstanding cyanotic congenital heart disease has been associated with intellectual impairment,[26] decreased school performance, and difficulties with social adaptation including persistence of a dependent lifestyle. However, confounding variables in establishing the effect of cyanosis on social and intellectual functioning include the possible contributions of cardiac surgery and circulatory arrest, the psychological effects of chronic illness, and the influences of parental and societal attitudes given the severity of illness. Throughout life, every potential response to limit and understand these effects should be made to bolster independence and self-confidence.

Recommendations for Management of the Cyanotic Patient

Recognizing and correcting any secondary situations that may provoke increased cyanosis, regardless of underlying congenital pathology, is important. Infection, dehydration, or erythrocytosis can all increase cyanosis. Other precipitants include worsening ventricular function, ischemic myocardial changes, increased atrioventricular valvular regurgitation, increased pulmonary hypertension, and alteration in renal or hepatic function. Not routinely resorting to phlebotomy for increased cyanosis without a search for other correctable causes is also important. Anemia or iron deficiency may cause profound fatigue and worsening symptoms of hyperviscosity. In addition to alleviation of intercurrent illness, therapeutics must be based on a thorough understanding of the underlying pathology causing cyanosis.

In general, steps should be made to increase the amount of oxygen in the blood. This may be performed by improving oxygen-carrying capacity by increasing the hematocrit, by the administration of oxygen if oxygen saturation is low, improving ventilation if pCO_2 is high, and by judicious choice of methods to optimize volume status. Tissue perfusion and oxygen extraction help determine oxygen content of mixed systemic venous blood. Abnormalities of both (e.g., decreased tissue perfusion with profound dehydration or increased oxygen extraction with systemic ventricular failure) may lead to decreased oxygen content of mixed systemic venous blood.

In the setting of intracardiac shunting these changes may account for acute or chronic increases in cyanosis. Thus depending on the clinical situation, patients may need either volume expansion or diuresis.

Augmentation of pulmonary blood flow should use methods to decrease pulmonary vascular resistance. Appropriate measures may include administering oxygen; eliminating acidosis; and the use of specific pulmonary vasomodulators, such as nitric oxide, bosentan, sildenafil, or prostanoids.[27] The use of home oxygen therapy has been suggested to improve pulmonary blood flow in patients with irreversible pulmonary vascular disease.[28] Only open-label trials have been performed with therapies including continuous IV prostacyclin[29,30,31] and continuous inhaled nitric oxide.[32]

Cyanosis may be lessened by improvement in ventricular function. This will occur on optimizing forward cardiac output and improving mixed venous O_2 saturation. Additionally, the use of angiotensin-converting enzyme (ACE) inhibitors even in patients with intracardiac shunting[33] may help to maximize ventricular function, particularly in cases with atrioventricular valvular regurgitation where afterload reduction enhances output. In the critically ill patient, the use of IV agents such as isoproterenol, milrinone, dobutamine, and nitroprusside may prove efficacious, although they have not been studied.

Concern arises about the ability of cyanotic patients to tolerate the reduction of partial pressure of oxygen produced during commercial airline flights.[35] Similar to native residents of high altitude, patients with congenital cyanotic heart disease have been shown to have a decreased ventilatory response to acute hypoxia. This has been shown to return to normal after surgery correcting the cyanosis. These data suggest difficulty in acute respiratory accommodation to atmospheric changes accompanying flight. We recommend minimization of cyanosis before flights if travel is desired or necessary. Metabolic demands and stress should be reduced, with utilization of baggage and transportation assistance coordinated with early airport arrival. Adequate preflight and in-transport rest, nutrition, and hydration are emphasized. Supplemental oxygen is provided at levels of baseline use to maintain oxygen saturations > 80%. If oxygen saturations are below 70% despite supplemental oxygen, even slight unexpected decremental changes might place a patient in jeopardy and air travel would not be recommended.

Pregnancy

Reproductive issues are of major concern for the growing population of young women with corrected or palliated congenital heart disease. Successful counseled and planned childbearing for women and men with congenital heart disease is currently the rule, with limited exceptions as discussed later. In advising such patients, the cardiologist must be familiar with both the physiology of existing cardiac lesions in the gravid state, as well as with contemporary guidelines for genetic screening of cardiac defects. Optimal care is provided in a comprehensive center by a team of specialists including cardiologists, high-risk obstetricians, anesthesiologists, fetal echocardiographers, and geneticists.

Hemodynamic changes occurring in pregnancy may have significant consequences for the patient with congenital heart disease. Increased blood volume, stroke volume, and heart rate lead to augmented cardiac output in the antepartum period. Decline in systemic vascular resistance due to hormonal influences may result in increased right-to-left shunting. The physiologic anemia of pregnancy may exacerbate preexisting difficulties with tissue oxygen delivery. Labor and delivery are accompanied by hemodynamic shifts from pain, uterine contractions, anesthesia effects, and bleeding.

Pregnancy outcomes for women with specific congenital heart defects have been detailed in a number of published reports.[35-38] However, most existing data regarding risks and success of pregnancy in congenital heart disease are anecdotal and may have changed with newer therapeutics. Ongoing efforts are directed at the development of tools for risk stratification of pregnancy-related complications in women with cardiac defects. A retrospective cohort study examined 276 pregnancies in 221 women with heart disease receiving obstetrical care at three major institutions from 1986-1994. Multivariate analysis identified five independent predictors of maternal cardiac events.[39] These included (1) prior cardiac events, (2) prior arrhythmia, (3) New York Heart Association (NYHA) functional class > II or cyanosis during the baseline antenatal visit, (4) left heart obstruction, and (5) myocardial dysfunction. Maternal NYHA class > II or cyanosis during the initial visit independently predicted neonatal complications such as prematurity, respiratory distress syndrome, and small-for–gestational age birth weight. Additionally, a higher proportion of pregnancies ending in miscarriage was found in mothers in each of these two groups. Additive peripartum risk was seen with maternal subpulmonary ventricular dysfunction, in analysis of a separate large congenital heart–specific pregnancy database and similar risk scale assessment.[40] Of note, in neither of the previously mentioned databases were patients with severe pulmonary hypertension enrolled in the study. However, most centers caring for patients with severe fixed pulmonary hypertension (primary or secondary, with or without intracardiac shunting) would argue that such patients carry prohibitive maternal risk of morbidity and mortality.[41] Even in the current era, maternal mortality in patients with the Eisenmenger syndrome approaches 36%.[42]

Recommendations for Managing the Pregnant Patient

If possible, women with congenital heart disease of childbearing age should undergo a comprehensive preconception evaluation including determination of ventricular function, assessment of left heart obstruction, examination for right-to-left shunting, and review of arrhythmias. Analysis of current medications should identify those contraindicated during pregnancy, with particular attention to warfarin and ACE inhibitors. Genetic counseling including karyotype examination or fluorescence in situ hybridization for microdeletion of chromosome 22 should be provided for patients with congenital heart disease, not only for those with identified hereditary defects. Patients are advised that cardiac fetal echocardiography at 16 to 20 weeks' gestation may allow early identification of potential fetal cardiac malformations.

Throughout pregnancy, patients should be followed at regular intervals. In our practice, we evaluate patients at least once during each trimester of pregnancy. Causes of increased cyanosis should be investigated and heart failure should be promptly treated. Strategies that may be employed during

labor and delivery, if necessary, include the use of early epidural anesthesia to control pain and avoid major alterations in systemic vascular resistance, the provision of supplemental oxygen, shortening the second stage of labor, and the employment of techniques designed to decrease volume shifts. The need for cardiac monitoring and/or pulmonary artery catheters should be evaluated on an individual case basis. Vigilance should be heightened in the first 48 hours (and at times up to several weeks) post partum with particular attention to fluid management, hemodynamic status, pulmonary vascular resistance, and potential for thromboembolism. The use of anticoagulant therapy to prevent thrombotic complications in the third trimester and postpartum in patients with right-to-left shunts is controversial. American Heart Association guidelines do not recommend endocarditis prophylaxis for uncomplicated vaginal deliveries or Cesarean section, although many centers deviate from this guideline in practice.[9]

Noncardiac Surgery

The primary cardiologist is often requested to assist in the management of adults with congenital heart disease undergoing noncardiac surgery. Recommendations must be individualized for particular patients and surgeries. A retrospective cohort study examined perioperative morbidity and mortality for 276 adults and children with congenital heart disease undergoing noncardiac surgical procedures.[43] Major risk factors associated with complications included the presence of cyanosis, congestive heart failure, and poor general health. Noncardiac surgical procedures in patients with Eisenmenger syndrome are associated with increased risk for complications.[44]

Recommendations

The primary cardiologist should actively assist in perioperative management decisions. Anesthetic induction regimens should be chosen with regard to their effects of maintaining oxygen saturation, as well as for hemodynamic stability.[45,46] Basic tenets of operative management for patients with shunts include avoiding acute increases or decreases in systemic vascular resistance, which may have important effects on shunt flow and systemic perfusion. Particular vigilance to avoid deep venous thrombosis and paradoxical embolism is warranted—all IV devices should include filters to prevent introduction of air or particles. Appropriate preoperative sedation, as well as postoperative pain control, should use agents that do not lower systemic venous resistance. Because hypovolemia will increase shunting and lower arterial oxygen saturations, patients should be carefully monitored for postural BP swings resulting in increased cyanosis. Scrupulous attention should be paid to control of blood loss and monitoring of the postoperative hematocrit.[46] Antibiotics should be administered according to American Heart Association guidelines for SBE prophylaxis (see Chapter 44).[9] Consideration should be given to overnight observation in intensive care settings for all but minor procedures. Procedures involving potential for marked changes in relative pulmonary blood flow should be performed in centers with expertise in acute IV and inhaled pulmonary vasodilators and ready access to extracorporeal membrane oxygenation support, ventricular assist devices, and organ transplantation.

Arrhythmia

Adults with congenital heart disease are at increased risk for both atrial and ventricular arrhythmias due to longstanding volume load, increased afterload, multiple surgical scars, and myopathic ventricles. Issues of arrhythmias associated with atrial septal defects and repaired tetralogy of Fallot are addressed later in this chapter. Various risk assessment strategies have been suggested to identify ACHD patients at risk for acute tachyarrhythmias and sudden death. Programmed ventricular stimulation (VSTIM) in a selected group of congenital heart disease patients has been used to identify a subgroup with decreased and increased risk of serious arrhythmic events.[47] VSTIM studies were performed on 140 patients with CHD with indications including spontaneous ventricular tachycardia or symptoms of arrhythmia; 38% of these studies were termed "positive" due to induction of sustained or nonsustained ventricular tachycardia. By multivariate analysis, positive VSTIM studies in this population were associated with sixfold increased mortality and threefold increased risk of sudden arrhythmia. However, 33% of patients with previously documented ventricular tachycardia had false-negative test results, thus limiting ability to predict outcome in patients without inducible arrhythmias during a VSTIM study.

Management strategies include antiarrhythmic drugs, transcatheter radiofrequency ablation, surgical maneuvers, and pacemaker or implantable telemetry monitoring for development of proarrhythmia, negative inotropic effects, or symptomatic bradycardia requiring pacemaker placement. Radiofrequency catheter ablation has been successfully used for control of arrhythmias with congenital heart disease and may provide years of freedom from the use of antiarrhythmic medications in selected patients.[48] Similarly, right- or left-sided Maze procedures have been effective in reducing incidence of atrial tachyarrhythmias if performed at the time of cardiac surgical repair.[49] Indications for prophylactic atrial or ventricular pacing, in single or multiple sites, to diminish arrhythmia and to improve atrial or ventricular function require further study.

Exercise and Athletic Participation

Adult survivors of congenital heart disease frequently raise questions about exercise limitations or benefits, or both. A survey of adults at a tertiary referral clinic for congenital heart disease demonstrated considerable patient confusion regarding the appropriate level of exercise for existing cardiac lesions.[50] Exercise tolerance and cardiorespiratory responses to exercise were studied in three groups of adult patients enrolled in the Second Natural History Study of Congenital Heart Defects.[51] Mean exercise duration was below normal at 94.2%, 90.8%, and 86.5% of predicted for patients with pulmonary stenosis, ventricular septal defect, or aortic stenosis, respectively. Several studies have examined the effects of surgical repair of selected cardiac defects on cardiopulmonary exercise capacity. Adults with unrestrictive atrial septal defect demonstrated significantly reduced preoperative cardiopulmonary exercise capacity.[52] At early postoperative follow-up (4 months), slight improvement was present with complete return to normal tolerance 10 years postoperatively. Functional exercise capacity after atrial septal closure is inversely correlated with age at operation.[53] Patients with Ebstein's anomaly

of the tricuspid valve have a reduction in exercise tolerance, which is improved after definitive repair.[54] Patients who have undergone the Fontan operation for tricuspid atresia or single ventricle have considerably lower maximal workload, anaerobic threshold, and maximal oxygen consumption than normal volunteers despite clinical presentation as NYHA functional class I or II.[55] To date, adults with congenital heart disease remain a paradigm for the multitude of comorbidities that combine to engender functional incapacity.[24]

Studies of physical training in patients with severe left ventricular dysfunction have demonstrated that supervised exercise conditioning can produce increased peak oxygen consumption, improve cardiac output, decrease resting heart rate, increase skeletal muscle blood flow, delay lactate accumulation during exercise, and improve sense of well-being.[56] Extrapolation from such data suggests that adult patients with congenital heart disease may benefit from regular aerobic conditioning, which may increase peripheral extraction and hence decrease myocardial work and increase functional capacity. Postoperative exercise training has been shown to benefit children after surgery for congenital heart disease by improving their fitness level.[57,58] However, the safety and utility of exercise rehabilitation programs for adults with congenital heart disease is not known.

Recommendations for athletic participation of adults with congenital heart disease are in evolution. Conservative restrictive guidelines can be extrapolated from the American College of Cardiology consensus statement.[59] Strenuous exercise is most restricted in adults with illnesses when experience has suggested catastrophic potential with exertion. These include severe systemic ventricular outflow obstruction, severe pulmonary hypertension (with near-systemic pulmonary artery BP), aortic root dilation > 4.0 to 4.5 cm, single coronary artery or fixed coronary obstruction, sustained or exercise-induced ventricular arrhythmia, systemic or pulmonary ventricular failure, or pulse oximetry saturation < 70%. Practically, in all other cases, given marked individual variation, we recommend reproduction of the desired level of strenuous exercise under physiologic monitoring. This should include measurement of transcutaneous oxygen saturation; $\dot{V}O_2$ max; anaerobic threshold; VE/VCO_2; duration of exercise and observation for electrocardiographic evidence of arrhythmia or ischemia; and echocardiographic assessment of transvalvar gradient, ventricular function, and pulmonary artery pressure. Risks and goals of athletic participation are then openly discussed with patients and family members.

Transplantation

Cardiac transplantation for congenital heart disease is offered for indications including (1) native cardiac anatomy not amenable to repair or palliation and (2) severe ventricular dysfunction after attempted repair.[60-62] Patients referred for consideration of cardiac transplantation benefit from joint management between adult congenital heart disease specialists and the cardiac transplant team. In some cases it is possible to avoid transplantation after optimizing medical or interventional therapy, or both. Patients considered to be appropriate candidates for transplantation include those with (1) progressively decreased ventricular function despite ongoing medical treatment, (2) requirement for IV inotropic support, (3) malignant arrhythmias unresponsive to standard medical or electrophysiologic treatment including attempted transcatheter ablation or automatic implantable cardioverter-defibrillator placement, and (4) unacceptable quality of life.[60] Complications of cardiac transplantation unique to patients with ACHD include the risk of bleeding after reoperation, adherence of structures to the sternum in patients with previous surgeries, technical difficulties posed by complex anatomy, and recipient sensitization to MHC antigens from multiple previous blood transfusions resulting in higher rates of graft rejection.[60,63]

Preoperative pulmonary hypertension conveys significant risk for post-transplant right heart failure and mortality.[64] In an era before widespread use of effective inhaled or IV pulmonary vasodilators, oral endothelin antagonists and phosphodiesterase inhibitors, and right ventricular (RV) support, patients with initial pulmonary vascular resistance > 2.5 Wood units (comparable with > 100 to 140 dynes-sec·cm^{-5}) were found to have a 3-month mortality rate of 17.9% compared with 6.9% in patients with resistances less than 2.5. All patients undergoing pretransplant evaluation should undergo assessment of pulmonary pressures with pulmonary vasodilator testing if raised pressures are diagnosed.[65] Patients with congenital heart disease and pulmonary artery resistance greater than 8 to 10 Wood units (comparable with 320-540 dynes-sec·cm^{-5}) may be considered for lung or heart/lung transplantation.[66,67] Single-lung transplantation with concomitant cardiac repair has been successfully performed in patients with end-stage pulmonary hypertension secondary to Eisenmenger syndrome; and recovery of impaired RV function has been demonstrated after transplant.[68] Considerations of heart/lung transplantation are generally reserved for patients with increased pulmonary vascular resistance as outlined earlier in addition to left ventricular dysfunction or complex intracardiac anatomy.

GUIDELINES FOR MANAGEMENT OF PATIENTS WITH SPECIFIC CONGENITAL CARDIAC LESIONS

Atrial Septal Defects

Atrial septal defects are congenital defects that allow communication between the left and right atria (Fig. 42–1). Atrial septal defects are typically classified as secundum-type (2-ASD), ostium-primum (1-ASD), sinus venosus, and coronary sinus defects. 2-ASDs comprise approximately 10% of all isolated congenital heart malformations and more than 75% of all ASDs.[69] Embryologically, the defect appears to stem from abnormal development of the septum primum, resulting in a failure to cover the fossa ovalis. 1-ASDs are a form of endocardial cushion defect almost always associated with abnormality of atrioventricular valve formation (in its most benign form "cleft" anterior leaflet of the mitral valve). Sinus venosus defects are located at the entrance of the superior vena cava to the right atrium and are frequently associated with "anomalous" right upper pulmonary venous drainage to the SVC-right atrial junction. They comprise 10% of all atrial septal defects and, compared with other ASDs, sinus venosus type ASDs are more commonly associated with elevation of pulmonary vascular resistance if left untreated. The least common type of ASD is the "unroofed" coronary sinus, which results in a connection between the coronary sinus and the left atrium.

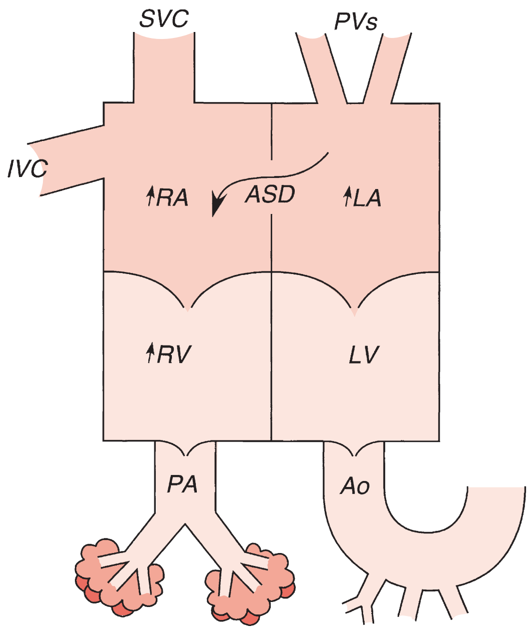

Figure 42–1 ASD physiology. Intracardiac shunting is governed by relative resistance to ventricular filling. Unless RV function is compromised, flow is left to right with enlargement of right-sided chambers. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

Physiologically, the direction and amount of shunting across an ASD depends on the size of the ASD, the respective right- and left-sided chamber compliances, and downstream arterial vessel resistances. Normally, the physiologic parameters are such that shunt flow is from left to right. Over time left-to-right shunting results in volume overloading and ultimately dilatation of the right-sided chambers. We rely primarily on physiologic confirmation of excessive RV volume loading by echocardiography, rather than primary catheterization-based documentation of significant shunting(pulmonary/systemic flow ≥1.5) as evidence of a hemodynamically "significant" shunt, although the superiority of this assessment in predicting clinical morbidity is unproven. We do not perform "routine" catheterization of patients with ASD for determination of intracardiac shunting. Transesophageal echocardiography or MRI, or both, are useful in further defining the location and size of the defect, right-sided chamber sizes, and associated anomalies such as anomalous pulmonary venous drainage.

Large shunts (Qp:Qs > 1.5 to 2.0) increase the risk for dyspnea; congestive failure; atrial arrhythmias; and, less commonly, pulmonary hypertension or paradoxical embolization. Increased shunting may occur with increasing patient age due to decreasing left ventricular compliance associated with aging, systemic hypertension, diabetes mellitus, obesity, and ischemic heart disease. All secondary influences on shunting should be medically minimized before assessing the importance of an ASD. Endocarditis prophylaxis is not recommended for isolated 2-ASDs. Although pregnancy is well tolerated in patients with 2-ASD and even a moderate degree of intracardiac shunting, there remains controversy concerning the need to close such defects before childbirth theoretically to decrease the rare risk of paradoxical embolization through this defect. We do not recommend ASD closure without hemodynamic indication.

Although somewhat controversial, symptomatic patients with large left-to-right shunts appear to have decreased symptomatology and atrial arrhythmias and improved longevity with ASD closure.[70,71] Although surgical patch or primary suture closure (with or without minithoracotomy) of ASDs remains one of the safest and most effective of adult cardiac surgical procedures, significant morbidity may ensue. Increasing age (with medical comorbidities) and the presence of pulmonary hypertension are independent risk factors for increased surgical mortality. Surgical success is generally uniform yet may be accompanied by minor but persistent shunting detectable in upwards of 7% to 8% of surgically treated patients by echocardiography.[72] The incidence of major or minor neuropsychiatric complications after cardiopulmonary bypass in this population has focused attention on transcatheter closure techniques.

In 1959 Hufnagel and Gillespie were the first to implant a device, or plastic button, on the atrial septum (via thoracotomy) to accomplish ASD closure.[73] The first intracardiac use of a double-umbrella–type device was pioneered by King and Mills in 1974.[74] Device design was refined by Rashkind in 1983 to resemble a barbed single disc and later modified to become a more flexible double disc.[75] Lock and colleagues[76] altered the wire configuration to allow springed joints on the device arms, forming the first of the modern "clamshell" varieties of closure devices. Subsequent device modifications (CardioSEAL-STARFlex, NMT Medical, Boston) have incorporated changes in device arm alloy (MP35N) to allow MRI compatibility, adding a second spring to each arm (to reduce and displace device-mediated cardiac stress and lower device profile), and to place nitinol microspring arms in a central interconnecting arm-to-arm mesh (to allow for auto-adjustment and maximal defect closure), as well as creating devices with bioabsorbable potential (Biostar, NMT Medical, Boston). However, double-umbrella devices have not received. Food and Drug Administration (FDA) approval for implantation to close atrial septal defects and therefore are typically used only for small- to moderate-sized (<12- to 14-mm maximal stretch diameter) secundum (2)–type ASDs, in off-label fashion after specific patient–physician discussion. Various types of currently implanted intracardiac closure devices are shown in Figure 42–2.

The only device approved by the FDA for catheter closure of 2-ASDs (for all age groups including pediatrics) is the Amplatzer Septal Occluder (ASO) device (AGA Medical Corp, Golden Valley, Minn). This device is constructed from a 0.004 to 0.0075 nitinol wire mesh, tightly woven into two flat discs (LA disc larger than RA disc), with a 3- to 4-mm connecting waist separating the two discs (with three Dacron polyester patches sewn into the discs and connecting waist, respectively, to increase "thrombogenicity"). The wire mesh can be stretched to form a single wire configuration (allowing transport within a guide catheter-delivery system), although original shape is reformed on deployment due to the memory properties of nitinol. Under FDA requirement, operators must be proctored at their own institutions before achieving independent implanter status.

For potential closure of 2-ASD with all approved and investigation closure devices, the atrial septum can be readily crossed from femoral venous access (on occasion, internal jugular or hepatic venous access may be used). The placement

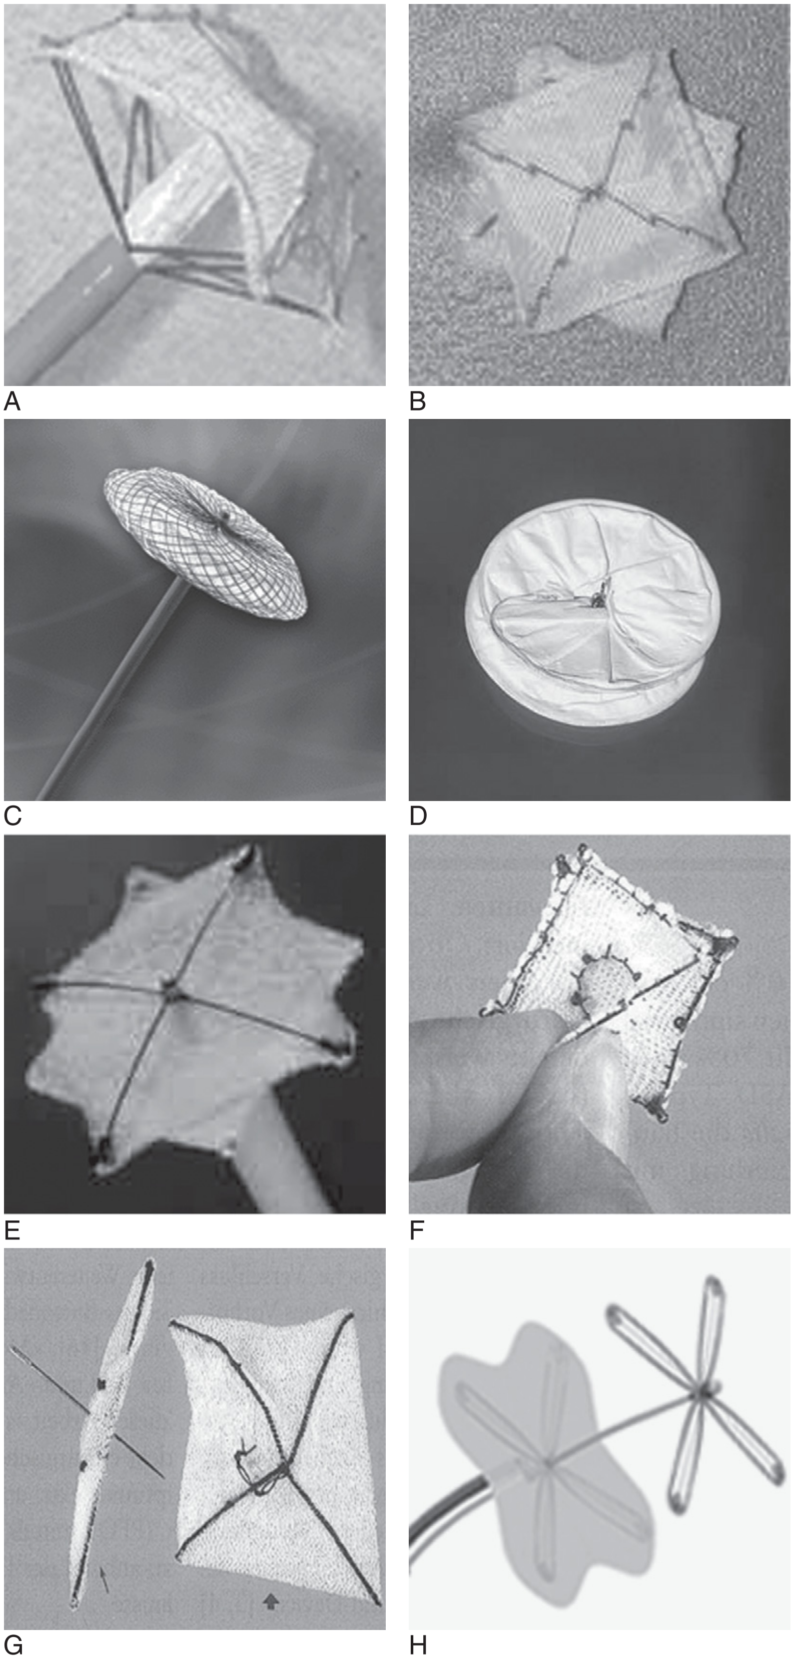

Figure 42–2 Currently implanted intracardiac closure devices. **A,** CardioSEAL-STARFlex (Nitinol Medical Technologies, Boston). **B,** CardioSEAL (Nitinol Medical Technologies, Boston). **C,** Amplatzer PFO Occluder (AGA Medical, Golden Valley, Minn). **D,** Helex occluder (W.L. of a large-caliber guiding sheath allows precise extrusion of compacted expandable devices in the desired location (Fig. 42–3). The majority of septal closure devices are designed as locked or attachable opposing structures that engage the rim of the tissue surrounding a central hole in the heart wall. Routine use of transesophageal echocardiography has been supported by increasing use of intracardiac echocardiography (ICE), and both greatly assist in appropriate device arm placement and success at defect closure.[77]

Clinical experience is greatest with the ASO devices, although in appropriate centers of expertise, results appear similar with various implants including off-label CardioSEAL

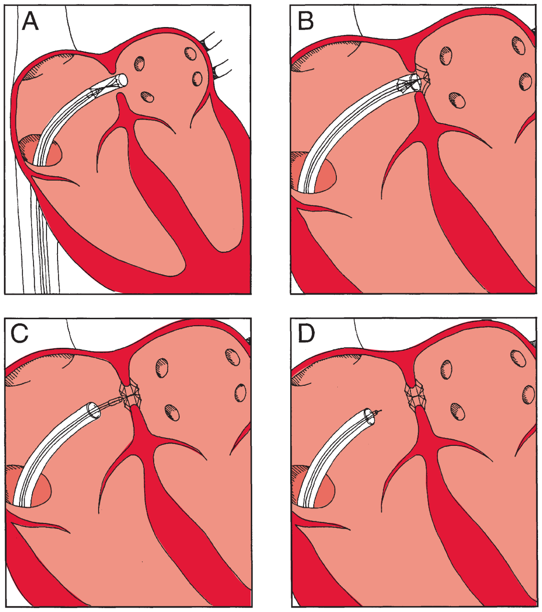

Figure 42–3 Technique of transcatheter deployment of Clamshell occluder for secundum-type atrial septal defect closure.

and investigational HELEX Septal Occluder (Gore Medical Products, W.L. Gore & Associates, Inc., Flagstaff, Ariz) devices.[78-80] Closure rates should typically achieve approximately 95% complete success for centrally located defects, with a < 1% to 7% complication rate and 0% mortality.[78-80] Device-related thrombosis or atrial perforations have been recently highlighted but are uncommon.[81,82] A typical postimplantation medical regimen includes aspirin 325 mg daily for at least 6 months with concomitant clopidogrel and 75 mg daily for 2 to 3 months, although data supporting such recommendations remain theoretic. Antibiotic precautions surrounding dental work or "dirty procedures" are recommended for the maximum of at least 6 months or until no residual bubble contrast shunting is recognized on transthoracic echocardiography.

Recommendations

We recommend closure of ASDs in the presence of echocardiographic evidence of RV volume loading (generally correlating with Qp/Qs > 1.5) that cannot be explained by concomitant confounding intracardiac pathology (e.g., pulmonary regurgitation, tricuspid regurgitation, or anomalous pulmonary venous return). We do not routinely measure Qp/Qs as a determinant for ASD closure. Surgical options are among the most successful of modern cardiac surgical procedures but still carry associated morbidity. 2-ASDs < 36 mm in stretch size (though typically < 32 mm stretch size) are most amenable to transcatheter device closure, though significant diastolic dysfunction and tendency to volume retention may remain. Greatest worldwide experience is with the self-centering Amplatzer ASO device for moderate to large 2-ASDs. This has become a standard of care as therapy. Nickel allergy, device thrombosis, and device-cardiac interaction (as evidenced by potential for early and late device erosions and as residual diastolic abnormalities) highlight the need for more subtle, compliant, and absorbable devices that will likely be fashioned along the double-umbrella motif.

Patent Foramen Ovale

The foramen ovale is a "flap valve" communication between the right and left atria, which in utero allows oxygenated blood from the placenta to preferentially cross over to the left side of the heart and perfuse the upper body. Shortly after birth, the pulmonary vascular resistance drops. Consequently, the left atrial pressure rises above the right atrial pressure, resulting in functional closure of the foramen ovale. In the majority of patients, this leads to fibrosis and scarring with ultimate closure of the "flap valve" communication. However, in up to 25% of the population, permanent closure does not occur, resulting in a patent foramen ovale (PFO). The presence of PFOs has been associated with "idiopathic" stroke/transient ischemic attack, migraine (particularly with aura), platypnea orthodeoxia, and decompression sickness. Despite highly publicized continued use as treatment for stroke, therapeutic closure of PFOs in patients with stroke and presumed paradoxical embolism (PPE) remains controversial because the causes and natural history of these embolic events are unclear.[83-86] The ability of clinical (multiple prior embolic events or silent events by brain scanning, occurrence with Valsalva) or echocardiographic ("large volume" right-to-left shunting, atrial septal aneurysm/hypermobile atrial septum) features to identify patients at high risk for recurrence is unknown, although several lines of evidence suggest that patients with hypermobile atrial septum may be at increased risk.[85] In an attempt to generate most meaningful data (to guide construction of sufficiently powered randomized controlled trials) from the disparate and uncontrolled nature and results of series of both medical treatments and percutaneous PFO closure, we chose to estimate the relative benefit of transcatheter device closure compared with medical therapy via systematic review and pooled analysis.[87] This suggested that approximately two thirds of recurrent thromboembolic events may be prevented by percutaneous PFO closure when compared with medical therapy, corresponding to a 4% absolute reduction in annual events. These data helped lay the foundation for the establishment of ongoing randomized controlled trials assessing the role of PFO closure in addition to short-term medical therapy versus prolonged best medical therapy as treatment for young adults with presumed paradoxical embolization via PFO.

A number of attempts at randomized controlled trials (PC Trial, PEPSI Trial) occurred throughout the past decade but failed largely due to a combined lack of (1) neurologist-cardiologist-primary physician teamwork and coordination of goal and effort; (2) modern precise definition of ischemic neurologic outcome; (3) data to generate realistic hypotheses and sample size requirements; (4) referring physician and investigator motivation to enroll all candidate patients into randomized expert care; (5) industry-based sponsorship of a sufficiently sized trial to adequately address power concerns; and (6) a "tipping point" mentality that stroke associated with PFO is a true and highly morbid disease, requiring study and relief. This milieu has radically shifted, with potential accomplishment of many, if not all, of the previously mentioned limitations, setting the stage for current, randomized, controlled comparison of percutaneous PFO closure and other therapies for persons affected by CS. The largest such trial, CLOSURE-1, is a > 1600-patient, randomized, controlled trial in > 80 participating centers (neurologist principal investigatorships), evaluating cardioSEAL-STARFlex versus tightly controlled

best medical therapy, sufficiently powered to test superiority of percutaneous PFO closure versus medical therapy in persons with imaging-confirmed index stroke, evaluating similar hard neurologic endpoints as primary outcome. A second trial, RESPECT, is a 300-patient trial comparing Amplatzer PFO Occluder PFO occlusion with clinician-determined "best medical therapy," powered to test equivalency of percutaneous PFO closure (trial estimates of < 1% endpoint occurrence) versus best medical therapy in persons with "clinically symptomatic" index stroke, evaluating similar symptomatology as primary outcome (The European "PC" trial was an early precursor to the U.S.-based RESPECT trial). The differences between the two trials (superiority versus equivalency trials, projected number of patients necessary for enrollment, definition of neurologic entry, and outcome criteria) likely belie the industry- and investigator-based differences in underlying acceptance of (1) individual series-based estimates of stroke/TIA recurrence, (2) cardiologists versus neurologists as primary assessors of cerebrovascular health, (3) standardization and precision of definition of ischemic neurologic injury, and (4) desire to be the pivotal concept trial rather than a supportive equivalent therapy.

In light of the previously mentioned trials, we strongly advocate the following measures:

- Rapid investigation of patients with cryptogenic stroke including prompt assessment for and anatomic definition of PFO. Recognition of presence of PFO requires clinician pursuit of diagnosis coupled with appropriate testing tools and technical interpretation. There is a wide range of sensitivity and specificity of currently available diagnostic tests for PFO. Although transthoracic echocardiography with Mueller maneuver (forcing right atrial pressure to bow the atrial septum leftward) may carry high sensitivity and specificity for PFO diagnosis in limited centers, only transesophageal or intracardiac echocardiography currently offer natural and anatomic detail of intracardiac shunting, though likely with lesser sensitivity in diagnosis. Therefore, although individual institutions may offer various "first-line" testing for the presence of intravascular shunting, we recommend transesophageal echocardiography for all patients with cryptogenic stroke and suspected PFO.
- Patient education regarding association of cryptogenic stroke and PFO, with emphasis on recognition of lack of randomized controlled data suggesting superiority of any particular therapy, as well as individual "risk factors" for recurrence of symptomatology. Patients should be counseled that unknown potential for systemic venous thrombosis or embolization persists after percutaneous PFO closure if anticoagulant therapy is not used.
- Removal or reduction of all potential procoagulant risks (e.g., trauma, obesity, inactivity, oral contraception, cigarette use).
- Enrollment of all eligible patients into randomized controlled trials evaluating safety and efficacy of treatment arms. Although we favor answering potential for superiority in trials on the basis of the most rigorous data analysis, both CLOSURE-1 and RESPECT remain reasonable enrollment options.
- PFO closure in patients not eligible for trial enrollment due to stroke recurrence despite compliant medical therapy (current potential after failure of warfarin use under FDA humanitarian device exemption rules for either cardioSEAL or AGA PFO occluder) or with inability to safely comply with medical therapy. Although we favor percutaneous PFO closure, surgical closure should be offered as a reasonable and accepted alternative. We are hopeful that randomized controlled assessment of percutaneous versus surgical PFO closure will occur on the basis of the results of completion of the trials noted previously.

Patent Foramen Ovale and Hypoxemia

Pressure overload of the right atrium may lead to pathologic right-to-left shunting in patients with a PFO. This may accompany chronic alteration of right-sided filling or capacitance (RV infarction, pulmonary embolism, Ebstein's anomaly) or transient decrease in RV filling seen with change from supine to an upright position (orthodeoxia-platypnea syndrome). We have closed PFOs with double-umbrella devices in more than 100 patients with RV infarction, Ebstein's anomaly, and the orthodeoxia-platypnea syndrome.[88] In all but two patients with Ebstein's anomaly, catheter closure relieved cyanosis and symptoms and eliminated the need for open-heart surgery (Fig. 42–4). The long-term benefits of PFO closure in patients with Ebstein's anomaly require further study.

Patent Foramen Ovale and Migraine

The recognition of an association between migraine syndrome with aura (M+A) and PFO appears to have come "full circle" over the past 2 decades. Initial concerns from cardiologists centered around postimplant precipitation of migrainous events "mimicking" original neurologic presentation in persons after percutaneous PFO closure. True incidence was not catalogued but was sufficient to separately raise suspicions for investigators implanting differing closure devices. Effects from general anesthesia, raised ambient catecholamines, particulate metallic embolization, and embolization of procoagulant microaggregates were all theorized as related to occurrence.

Neurologists long suspected M+A as a risk factor for stroke in the young, both from clinical and pathophysiologic concerns. Analysis of the large Lausanne stroke database highlighted the additive risk of M+A in the occurrence of ischemic stroke, particularly in the young.[89] Smaller epidemiologic studies have suggested that PFO prevalence in persons suffering M+A, regardless of occurrence of CS, was as high as that seen in young persons with CS without M+A.[90,91] Etiologic potential for right-to-left passage of as yet unclear circulating factors via PFO in patients with these syndromes requires further assessment.

Despite case series documenting PFO closure effects in persons with M+A,[92,93] given the competing concerns of both precipitation and reduction of M+A in persons with and without prior M+A receiving therapy for PFO, there is little reason, at the present, to expect a given clinical outcome from any specific treatment. Although improved basic etiologic and epidemiologic study of this phenomenon is required, as well as study of the effects of various antiplatelet and anticoagulant postimplant "protective" regimens currently employed, randomized placebo (sham procedure) controlled trials comparing PFO closure with cardioSEAL-STARFlex + short-term antiplatelet therapy versus best medical antimigraine therapy in patients with resistant migrainous symp-

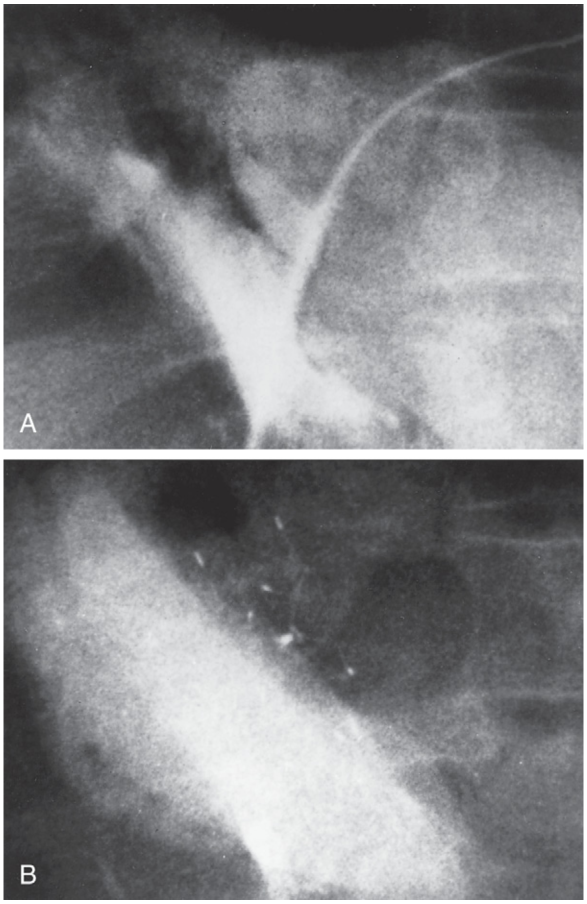

Figure 42–4 Intracardiac passage of contrast across the foramen ovale, from right atrium to left, via a patent foramen ovale (PFO), is noted in this patient with orthodeoxia-platypnea syndrome. Camera is situated left anterior oblique with cranial angulation, with patient laying supine, head towards the top of the page. In **(A)** a wire is seen extending vertically from the bottom (IVC) of the angiogram passing through the right atrium, the atrial septum, the left atrium, and extending to the left upper pulmonary vein (*top right corner*). The patient, status post thoracotomy, was unable to work, given resting aortic oxygen saturation: supine 100%, standing 82%. A clamshell occluder was implanted on the atrial septum, closing the PFO. In a right atrial angiogram **(B)** in similar projection, radiopaque markers highlight the distal most ends of each of the device arms (2 superior arm markers are seen on each side of the septum, with only one inferior left atrial marker visible in this projection), with a more prominent central opacity in the device hub, where all 8 of the arms connect together. Contrast flow is limited by effective PFO closure to the angiographically inferior and leftwardly projected right atrium. After PFO closure, the patient returned to work with finger oximetry: supine 100%, standing 100%.

toms, are completed and awaiting analysis in the United Kingdom (MIST I, and are under way in the United States with both the cardioSEAL-STARFlex, as well as the Premere (St Jude Medical, Inc., St. Paul, Minn) PFO closure system (MIST II and ESCAPE trials, respectively). We do not recommend PFO closure at the present for persons with M+A without CS, though we strongly support further study, within the context of these trials.

Recommendations

The decision to close PFOs associated with presumed paradoxical embolization is complicated by the high frequency of PFOs in the normal population (25%) and the common occurrence of idiopathic strokes in adult populations. Only randomized prospective trials will successfully address these issues. At present, transcatheter PFO closure is recommended for (1) patients with recurrent neurologic events despite compliant medical therapy (Coumadin) or patients with an absolute contraindication to anticoagulation, (2) PFO associated with platypnea orthodeoxia (see Fig. 42–4), or (3) within the constraints of randomized controlled study for control of cryptogenic stroke or refractory migraine.

Biscuspid Aortic Valve

Bicuspid aortic valve is the most common congenital heart defect in the older population, found in 1% to 2% of adults (older than the age of 18 years), and may be associated with other left-sided obstructive lesions, such as aortic coarctation. Progressive pathological dilation of the aortic root, with or without dissection, may be seen even in the absence of obstructive gradient or regurgitation. Stenosis of the bicuspid valve is associated with (though not dependent on) increasing age and presence of fibrocalcific disease. Aortic insufficiency occurs in younger patients and may be an isolated hemodynamic lesion, due to endocarditis or cystic medial necrosis/aortic root dilation. Endocarditis prophylaxis is recommended for all adults with bicuspid aortic valves.

Although the First and Second Natural History of Congenital Heart Defects Studies outlined the course and treatment of bicuspid aortic valve disease primarily in infants and children, the natural history of bicuspid aortic valve disease and criteria for intervention in the older patient are less well defined.[94,95] Sudden death in the occasional asymptomatic patient with apparent preserved ventricular function and only moderate obstructive gradient suggests inability to extrapolate from natural history and intervention studies derived from adults with acquired calcific stenosis.

Surgical aortic valve replacement is the treatment of choice when aortic root surgery is required. Preference for the more detailed pulmonary autograft to the aortic position and subsequent homograft implantation into the pulmonary position ("Ross" procedure) compared with "standard" homograft, tissue, or prosthetic valve alternatives has fallen out of favor. Excellent results can be obtained with all the approaches noted earlier, although each procedure carries its own immediate and long-term complications.

The acceptance of balloon aortic valvuloplasty (BAV) as palliation for children with bicuspid aortic stenosis is in contradistinction to the treatment of elderly patients with calcific AS. Two reports have underscored the utility of BAV in selected young and intermediate-aged adults with noncalcified stenotic aortic valves.[96,97] Patients with increased valvular calcification demonstrated a trend toward higher gradients both before and after BAV and decreased incident-free survival compared with patients without calcified valves. Balloon-mediated worsening of aortic regurgitation, a rare adverse

sequelae of BAV, did not preclude potential for subsequent successful surgical valvuloplasty.

Recommendations

The previously mentioned findings support BAV for non-calcified congenital bicuspid aortic stenosis in young- and intermediate-aged adults. This procedure can provide effective palliation and prolong the interval to surgical intervention without significantly increasing cardiac morbidity or serious complications. Immediate recognition of the uncommon complication of balloon-induced avulsion of a valvular cusp during BAV allows effective and timely surgical therapy. Surgical options remain acceptable for the symptomatic patient with calcific disease, noncalcific disease associated with enlarged aortic root (>4.5 cm) or greater than or equal to moderate valvar regurgitation. We recommend an attempt at balloon valvuloplasty for symptomatic patients 40 years old and younger with at most a mildly calcified bicuspid aortic valve, gradient ≥ 60 mm Hg with preserved ventricular function, or gradient < 60 mm Hg with associated ventricular dysfunction. Despite treatment of valvular disease, vigilant lifelong assessment of the ascending aortic health is warranted.

Pulmonary Stenosis

Pulmonary stenosis (most commonly valvar, although branch pulmonary artery and subvalvular obstruction can occur as well) occurs in > 10% of patients with congenital heart disease. Adult presentations may range from no symptomatology to profound fatigue and dyspnea, depending on the degree of stenosis and RV impairment.

The First and Second Natural History of Congenital Heart Disease Studies led to classification of degree of stenosis as mild (RV systolic pressure ≤ 50 mm Hg), moderate (RV systolic pressure 50 to 100 mm Hg), or severe (RV pressure > 100 mm Hg).[98] Given the unclear natural history of valvar pulmonary stenosis in adults, criteria for timing and nature of intervention has become dependent in large part on development of symptomatology, extrapolation from the natural history in children, and decreasing risk of interventions.

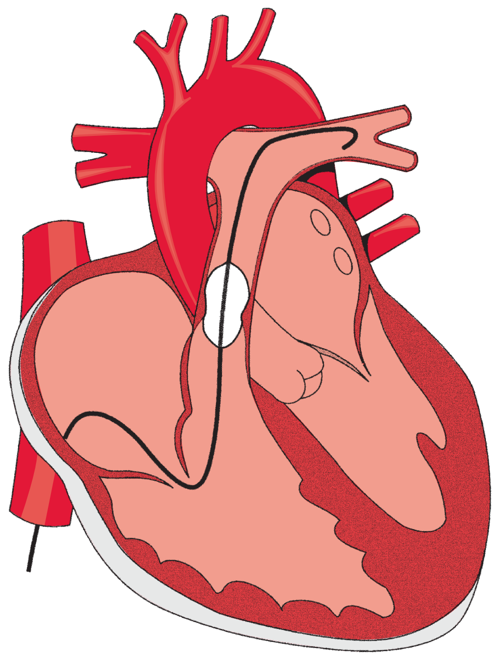

Figure 42–5 The technique of balloon pulmonary valvuloplasty.

Although open surgical valvotomy was historically the initial therapeutic approach, the present treatment of choice for patients with nondysplastic valvar pulmonary stenosis is balloon pulmonary valvuloplasty (Fig. 42–5). Numerous single-center reports (each with 4 to 53 patients) have demonstrated similar immediate gradient reduction with BPV in young and middle-aged adults, aged 13 to 55 years, using standard single, Inoue, or double balloon techniques to achieve a balloon-to-annulus ratio between 1.1 and 1.4.[99] The mean follow-up in these series ranged from 0.5 to 6.9 years and, when compared with results in pediatric-aged individuals, revealed a decreased incidence of periprocedural morbidity and restenosis in the adult. Hemodynamically compromising or therapy-requiring infundibular spasm is uncommon and has not been seen in either our experience or in the largest reported series, although individual instances of surgically treated pericardial tamponade, severe infundibular obstruction, periprocedural sepsis, and postprocedural diffuse pulmonary edema have been reported. Brief inflations with rapidly deflating balloons allow avoidance of prolonged reductions in cardiac output in the elderly or those with low output at baseline. Pulmonary regurgitation after BPV is usually mild, though single-center study suggests high potential (40% of cohort) for surgical valve intervention at late (30-year) follow-up.[100]

Recommendations

Given the low attendant morbidity of BPV, we perform this procedure for any adult patient with gradient > 40 mm Hg and normal RV function (lower gradient if cardiac output is reduced, RV systolic function appears subnormal or RV end diastolic pressure is > 12 mm Hg) either in the individual with unoperated valvar PS or with recurrent VPS after initial surgical treatment. Long-term follow-up for potential effects of pulmonary regurgitation on RV function is warranted.

Aortic Coarctation

Aortic coarctation (CoA), typically a narrowing of the descending aorta at the site of insertion of the ductus arteriosus, distal to the origin of the left subclavian artery, occurs in 5% to 10% of patients with congenital heart disease. An accompanying bicuspid aortic valve is present in 40% to 80% of patients with CoA.

Clinically detectable CoA in the adult, with a resting gradient ≥ 20 mm Hg between upper and lower extremities, carries an increasing risk of progressive left ventricular dysfunction, persistent systemic arteriolar systolic hypertension, premature cerebrovascular and coronary atherosclerosis, and the potential for dissection or rupture of the aorta and coronary or cerebral vessels (especially during pregnancy, surgery, or catheterization) (Fig. 42–6). Diagnostic modalities employed to confirm the diagnosis of aortic coarctation and further delineate precise anatomic detail, the presence of cerebral vascular anomalies, and the presence of LV hypertrophy are echocardiography and MRI.

Because of a combination of amplification of the gradient wave, as well as stress on the myocardium and vasculature at all portions of ejection phase in the cardiac cycle (ventricular-arterial coupling), the effects of seemingly “mild” gradients across CoA may be profound. We consider indications for repair to be (1) the presence of a resting gradient ≥ 20 to 25 mm Hg with normal LV function, (2) less gradient with accompanying abnormal LV function, or (3) systemic hypertension that requires more than “simple” therapy to achieve normotension. Surgical end-to-end, or bypass, repair has previously been the standard approach, with excellent results and perioperative mortality of ≤ 2% for native CoA repair. Perioperative concerns of low, but present, risk of spinal cord ischemia or bleeding from collateral vessels are amplified in the patient with recurrent stenosis after initial repair. Late postoperative complications including the development of aortic aneurysms and recurrent coarctation have been reported in up to 20% of patients undergoing surgical repair, although the surgical risk of mortality at reoperation, paraplegia, and late aneurysm formation has been estimated at ≤ 2% at appropriate centers. A high incidence of late postoperative recurrence of systemic hypertension, inversely correlated with age at repair, has been noted. Patients must be screened on a continuous basis for sequelae of aortic and systemic capacitance vessel noncompliance, aneurysms of the cerebral vasculature,[101] aortic dissection, and premature coronary atherosclerosis. We recommend that patients be examined yearly with particular emphasis on symptoms suggesting lower extremity or coronary ischemia or cerebral aneurysm. In addition, we suggest noninvasive imaging with MRI every 3 to 5 years (more frequently if aneurysm or restenosis is present) and exercise testing as suggested by history and examination.

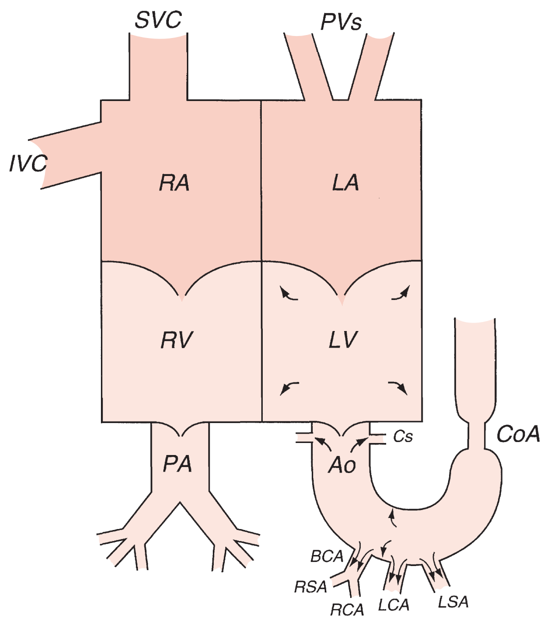

Figure 42–6 Aortic coarctation physiology. Narrowing in the descending aorta, just distal to the origin of the left subclavian artery. Wall stress is raised in all proximal chambers and vessels, leading to potential for advanced atherosclerosis, vascular dissection or rupture, and chamber hypertrophy. BCA, brachiocephalic artery; CoA, aortic coarctation; LCA, left carotid artery; LSA, left subclavian artery; RCA, right carotid artery; RSA, right subclavian artery.

In children and adults, balloon dilation or stenting of recurrent, or persistent, CoA following surgical correction is now considered the therapy of choice. Moreover, balloon dilation or stenting is also considered an effective alternative to surgical correction as therapy for native CoA, with up to 15-year follow-up reported at some centers.[102-109] Success (defined either as gradient reduction of ≥ 50% and an increase in angiographic luminal diameter ≥ 30% or, more recently, as a residual gradient ≤ 20 mm Hg with near universal reduction in antihypertensive therapy) is high (>80%) and morbidity is low using balloons chosen to be 3 to 4 times the diameter of CoA and not more than 150% the transverse arch diameter. Estimates of complications include procedure-related death in 0.7%, periprocedural stroke in 0.6%, transmural (0.7%) or intimal dissection (1.6%) with rare need for surgical intervention, and postprocedural aneurysm (7% to 12%). Risk of complication may be increased with increasing age and in the presence of concomitant bicuspid aortic valvular disease.[110] Balloon-assisted stenting of the aorta (Fig. 42–7) without prior maximal balloon dilation permits use of smaller, non-“oversized” balloons, theoretically with less risk of dissection and rupture of the aortic wall.[111] Care should be taken to avoid extrapolation of results obtained with similar techniques in children to the adult population, especially given the potential for increased changes in capacitance, compliance, and atherosclerosis in the walls of conduit arterial vessels proximal to the CoA. The relative safety of surgical versus transcatheter balloon/stenting repair of CoA in adults who may wish to face future pregnancies or sustain significant physical exertion remains to be clarified. Standardization of indication, procedural technique, follow-up, and outcomes assessment remains the major limitation of most studies. The usefulness of surgery versus endovascular transcatheter therapies, when concomitant aortic dilation or aneurysm is present, remains undefined. We await results of newly formed interventional registries, as well as studies assessing ventricular-arterial coupling,[112-114] to better assess safety and efficacy of catheter-based and surgical therapies.

Recommendations

We recommend balloon-assisted stent implantation, or balloon dilation alone, as effective alternative therapy for all adults with native or recurrent CoA and > 20 mm Hg gradient, or < 20 mm Hg gradient with decreased LV function or symptoms of LV failure, coronary ischemia, or lower extremity claudication. Definition of indication and technique for catheter-based, as well as surgical intervention based on natural outcomes in the modern era, coupled with standardized long-term follow-up, is eagerly awaited. We consider long-term annual interviews and examinations coupled with noninvasive imaging at intervals ≤ every 3 to 5 years to assess systemic arterial and left ventricular sequelae after CoA repair to be essential. Optimal management of the patient with aortic coarctation with associated aortic dilation remains undefined.

Tetralogy of Fallot

Tetralogy of Fallot (TOF) is the most common cyanotic congenital lesion that allows survival into adulthood, with approximately 2000 new persons reaching adulthood with TOF each year in the United States. Modern understanding of

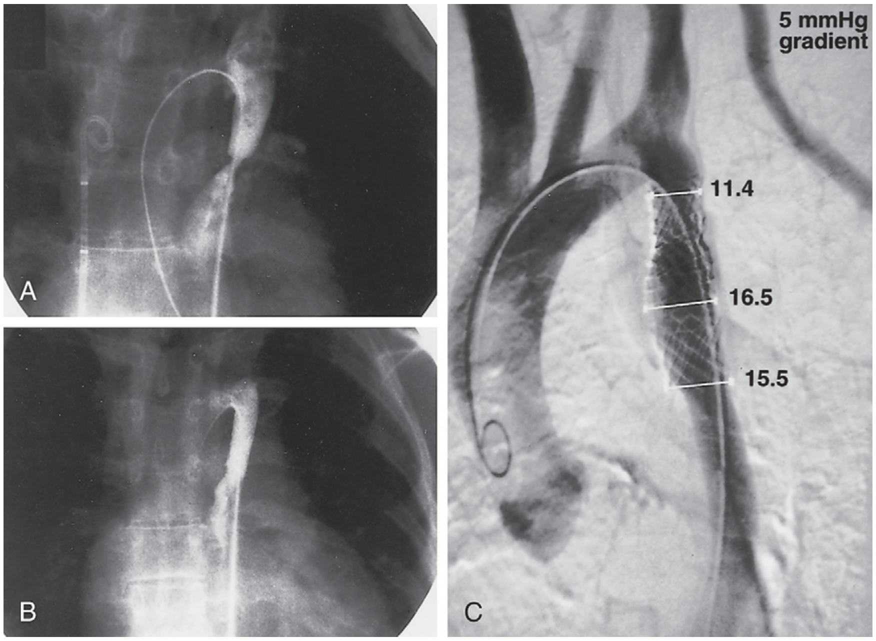

Figure 42–7 **A,** Unrecognized coarctation of the aorta (80 mm peak systolic gradient) leading to left heart failure and premature atherosclerosis of the coronary and cerebral arterial vasculature. Initial balloon dilation and stent implantation, with small distal dissection (**B**), later covered with a second stent (**C**). A residual gradient across the entire segment of < 5 mm Hg was noted.

TOF considers this lesion to more appropriately be classified as "monology" (i.e., caused by a single unifying abnormality, namely hypoplasia and displacement of the conal, or infundibular, septum). This anterior and superior displacement results in obstruction of the RV outflow tract (pulmonary stenosis) with resultant RV hypertrophy, leaving behind a ventricular septal defect in the conal septum (Fig. 42–8). The aortic annulus is intimately opposed to the conal septum, and displacement of one leads to opposing displacement of the other (i.e., posterior inferior displacement of the aortic annulus taking a position overriding the ventricular septum).

The degree of hypoplasia and septal malalignment determines the severity of encroachment into the RV outflow tract (although always associated with a large conoventricular VSD) with clinical presentations ranging from (1) minimal RV outflow obstruction ("pink" TOF) with predominant left-to-right shunting; (2) moderate RV outflow obstruction (most common), with bidirectional shunting and cyanosis; and (3) severe forms of RV outflow obstruction (pulmonary atresia) in which cyanosis is obligatory and pulmonary artery flow arises from persistent primitive aorta-pulmonary artery collaterals.

In patients with TOF/pulmonary atresia, aorta-pulmonary artery collateral vessels make up many/all of the various subdivisions of the lung vascular tree, ranging from the main or central pulmonary arteries (which may be absent) to individual/multiple proximal branch pulmonary arteries, to subsegments of lung vasculature. These collaterals frequently have failed involution, have retained stenoses and abnormal vascular walls, and may undersupply or oversupply particular lung segments.

Although TOF is typically diagnosed and repaired in childhood, presentation during adult years can occur in patients who have previously undergone palliative operations, as well as in those without prior operations. In the past, before development of a successful complete repair strategy, patients were managed with systemic-pulmonary arterial shunts (central Waterston, Potts, and classic/modified Blalock-Taussig shunts; also see Table 42–1). Residual postoperative shunt complications include pulmonary artery distortion or pulmonary vascular disease/hypertension, and peripheral pulmonary artery stenoses. Complete repair of TOF includes obliteration of any preexisting shunts, elimination of RV outflow obstruction (with or without transpulmonary annular incision and patching), and VSD closure. Additional residual postoperative lesions may include residual VSD, RV outflow obstruction, and pulmonary regurgitation.

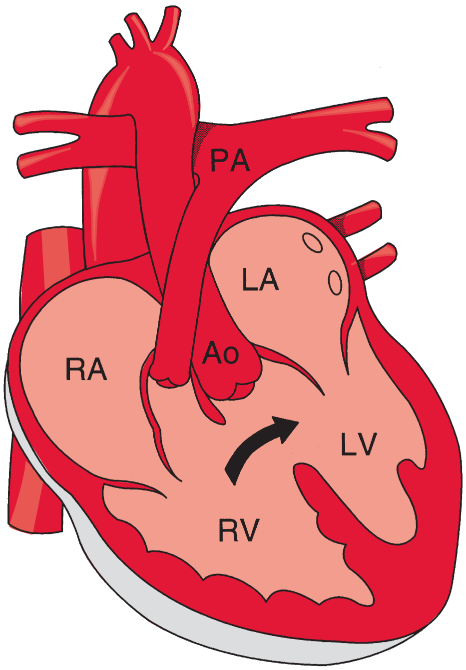

Figure 42–8 Tetralogy of Fallot.

Data regarding long-term follow-up of repaired TOF reveal excellent long-term survival after the initial operative period, with 32-year survival of 86% compared with 96% in a control-matched population, and appear most favorable when (1) VSD is closed, (2) RVOT obstruction is near completely relieved, and (3) severe PR and RV dysfunction is not present.[115] Multicenter data have suggested 35-year survival > 90%.[116] Although the majority of patients have excellent

functional capacity, some patients experience exercise limitation, right or left ventricular failure (Table 42–2), RV outflow obstruction or aneurysms (<29%), arrhythmia (<33%), and sudden death (1% to 3%).[117] Although promising, data regarding surgical repair of tetralogy for neonates and young infants are insufficient to assess long-term outcomes.[118,119]

Implicated risk factors for death after TOF repair have most commonly been sought as risks for sudden cardiac death, with little discrimination between worsened functional status and cardiac muscle dysfunction leading to premature death versus presumed arrhythmic death. These risks have been mostly defined in single-center cohort studies, with more robust data from multicenter combined assessments.[118,120] Of note, most series have not considered immediate surgical risk in such assessments (see later) and have excluded either immediate or first-year nonsurvivors, who frequently comprise a substantial population (some series up to 10% to 30%).[115,121] Single-center cohorts have continued to suggest older age at repair, prior presence or absence of palliative shunts, radiographic cardiothoracic ratio, presence of RV outflow tract patch, increased RV systolic pressure, and LV dysfunction as makers for poor outcome, in addition to pure electrical markers. Multicenter trials have emphasized older age at repair and presence of pulmonary regurgitation,[116] as well as older patient age, presence of prior palliative surgery, and increased radiographic cardiothoracic ratio as independent risks for poor outcome,[118] in addition to specific additional markers of electrical instability.

Increasing time from surgery, in and of itself, has been postulated as changing the risk of death post TOF repair, with single-center cohort data confirming risk of sudden death increasing from 1.2%, 2.2%, 4%, and 6% at 10, 20, 25, and 35 years after operative repair, with mortality risk of 0.27%/year until 25 years after surgical correction and 0.94%/year thereafter.[121]

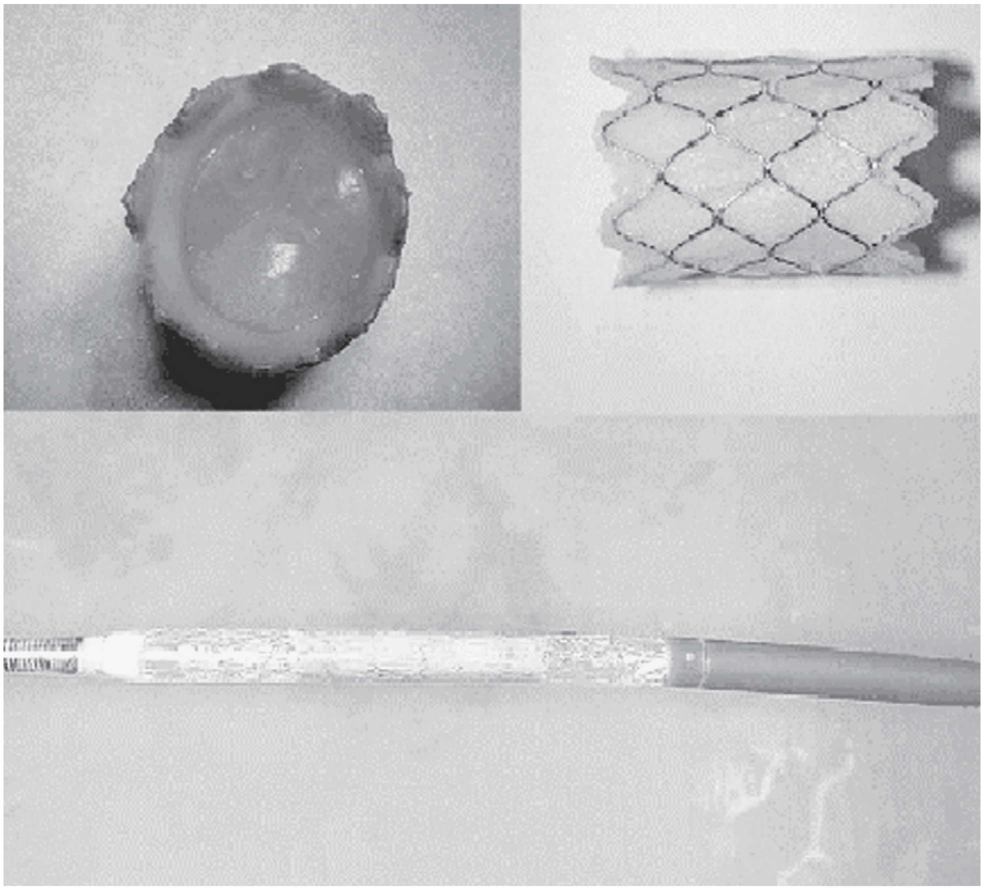
Risks for worsened functional capacity after surgical repair of tetralogy have been studied in a more modern era, using NYHA functional status (with its subjective limitations) as a standard of functional ability. RV outflow patch, as well as transannular patch repair, had similar risks for worsened functional ability, as well as for cardiac death, in single-center cohort assessment.[1] A single-center cohort study using MRI measures of RV and LV function suggests not only older age at repair, but lower LVEF and RVEF (correlating with each other, as well), as markers for worsened clinical status by NYHA functional class,[122] confirming older reports of the importance of LV function in patients with tetralogy.[123-125] Of note, in this single-center study,[126] PR fraction and RV diastolic dimensions did not independently correlate with functional status. Similar findings raising questions regarding the negative predictive potential of PR fraction include additional single-center cohorts emphasizing presence of RV outflow aneurysm or akinesia as an independent risk for worsened function (rather than PR fraction),[127] as well as lack of RV functional improvement in single-center reports after surgical PV replacement for pulmonary regurgitation in patients with tetralogy.[128,129]

Atrial arrhythmias including sinus node dysfunction, atrial flutter, and atrial fibrillation have been noted in up to one third of repaired patients and correlate with the presence of old scar or hemodynamic abnormalities. Acute intervention is frequently recommended, especially with associated ventricular or atrial dysfunction. Control of frequently recurring or incessant atrial flutter may be equally effective with radiofrequency ablation compared with the most effective medical therapy, and strategies are frequently combined. Late-onset complete heart block has been diagnosed with an incidence of 4% after a mean follow-up of 20 years.[130] The strongest risk factor for the development of complete heart block is the presence of perioperative complete heart block at the time of surgical repair.

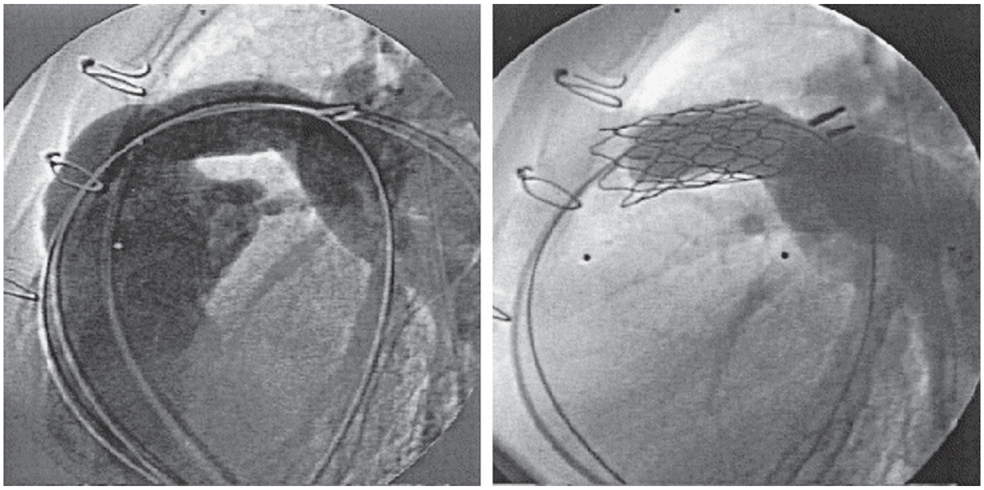
Although pulmonary valve replacement has been proposed as a treatment option for symptomatic patients, several investigators noted that placing a pulmonary valve in patients with severe RV dilatation and dysfunction may not lead to adequate functional recovery of the RV.[131-133] These observations have led several centers to advocate pulmonary valve replacement before the onset of symptoms in order to preserve RV mechanics.[131,134,135] Uncertainty regarding the optimal timing of intervention continues. Although PR is the primary source of chronic RV volume overload in these patients and correlates closely with RV size, major adverse clinical outcomes in adults with TOF and PR including death, high-grade ventricular arrhythmia, and heart failure relate primarily to effects of PR on the RV myocardium-dilatation and dysfunction, as measured by end diastolic volume Z scores and increasing myocardial fibrosis.[136,137] Until these predictors are better defined, we currently recommend following all patients with TOF and pulmonary regurgitation with serial MRI (RV forward and regurgitant volumes, ventricular function and scarring, and presence of additional anatomic abnormalities) combined with assessment of functional capacity (cardiopulmonary metabolic exercise testing) and electrocardiographic and rhythm parameters, to assist in the accumulation of sufficient potential predictive data.

An investigational percutaneous pulmonary valve has been developed, using bioprosthetic valve leaflets (bovine jugular vein) mounted on a balloon expandable stent (Fig. 42–9).[138,139] Initial procedures have been conducted within regurgitant tube conduits with relatively definable diameters, although eventual extrapolation of technique to larger and less definable outflow positions is expected.

After surgical repair of TOF, patients may have a ≤ 25% incidence of recurrence or residual obstruction at any level of



A



B

Figure 42–9 Percutaneous pulmonary valve stent implantation. **A,** De novo bovine jugular vein valve sutured within stented framework and on delivery balloon, when implanted. **B,** results in no pulmonary regurgitation on angiography. Bottom **(B)** left angiogram taken in a lateral position with patient's head toward the top of the page, notes sternal wires in vertical positioning on the left. Wires extend from the inferior vena cava (off the bottom of the page) to the right atrium and ventricle (vertically along the left side of angiogram), through the pulmonary valve and main pulmonary artery (superior horizontal coursing), extending to the more distal pulmonary arteries (vertically along the right side of the angiogram). In systole (bottom left angiogram), contrast fills the right ventricle, right ventricular outflow and main pulmonary artery and distal pulmonary arteries. The struts of the stented valve implant are minimally visible in the pulmonary valve position (superior horizontal portion). The stented valve must be in the open position, allowing passage of blood and contrast to the distal pulmonary vasculature. In the bottom rightward angiogram, taken in simlar angulation in diastole, contrast does not regurgitate back to the right ventricle after passage to the pulmonary arteries. The struts of the stented valve are well visualized. (Modified from Bonhoeffer P, Boudjemline Y, Saliba Z, et al: Percutaneous replacement of pulmonary valve in a right ventricle to pulmonary artery prosthetic conduit with valve dysfunction. Lancet 2000;356:1403-5; and Bonhoeffer P, Boudjemline Y, Qureshi SA, et al: Percutaneous insertion of the pulmonary valve. J Am Coll Cardiol 2002;39:1664-9.)

the RV outflow. In adults, use of balloon dilation and balloon-assisted stent implantation as primary therapy for native and postoperative narrowings in the RV outflow (with or without conduit/homograft placement), as well as in the proximal and distal pulmonary vasculature, have success rates similar to those observed in children. Pulmonary artery dilations are the most commonly performed interventional procedures in our catheterization laboratory (Fig. 42–10). A strategy combining dilations with low- or high-pressure balloons may achieve up to 75% procedural success in relief of obstruction in peripheral pulmonary arteries (defined either as an increase of ≥ 50% of predilation vessel diameter, an increase of > 20% of flow to the affected lung, or a decrease of > 20% in systolic RV-to-aortic pressure ratio).[140] Dilation of vessels that exhibit kinking or significant recoil (proximal branch PAs) can be improved with placement of intraluminal stents, achieving a > 90% initial procedural success rate.[141] Stent implantation within stenotic valved homografts or conduits must be tempered by the potential for an increase in pulmonary valvar insufficiency. Complications of conduit/vessel rupture, aneurysm formation, or development of high-flow reperfusion edema may occur and infrequently (each < 1% incidence) have been correlated with oversizing balloons (especially in calcified conduits or homografts) and with postprocedural mean PA pressures ≥ 40 mm Hg. Balloon dilation or stent implantation remains the procedure of choice for such patients when additional surgery is not required and when obstruction is at the level of the pulmonary trunk or beyond.

We have extended these dilation techniques to adult patients with either isolated peripheral pulmonary artery stenoses or acquired chronic distal thromboembolic pulmonary hypertension (Fig. 42–11).[142] Most were profoundly debilitated and were referred for evaluation for lung transplantation. The most frequently encountered complication was early development of transient reperfusion pulmonary edema in segments of lung with restored pulmonary blood flow after dilation. After 3 to 4 years of follow-up, survivors have improvement in exercise tolerance.

Embolization coils (see PDA), vascular occlusion devices, and covered stents have been used in adults with TOF to eliminate both residual central aorta or systemic artery to pulmonary artery shunts, as well as duplicate aorta to pulmonary artery collateral vessels.

Recommendations

The adult with repaired TOF faces excellent chances of prolonged survival. Long-term risks include development of (1) RV central or peripheral outflow obstruction, (2) pulmonary regurgitation, (3) RV dilatation and scarring, (4) residual shunting at the septal, aorta-pulmonary shunt or collateral level, (5) conduction disease with potential heart block, (6) atrial arrhythmias, (7) ventricular arrhythmias, and (8) sudden death. Patients should undergo annual interview and physical examination, pulse oximetry, and ECG. We recommend 24-hour ambulatory ECG monitoring every 2 to 3 years and either echocardiography or MRI every 3 to 5 years, more frequently if anatomic, arrhythmic, or functional abnormality is documented. Exercise and metabolic cart cardiopulmonary testing should be performed every 3 to 5 years. We consider balloon dilation or stent implantation to be the procedure of choice for relief of outflow obstruction and transcatheter embolization to be the procedure of choice for elimination of residual shunting/extraneous vessels when additional surgery is not required. The role of percutaneous pulmonary valve implantation as compared with surgical valve replacement and RV remodeling remains undefined. Although electrophysiologic study (EPS) may highlight highest-risk populations for sudden cardiac death (SCD), widespread application of EPS to the total adult TOF population remains impractical given the relatively low overall SCD rate. Aside from the group of TOF adults experiencing aborted SCD, there remains little consensus regarding other subsets of patients with TOF for whom benefit would exist with prophylactic implantation of ICD.

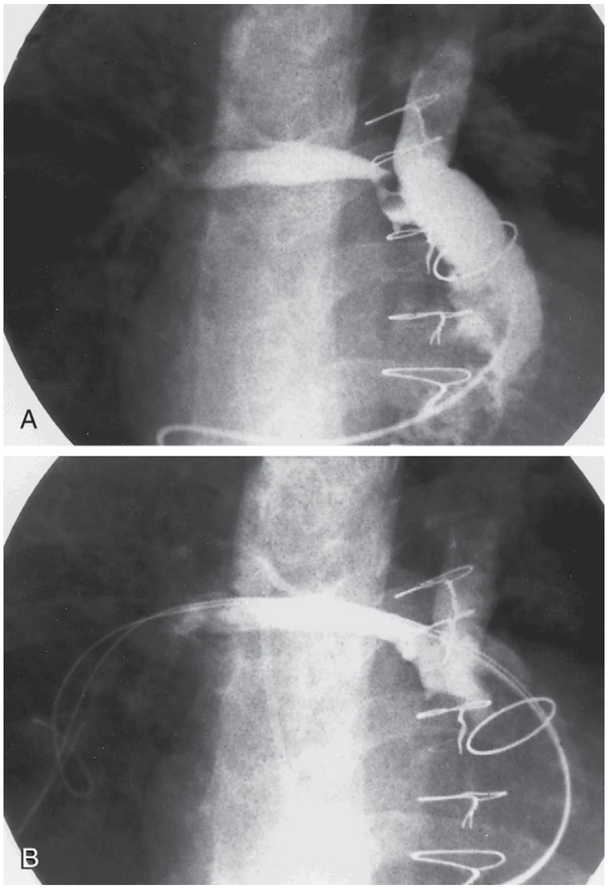


Figure 42–10 High-pressure balloon dilation of postoperative proximal RPA stenosis (**A**) leads to elimination of gradient, increased angiographic vessel caliber (**B**), and resolution of flow imbalance by nuclear lung scintigraphy. In **(A),** catheters and wires are placed via the IVC (off the bottom of the angiograms) through the right atrium (from leftward and inferior) through the right ventricle (vertically and superior) and right ventricular outflow to the distal pulmonary arteries. Contrast fills the main and proximal branch pulmonary arteries. At the junction of the sternal wires and the horizontally imaged right pulmonary artery, lack of opacification represents postoperative proximal right pulmonary artery stenosis in this patient. High pressure balloon dilation was performed, and the proximal branch pulmonary arteries are reimaged **(B),** showing resolution of the stenosis, with continuity of contrast opacification. The gradient was eliminated and vessel caliber was increased.

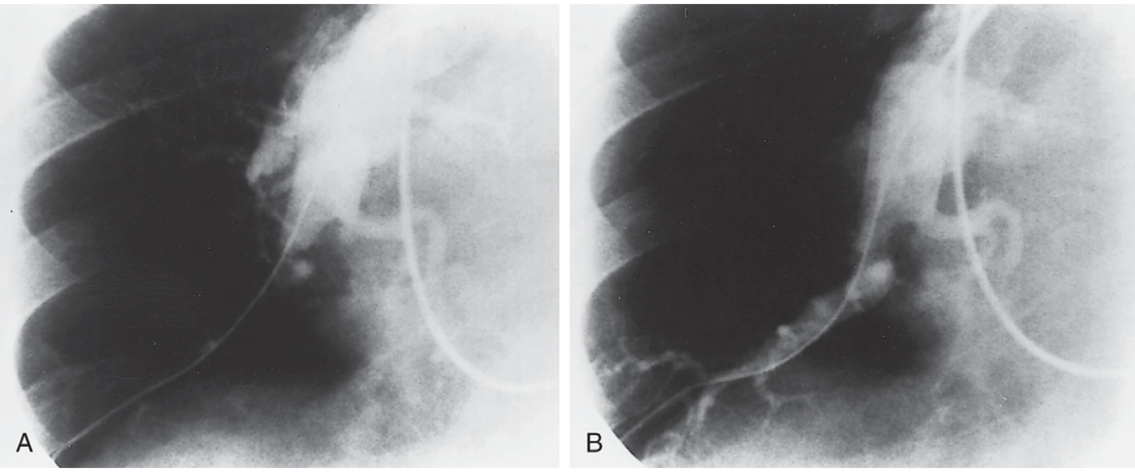

Figure 42–11 Right lower lobe segmental vessel before (**A**) and after (**B**) 7-mm balloon dilation. Mean central PA pressure fell from 60 mm Hg to 40 mm Hg. Reperfusion pulmonary edema was recognized 15 minutes after dilation.

Patent Ductus Arteriosus

The ductus arteriosus remains patent in approximately 0.07% of live births (5% to 10% of all congenital heart disease), connecting the descending aorta and the junction of the main and left pulmonary arteries. Anatomically, it varies in size and shape and may be calcified or aneurysmal. Difference in relative vascular resistance and physical restriction of the ductus determine the degree and nature of intravascular shunting (typically left to right) (Fig. 42–12). Patent ductus arteriosus in the adult is usually asymptomatic, although it may produce symptoms caused by increased volume load on the left ventricle. The diagnosis should be suspected in the setting of a continuous murmur at the left upper sternal-subclavicular border.

Endocarditis remains a constant risk (≈0.5% to 1.0% per year), although this is debated in the modern antibiotic SBE prophylaxis era. The risk of developing left ventricular dysfunction increases with age. Although operative closure in infancy is both safe and relatively straightforward, surgical repair requires general anesthesia, thoracotomy, and postoperative recuperation. In adults, surgical closure may be more complicated due to anatomic features of the patent ductus (calcification, friability, and aneurysmal dilatation), as well as increased incidence of multiple organ system comorbidity.

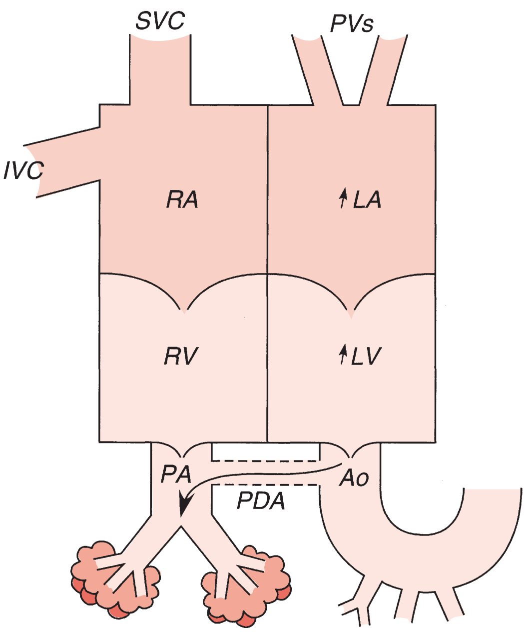

Figure 42–12 PDA physiology. Intravascular shunting is governed by relative resistance of pulmonary versus systemic arterial bed. Unless pulmonary vascular disease exists, flow is left to right with enlargement of left-sided chambers.

A transarterial transcatheter device approach to PDA closure was devised by Porstmann and colleagues.[143] Today, the most common devices used for transcatheter PDA occlusion are the Amplatzer PDA Occluder device and embolization coils, with nearly universal success at closure of PDA with one device or another.[144,145] The inexpensive cost along with the ease and effectiveness of occlusion make the embolization coils the ideal device for closure of PDAs.[146-149] We tend to use coils (single versus multiple, standard, controlled delivery, or shaped) for PDAs that have a minimal diameter < 3 to 4 mm and Amplatzer PDA Occluders for PDAs that have a minimal diameter ≥ 4 mm.

In our clinical service, we close all audible PDAs via a transcatheter approach. Patients do not leave the catheterization laboratory with evidence of residual ductal flow. Post device closure, bacterial endocarditis precautions are maintained for 6 months.

Recommendations

Despite unclear risks of bacterial endocarditis in the current antimicrobial era, we recommend transcatheter PDA occlusion as the procedure of choice for adults with audible PDA and PDA associated with left ventricular dysfunction. Coil embolization is the device of choice, with the use of alternative occlusion devices such as the Amplatzer device for PDAs with a minimal lumen diameter of ≥ 3 to 4 mm.

Ventricular Septal Defects

Isolated ventricular septal defects are the most common congenital defect seen in childhood, although they are much less frequently encountered in adult life due to either spontaneous or surgical closure during infancy or childhood. Anatomical classification is based on septal location including perimembranous, subpulmonary, AV canal-type, and muscular. Nature

and degree of intracardiac shunting depend on the relative pressure difference, ventricular chamber compliance and capacitance, and anatomic restriction of the VSD (Fig. 42–13). VSD closure is recommended for relief of symptoms (dyspnea, exercise incapacity) when accompanied by excessive pulmonary blood flow (typically with pulmonary/systemic blood flow ratio > 1.5 to 2.0) and left ventricular volume loading, in the absence of excessive pulmonary vascular resistance (typically < 7 to 8 Wood units·meter^2 or 280 to 430 dynes-sec·cm^{-5}) without reactivity to pulmonary vasodilators). We also consider closing VSDs with a pulmonary/systemic flow ratio < 1.5 to 2 if left ventricular failure is present. Spontaneous closure of tiny or small defects has been reported even into adulthood. We recommend that adults with persistent, nonhemodynamically significant VSDs have an interview and physical examination every 2 years with echocardiography every 3 years to screen for development of aortic regurgitation, arrhythmia, and potential for SBE. Excessive flow and pressure entering the pulmonary vasculature may contribute as an additional "trigger" to the development of pulmonary vascular hypertension and potential for shunt reversal, cyanosis, and the sequelae of Eisenmenger's disease.

We have applied transcatheter closure techniques for the treatment of congenital, postoperative residual, and acquired forms of VSDs using FDA-approved double umbrella devices in an attempt to eliminate the need for, or reduce the risk and complexity of, surgical repair.[76,150,152] To date, the majority of closures have been in patients with muscular VSDs

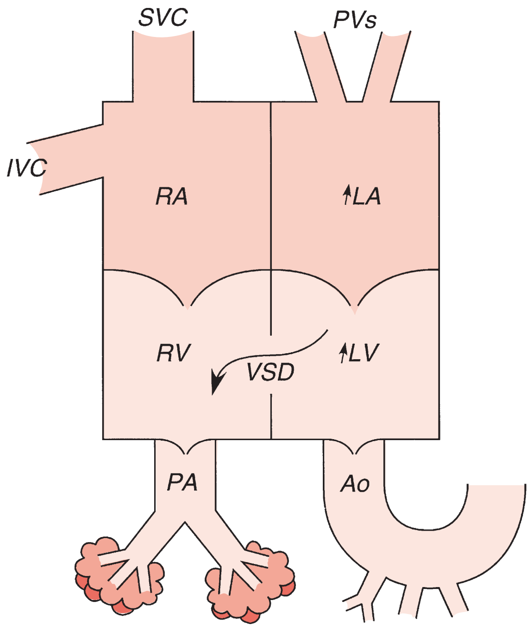

Figure 42–13 VSD physiology. Intracardiac shunting is governed by relative resistance to ventricular contraction and less so by ventricular filling. Unless RV function is significantly compromised or severe pulmonary hypertension/vascular disease exists, flow is left to right with enlargement of left-sided chambers.

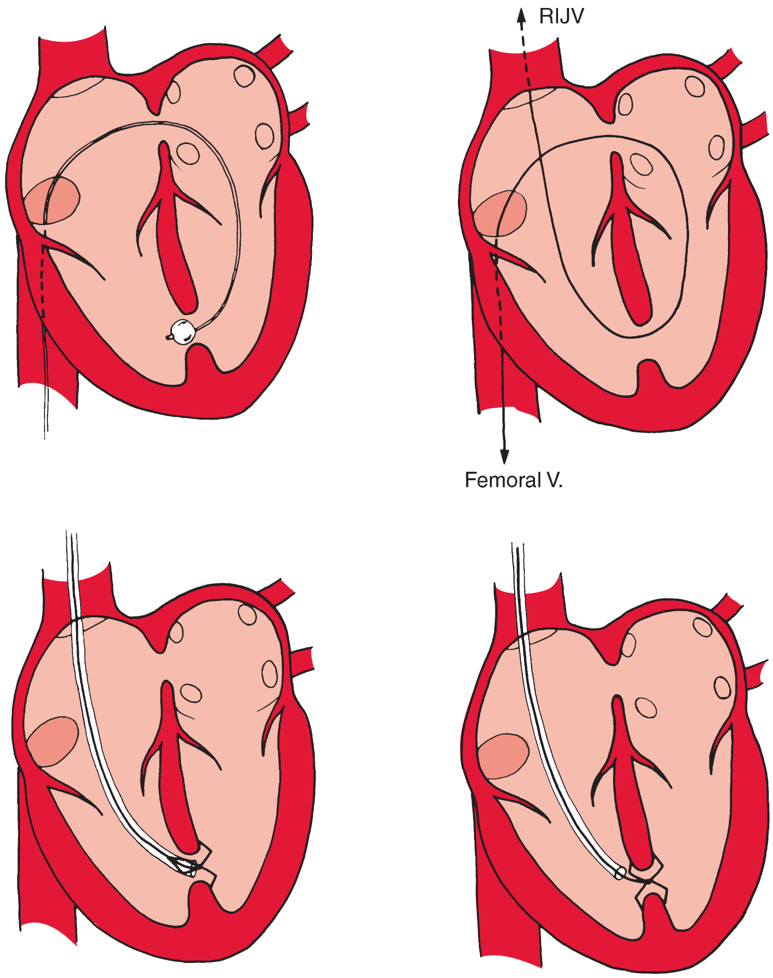

Figure 42–14 Transcatheter technique of ventricular septal defect (VSD) closure. The VSD is more commonly approached from the left ventricular side to ensure guidewire positioning through the greatest portion of the hole. After "snaring" the guidewire, the device is typically deployed from the systemic venous circulation. RIJV, right internal jugular vein. (See text for discussion).

anatomically distant from the aortic valve (not the commonly encountered congenital perimembranous VSD), or with post–myocardial infarction (MI) ventricular septal rupture.

Transcatheter closure technique requires significant operator experience to reduce procedural morbidity and is one of the most technically demanding of interventional catheter procedures performed in our laboratory (Fig. 42–14). A guidewire is typically placed from a transseptal approach (occasionally a retrograde arterial approach is used, especially in patients with TOF with postoperative residual patch-margin defects) into the left atrium and ventricle and across the VSD. The left-to-RV approach assists subsequent passage of a balloon flotation catheter through the widest portion of the defect. The guidewire is snared and delivered from either the contralateral femoral vein or a jugular vein, depending on the location of the defect. Balloon stretch sizing of the central portion of the defect may assist choosing device size. A curved guiding sheath follows the guidewire through the right or left side of the heart across the central channel of the defect. A device system is delivered in a fashion similar to the technique described for ASD closure. The guiding sheath frequently traverses the intraventricular septum at an acute angle, making fluoroscopic confirmation of arm positioning difficult during deployment. The use of transesophageal echocardiography greatly assists in appropriate placement of the arms of the device and successful closure of the defect.

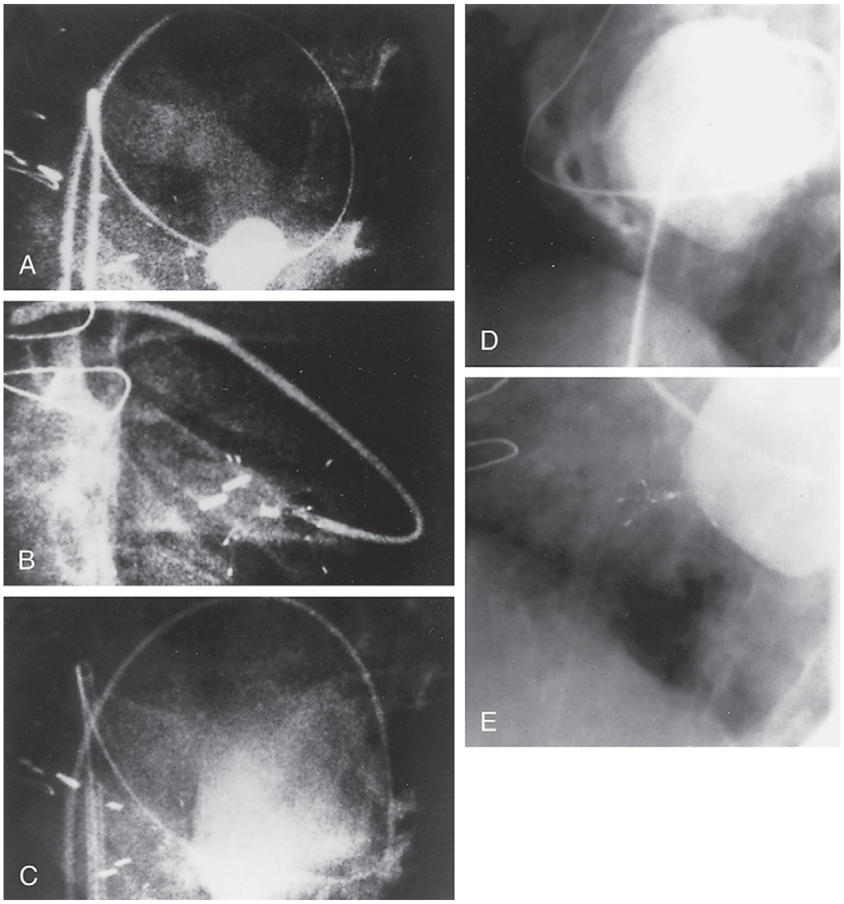

Figure 42–15 Balloon stretch sizing (**A**) of the central necrotic portion of a postoperative residual patch margin defect after primary surgical repair of ventricular septal rupture (VSR) following myocardial infarction (MI) in a patient requiring mechanical inotropic support. Transseptal deployment of a Clamshell occluder (**B**) leads to modest acute decrease in angiographic shunt (**C**), but patient markedly improves to NYHA II symptoms. Shunt flow (**D**) can be totally eliminated (**E**) in some patients with postoperative residual shunting after VSR following MI. Angiograms are performed in left anterior oblique position, with caudal angulation. Sternal wires are thrown to the left portion of the angiograms. Patient's head is towards the top of the page. In **(A),** a guidewire arteriovenous loop has been placed from IVC (*bottom left*) vertically throught the RA, (in circular fashion) transseptally to the LA (*top middle*), to the LV (vertically towards the right) across the VSR (sizing balloon is inflated within the defect) to the RV and back to the RA (wire overlap towards the mid left portion of the angiogram) and back through the IVC and exteriorized out the femoral venous vessels. In **(B),** a clamshell occluder has already been deployed within the defect, and radio-opaque markers are visualized on the distal tips of the 4 RV and 4 LV (2 superior and 2 inferior on each side) device arms. The device remains attached to its delivery system. Contrast injection **(C)** is performed within the LV **(C)** while the device is still attached to its delivery system, demonstrating persisting transseptal shunt (contrast seen towards the bottom left of the angiogram, within the RV). Radio-opaque device markers are not well visualized. After device release (**D** and **E**), the device shifts in position, more firmly sealing the defect, and preventing residual shunting in this patient. Contrast injections within the LV (rightward within the angiogram) fail to demonstrate shunt to the RV. The radio-opaque device markers are better seen **(E)**, especially on the leftward RV side of the septum.

Review of procedural, short-term, and intermediate-term outcomes of transcatheter muscular VSD closure has been most rigorously reported using double-umbrella devices in 170 highly complex and highest-risk patients, with predefined assessment of adversity and outcomes scales.[151] Procedural success was high, with successful implant in 99% of patients, with accompanying marked improvement in clinical severity scale. Potential for device-related adversity was considerable (seen in 20% of patients), and similar patients and families should be appropriately counseled.

Post–Myocardial Infarction Ventricular Septal Rupture

Although surgical advances have dramatically improved the short- and intermediate-term survival of adults with ventricular septal rupture (VSR) after MI, operative risk remains substantial and may be compounded by the location of the VSR, the presence of right or left ventricular dysfunction, multiple organ system failure, medical comorbidities, or prior incomplete surgical attempt at repair. Since February 1990, we have used double-umbrella closure devices (most recently cardioSEAL and cardioSEAL-Star-Flex devices, with only the cardioSEAL approved for limited indications) in attempts to limit VSR after MI. Primary "acute" ventricular septal rupture typically forms a serpiginous tract with a wide (18 to 21 mm) necrotic "lake" within the septum. More mature defects and postoperative patch margin dehiscence defects ranged from 8 to 25 mm by maximal balloon stretching (Fig. 42–15). To date, we have not encountered a defect that was not anatomically or procedurally amenable to device implantation, although success widely varies with techniques and devices used. To date, single-center experience of transcatheter closure of post-MI ventricular septal rupture closure remains anecdotal, though encouraging. We expect future trials of a more aggressive combined transcatheter-surgical strategy with larger devices and an intense medical-surgical collaboration in an attempt to offer prolonged improvement in those patients felt to be at extreme surgical risk.

Perimembranous Ventricular Septal Defect Closure

The use of specifically designed, investigational AGA Amplatzer membranous devices in the closure of perimembranous VSDs has been reported in single-center and multicenter studies. Experience is limited, indications for use are unclear, adversity remains not fully defined, and further study is required.[153,154]

Recommendations

Transcatheter device closure (particularly using double-umbrella CardioSEAL devices) of native or postoperative residual VSDs anatomically distant from the aortic valve has reduced the need for operation, as well as operative morbidity, in many patients with complex defects. At present, until larger devices are available, closure of a ventricular septal rupture after MI appears most successful when orchestrated by a combined surgical-medical team employing a strategy of expeditious primary surgical repair followed by transcatheter device closure of a residual defect, as required. Because of the technical demands of these procedures, transcatheter device closure of VSD and post-MI ventricular septal rupture remains limited to few centers.

Postoperative Residual Defects, Collaterals, and Fenestrations

Embolization coils and occlusion devices have been used in adults (as in children) at high or prohibitive surgical risk to successfully eliminate the following:

- Residual central aorta or systemic artery to pulmonary artery shunts or collaterals
- Systemic venous-to-pulmonary artery or pulmonary venous shunts or collaterals
- Interatrial baffle communications or iatrogenic Fontan fenestrations
- Left superior or inferior vena caval connections to the left atrium
- Coronary artery fistulae
- Systemic and pulmonary arteriovenous malformations
- Paravalvar leaks (Fig. 42–16)

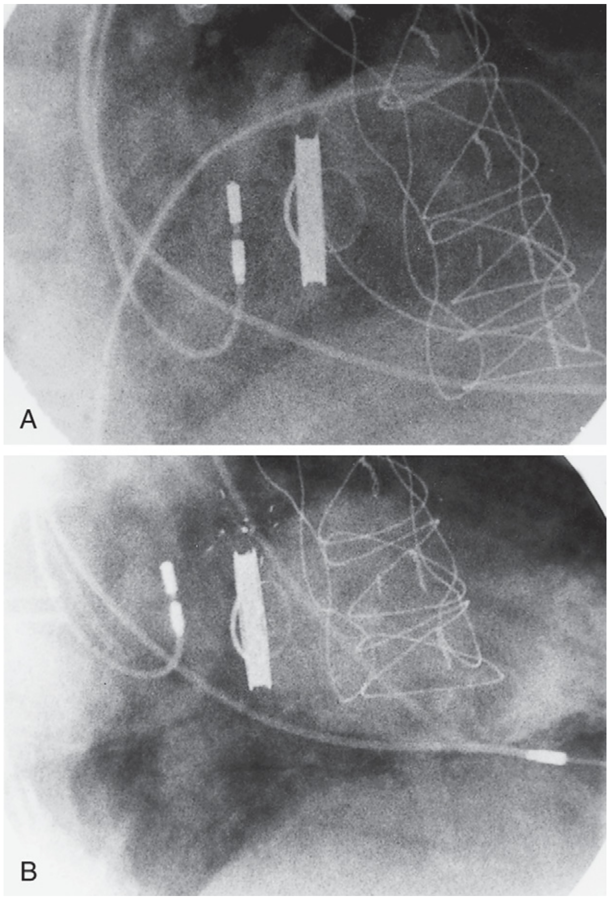

Figure 42–16 Paravalvar mitral regurgitation (**A**) resulting in left atrial hypertension and dyspnea is eliminated after placement of an occlusion device (**B**), with resolution of symptomatology. In **(A),** angiography (over a guidewire placed transseptally from the IVC—off the bottom of the angiogram—vertically through the RA to the LA and via the paravalvar leak—horizontally and superiorly in the angiogram—to the LV) demonstrates superior paravalvar passage. Patient had left atrial hypertension and dyspnea, which were eliminated after closure of the tract passage with a CardioSEAL occlusion device **(B)**. The radio-opaque distal markers of the device are seen superior to the prosthesis ring.

The investigational nature of most of the transcatheter techniques discussed in this chapter, as well as the need for their continued use and for further exploration of novel therapeutics, has been underscored in ACC/AHA guidelines on interventional catheterization in patients with congenital heart disease.[155] This is in large part due to the growing complexity seen in the adult "survivor" with congenital heart disease, coupled with past difficulties in conducting large-scale randomized trials. It is our expectation that in addition to improvements in the tools listed here, the near future will see the following, all from transcatheter access, with increasing collaboration between pediatric and adult medical cardiac interventional units and cardiac surgical teams:

- Capacity to locally deliver medical and genetic therapeutic agents
- Ability to implant intravascular and intracardiac valves and semipermanent measuring devices
- Creation of shunts
- Ability to suture, finely excise, and extract

Treatment of Severe Idiopathic Pulmonary Hypertension

Michael J. Landzberg

CHAPTER CONTENTS

CURRENT STATE OF DIAGNOSIS

Medical and legal discussions surrounding modern use of anorexigens,[1] coupled with increasing understanding of pathophysiology and availability of pharmacotherapies directed at vascular inflammation,[2] have all helped to raise awareness of severe pulmonary hypertension (PHT) for caregivers and patients. Whereas the classification of "primary" (or unknown etiology) pulmonary hypertension (PPH), which was used in earlier editions of this text, comprised a relatively small percentage of pulmonary hypertensive disorders, a newer classification of "pulmonary arteriolar hypertension" (PAH), either of a familial (occurring in ≈ 6% of PAH cases) or sporadic, nonfamilial "idiopathic" (iPAH) nature, has expanded the clinical entity to include various disorders sharing common pathophysiologic and anatomic features of vascular inflammation. Similarities among these syndromes have been sufficient to allow standardized study populations for testing of mechanisms of disease and application of therapeutics.

EPIDEMIOLOGIC ASSOCIATIONS

Multicenter registries established from 1981 through the present[3,4] have determined the prevalence and incidence of iPAH to be 1 to 2/million and 1 to 2/million/year, respectively, and have established a number of exposures or concomitant conditions associated with PAH (Table 43–1). Among the more important of these are scleroderma, especially of the limited skin involvement type, with estimated prevalence of PHT of 12% to 14%; HIV, with estimated cumulative incidence of 0.5%; and portal hypertension, with estimated prevalence between 0.25% and 2%.[5-7] An association (typically > 2:1) with female gender remains unexplained and persists for PAH associated with many other triggers. The tremendous differences in therapy and outcomes for patients with severe PAH associated with valvular or myopathic heart disease, or proximal or distal chronic thromboembolic disease, mandate a thorough search for "secondary" etiologies (Table 43–2).

Analyses of epidemiologic databases have suggested similar, untreated survival of patients with severe PAH regardless of etiology, with median survival between 2.8 and 3.4 years for the affected adult patient (Fig. 43–1). Survival correlates with variables relating to right ventricular function (typically assessed by hemodynamic measure of systemic cardiac output/mixed venous oxygen saturation and right atrial pressure) and physical capacity (typically measured by 6-minute walking capacity).[8] The improved survival seen in persons with severe PAH associated with Eisenmenger syndrome, or shunt-related PHT with associated cyanosis (10- to 20-year survival > 80%),[9] suggests that increased pulmonary afterload is better tolerated when it is shared between right and left heart chambers.

CURRENT PATHOBIOLOGIC PARADIGM OF IPAH

An important concept in the pathophysiology of iPAH is that exposure to specific triggers in an individual with an underlying genetic predisposition initiates a cascade of events that lead to the development of iPAH. Although various potential triggers have been identified, our understanding of the vascular biology of this disease continues to hold that abnormalities of the pulmonary vascular endothelium are central to the pathophysiologic process. Endothelial injury may initiate a cascade including endothelial dysfunction, growth factor and cytokine imbalance, coagulation abnormalities, and platelet-endothelial cell-leukocyte imbalance. Imbalance of "vasomodulators" including mitogens; vasoconstrictors; and vasodilators, such as endothelin, prostacyclin, nitric oxide, and their controlling substances, contributes to inflammation (Fig. 43–2). These in turn lead to pulmonary vasoconstriction, vascular smooth muscle (SM) cell proliferation, thrombosis in situ, and further vascular injury.

DIAGNOSIS AND RISK STRATIFICATION

Persons with PHT typically come to attention either due to symptoms (dyspnea, chest fullness or pain, bloating, volume retention, palpitations, or syncope), incidentally during evaluation for other disease, or during screening for PAH among

families or patients with identified risks. Typically, diagnosis may be suggested by evidence on cardiac examination of right ventricular failure or a loud pulmonary component of the second heart sound but is strengthened by echocardiography, with estimates of right ventricular and PA pressures ascertained by measure of Doppler-based tricuspid velocities. In general, systolic PA pressures > 50 mm (or ½ systemic levels) or < 36 mm (or ⅓ systemic levels) tend to define or exclude diagnosis of PHT, with intermediate values frequently requiring further assessment. Although echocardiography does reliably assess systolic ventricular function, it can only estimate pressures and diastolic cardiac function. Thus, confirmatory testing relies on hemodynamic assessment at cardiopulmonary catheterization. Typically, this includes measurement of right- and left-sided pressures, flow, and resistance (assisting in diagnosis and prognostic assessment); limited angiography as indicated; and maneuvers to test reactivity of pulmonary flow and resistance to acute administration of pulmonary vasodilator agents (typically inhalation of nitric oxide with or without oxygen, inhalation, or intravenous administration of specific prostanoids or acetylcholine or adenosine). Catheterization should be performed in regional specialty centers to decrease associated risk and improve reliability of diagnosis and testing. In general, catheter-based measurement of mean PA pressure > 25 mm (or systolic pressure > ⅓ to ½ systemic levels) defines PHT. Exercise-induced PHT remains less well defined but is suggested when mean PA pressure rises to > 30 mm Hg on exertion.

Response to acute administration of pulmonary vasodilator therapy has classically been described as a ≥ 20% decrease in systolic PA pressure with stability or improvement in pulmonary blood flow; this response is observed in 10% to 20% of tested patients, potentially reflecting a subset of patients with an earlier, or less lethal, phase of disease. Although a positive vasodilator response was initially felt to correlate with improved functional and survival outcomes in response to therapy with calcium channel blocker (CCB) therapy (>80% five-year survival),[10] a contemporary study has suggested a lesser correlation of percentage reduction in PA pressure with long-term responsiveness to CCB therapy and has led to a suggestion of adding an absolute fall of mean PA pressure to ≤ 35 mm Hg to be classified as a "responder." This more stringent definition of response improves prediction of improvement with CCB therapy.[11] In the past, acute vasodilator responsiveness was critical to risk stratification and choice of therapy and still carries importance for both aspects of care. However, favorable long-term effects on PA pressure, functional capacity, and survival have been documented with newer agents (prostanoids, endothelin antagonists) among patients who do not demonstrate acute vasodilator responsiveness, raising new hope for such patients.

Accurate differential diagnosis and elimination of additional treatable etiologies for PAH mandate additional patient testing, typically including CXR; pulmonary function testing including measurement of diffusion capacity; high-resolution chest CT scan, typically with angiography and pulmonary embolism protocol; serological testing (collagen vascular screening, liver and renal function, complete blood count and assessment, HIV testing when appropriate); abdominal ultrasound with or without flow assessment in the portal veins or liver-spleen scintigraphy when appropriate; sleep testing as appropriate; and TB testing when indicated (see Table 43–2). Disease-specific therapies including oxygen administration, positive airway ventilation, alternative organ therapy or transplantation, surgical pulmonary endarterectomy,[12] or balloon

Table 43–1 Exposures and Conditions Associated with Pulmonary Arteriolar Hypertension

Anorexigens (Dexedrine, aminorex, fenfluramine)
Catecholamines (cocaine, pheochromocytoma)
Portal hypertension/cirrhosis
Connective tissue diseases (scleroderma, mixed connective tissue disease, systemic lupus, rheumatoid arthritis)
Infection (HIV, tuberculosis, schistosomiasis)
Chronic lung disease, hypoxia, sleep apnea
Large-volume or high-pressure intracardiac or intravascular shunting
Myeloproliferative disorders
Sickle cell disease/hemoglobinopathies/platelet diseases
Toxin ingestion (L-tryptophan, toxic oil)

Table 43–2 Causes of Secondary Pulmonary Hypertension and Potential Studies to Elucidate the Diagnosis

Secondary Causes of PHT	Possible Diagnostic Studies
Chronic thromboembolic PHT	V/Q scan, CT or direct angiography
Pulmonary vein obstruction	MRI, CT, catheterization
Congenital heart disease	Echocardiography, MRI
Left atrial hypertension	Echocardiography, BNP, hemodynamic measure
Pulmonary airway disease	PFT, ABG
Hypoventilation	Sleep apnea testing
Interstitial lung disease	PFT, ABG, chest CT
Rheumatologic disease	Serology, tissue biopsy, chest CT
Cirrhosis	LFTs, ultrasound, CT, biopsy
Peripheral pulmonary stenosis	V/Q scan, angiography, MRI
Hemoglobinopathies	CBC and smear, electrophoresis

ABG, arterial blood gas; BNP, B-natriuretic peptide; CBC, complete blood count; CT, computed tomography; LFT, liver function test; MRI; magnetic resonance imaging; PFT, pulmonary function testing; PHT, pulmonary hypertension; V/Q, ventilation-perfusion.

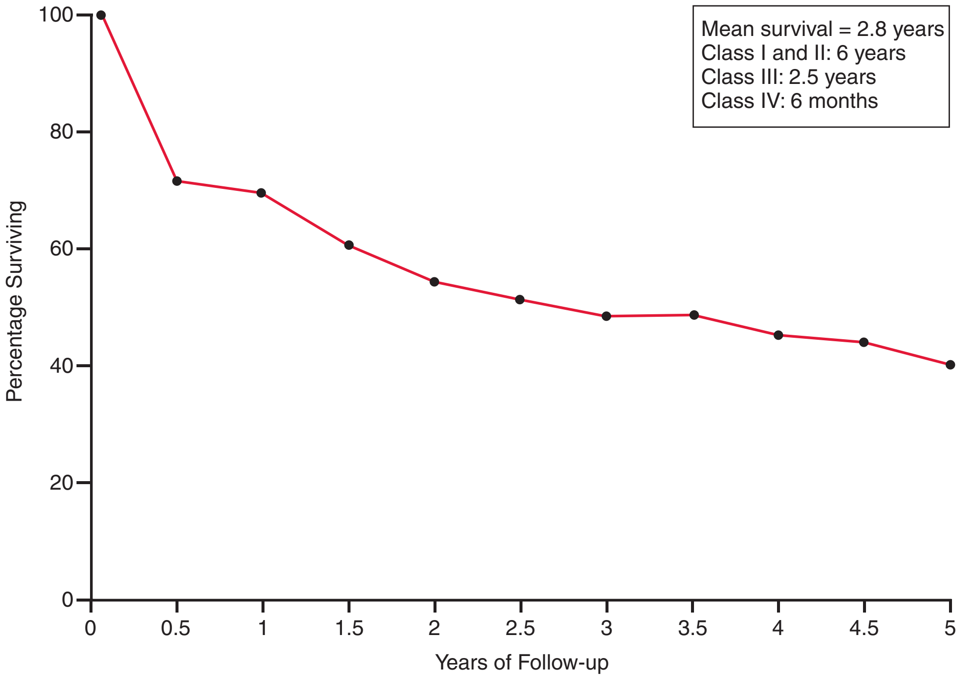

Figure 43–1 Untreated survival with severe PAH. (Modified from D'Alonzo GE, Barst RJ, Ayres SM: Survival in patients with PPH: Results from a National Prospective Registry. Ann Intern Med 1991;115:343-9.)

pulmonary angioplasty[13,14] may be indicated as primary therapy on the basis of the results of such testing.

Functional capacity, as assessed by exercise testing, with formal measurement of 6-minute walking capacity (typically used due to ease and patient functional restriction) or cardiopulmonary exercise testing with measurement of maximal oxygen consumption,[15] has become routine as a prognostic tool, both for initial survival prediction and response to therapy. Subjective assessment of functional capacity using NYHA or WHO functional scales has correlated with both untreated and treated outcomes and has been used to define populations in randomized controlled trials.[16] Dyspnea scales have been used in randomized controlled trials, although their individual additive prognostic potential remains undefined. Serologic testing of biomarkers including troponins and measurement of natriuretic peptides remains under investigation but appears promising as markers of disease severity.

CURRENT STATE OF THERAPY

CCBs were the first widely accepted therapeutic agents for patients with PAH. Their use was modeled on the "vasoconstrictor" model of pulmonary arteriolar hypertension, envisioning pathology to be due to a disorder and disregulation of small pulmonary arteries, characterized by lamellar intimal fibrosis, medial hypertrophy, and neovascular plexiform lesions. To date, no randomized trial exists that tests effect and risk of CCB, although nifedipine has remained the prototype therapy for the small percentage of patients (5% to 15%) who are "responders" to acute administration of vasodilator agents during cardiopulmonary catheterization. Given that clinical effect typically requires drug doses 5- to 10-fold higher than those commonly used to treat hypertension and that such dosage requirements are unpredictable and may be accompanied by considerable adverse effects, dose-response testing is typically performed with indwelling PA pressure monitoring to identify eventual effective target dosage. Most centers will recommend achieving this goal dosage in a graded fashion to allow adverse effects to be minimized as the systemic vasculature accommodates to the drug effect. More recent uncontrolled databases suggest that CCB use may be even less effective than previously thought[17] and may require a change to a more stringent definition of "acute vasodilator responsiveness" to better define the population for whom this class of medication will be effective. CCB therapy is generally believed to be contraindicated in those patients presenting with substantial right atrial pressure elevation or marked decrease in cardiac output.

The use of what is considered "conventional" PAH therapy including warfarin, oxygen, digoxin, and diuretics is controversial. Benefit of warfarin has been extrapolated from subset analyses of retrospective single center studies and is based on pathologic data from lung biopsies and postmortem examinations, confirming in situ thrombosis within the pulmonary vasculature. Warfarin is generally advised, with a target INR of 2.0-3.0, dependent on individual patient risk of bleeding. Multicenter randomized controlled trials of other therapeutic agents for PAH have noted use of oral anticoagulants at time of inclusion in 51% to 86% of enrolled patients.

Long-term digoxin administration for patients with right heart dysfunction due to PAH has not been studied. Its use has been declining, with digoxin administration at time of inclusion in multicenter RCTs in 18% to 53% of subjects. Diuretic therapy may assist in volume control and is likewise unstudied in the chronic state, and its use has been documented in 49% to 70% of patients during multicenter RCTs of other therapies for PAH. Use of oxygen, other than that defined for appropriate patients with chronic lung disease and hypoxemia, is unsupported.

Over the past decade, the "vasoconstriction" monolayer model of iPAH has been replaced with the vascular wall inflammation paradigm discussed earlier, with the introduction of novel therapies reflecting this change in pathobiologic

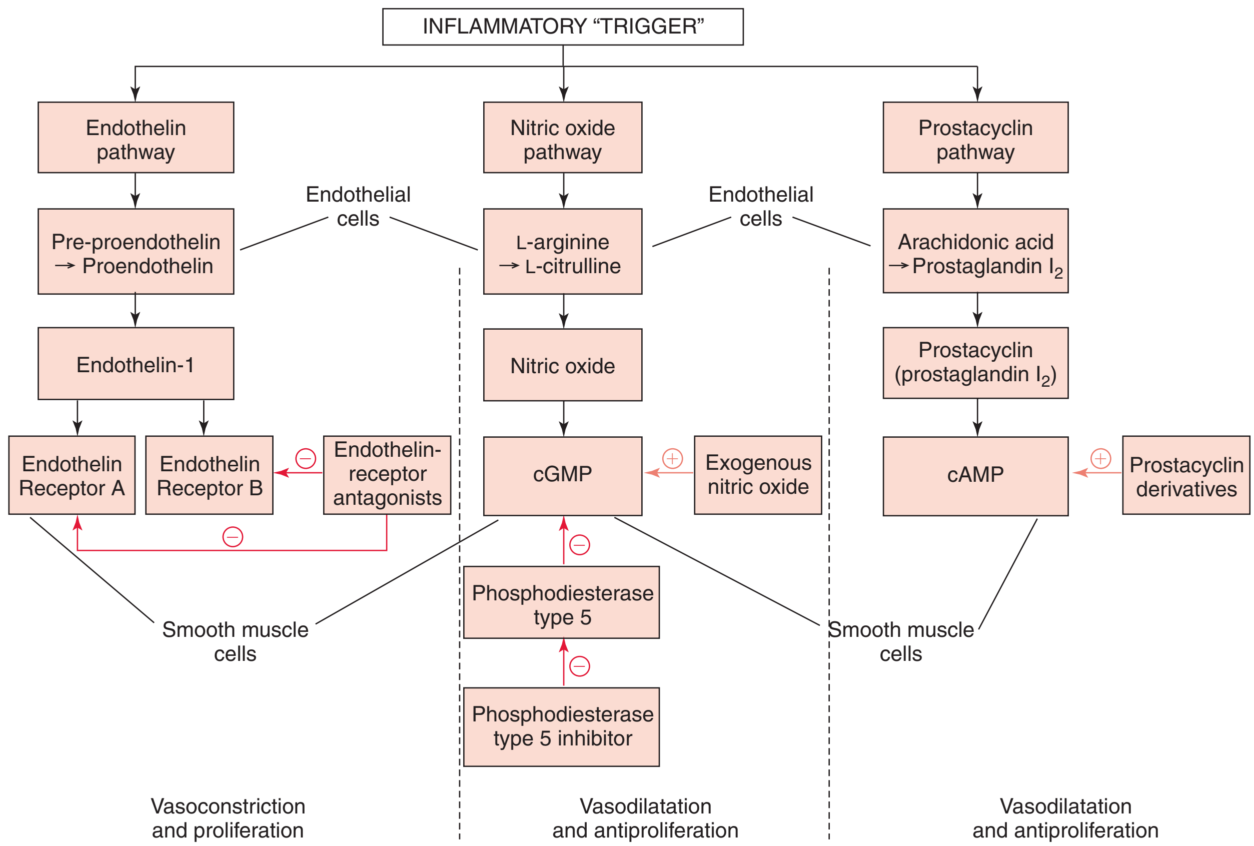

Figure 43–2 Current vascular inflammation and constriction model of iPAH. (Modified from Humbert M, Sitbon O, Simmoneau G: Treatment of pulmonary arterial hypertension. N Engl J Med 2004;351:1425-36).

thought. For the majority of affected patients, modern treatment focuses on mediators of chemotaxis, cellular proliferation and differentiation, and regulation of vasoactive peptides and growth factors. These mediators currently include prostanoids (intravenous, inhaled, oral), endothelin antagonists, nitroso-compounds, and phosphodiesterase inhibitors.

Prostanoids

Earliest multicenter randomized clinical trials focused on the use of the intravenous prostanoid, epoprostenol. Patients treated with epoprostenol + conventional therapy showed improved survival and exercise tolerance, increased cardiac output, and decreased pulmonary vascular resistance when compared with controls using conventional therapy alone.[18] These results have been confirmed both in patients with iPAH, as well as in patients with PAH associated with scleroderma. Longer-term benefit had been demonstrated in multiple subsequent studies (Fig. 43–3).[19] However, the personal and financial costs of epoprostenol use are protean, with a need for continuous administration via a commercially available personal pump attached via tubing to a centrally placed indwelling catheter and daily personal admixture of drug. Common drug side effects include flushing, headache, peculiar jaw pain with the first bite of each meal, boney and muscular pain, local and systemic infection, nausea, diarrhea, hypotension, tachyphylaxis, and potential for severe and potentially life-threatening rebound PHT on drug withdrawal. Typical dosing begins at 0.5 to 2.0 ng/kg/minute, with adjustments based on effect and tachyphylaxis, typically every 3 to 10 days. Eventual "plateauing" of dose may occur, without the need for dosage augmentation. Periodic invasive hemodynamic assessment is required to ensure adequacy of dosage, as well as avoidance of overdosage. This medication is currently FDA approved for PAH patients who are in functional class III-IV. Pharmaceutical cost may range from \$75,000 to \$150,000 yearly. Drug benefit is modest including improved 6-minute walk distance of 20 to 30 m and extension of survival to 63% at 3 years. Predictors of survival at the start of therapy have included functional class (poor prognosis if initial 6-minute walk < 250 m), cardiac index, mean right atrial pressure (poor prognosis if ≥ 12 mm Hg), and mean PA pressure, with predictors of survival after 1 year of therapy including improvement in cardiac index and decrease in right atrial pressure. The strongest predictor of long-term survival may be the ability to achieve a 6-minute walk ≥ 380 m.[19a]

Multicenter randomized clinical trials, all of which have required right heart catheterization for entry, have shown favorable effects for other prostanoids and include the following:

- The Treprostinil (SQ prostanoid; tricyclic benzidine analogue of prostacyclin) Study[20]: This was a 12-week, double-blind, randomized, controlled trial including 470 patients (81% women), 271 with iPAH, 90 with connective tissue disease, 109 with congenital heart disease, with a mean age of 44 years at enrollment. Functional capacity was WHO Functional Class (FC) II (12%), III (81%), IV (7%), with a

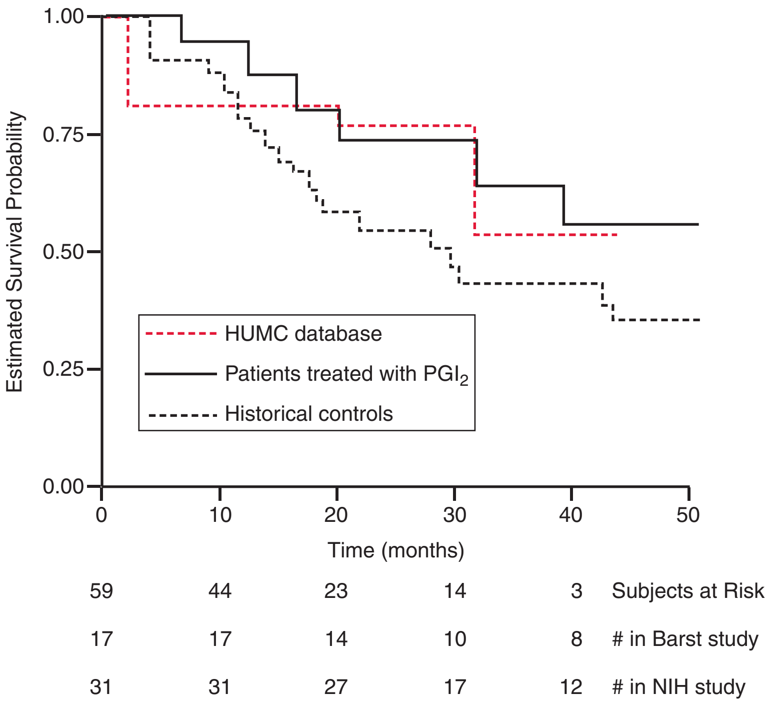

Figure 43–3 Survival in severe PAH: treatment with epoprostenol. (Modified from Shapiro SM, Oudiz RJ, Cao T, et al: Primary pulmonary hypertension: Improved long-term effects and survival with continuous intravenous epoprostenol infusion. J Am Coll Cardiol 1997;30:343-9.)

mean baseline 6-minute walk distance of 327 m. Study drug was started at 2 ng/kg/minute, with weekly dosage increases and endpoints measured at 12 weeks including 6-minute walk and hemodynamic parameters. At trial conclusion, there was only a 10-m difference in 6-minute walk distance between the study groups. However, this difference increased as the final tolerated drug dosage increased, with 36.1 ± 10 m difference between groups when the study drug dosage was > 13.8 ng/kg/minute. Benefits persisted at 18 months of therapy, with the most common side effect being infusion-site pain. This medication is currently FDA approved for patients with PAH and WHO FC III or IV and has the benefits of being a more stable compound, requiring a smaller mechanical pump, and a nonintravenous administration. Local injection-site pain has been frequent, though various strategies have been designed to reduce such. Financial cost per year has been estimated (Medical Letter-2002) at $93,000.

- The Beraprost (oral prostacyclin analog) ALPHABET Trial[21] Study: This was a 12-week double-blind randomized controlled trial that enrolled 130 patients, 62% of whom were women, 63 with PPH, 13 with connective tissue disease, 24 with congenital heart disease, 21 with portal hypertension, 9 with HIV, and with mean age at enrollment of 45 years. Functional capacity at enrollment was WHO FC II (50%), III (50%), and IV (0%) with a mean baseline 6-minute walk of 373 m. The study drug was started at 20-mcg po qid, with weekly dosage increases, with a maximal dose of 120 mcg qid (mean 80 mcg qid), with endpoints measured at 12 weeks including 6-minute walk and hemodynamic parameters and Borg dyspnea index. At trial end, there was nearly a 30-meter difference in 6-minute walk distance between the study groups. This difference was more pronounced in patients with iPAH compared with those with other recognized triggers of PAH. Continued drug benefit after 1 year of therapy was lost in a subsequent trial, and this agent is currently not FDA approved for use in PAH.[22]
- The Iloprost (inhaled prostacyclin analog) AIR Trial[23] Study: This was a 12-week, double-blind randomized trial, with enrollment based on baseline 6-minute walk (mean 323 m). Study drug was started at 2.5 to 5.0 mcg inhaled 6 to 9 x/daily with overnight "breaks," with dosage adjustments over the first 8 days and assessment at 12 weeks of a combined endpoint defined as 10% improvement of 6-minute walk plus improved WHO FC, hemodynamic parameters, Borg dyspnea scale, and quality of life scale. Of the 203 patients enrolled, 67% were women—102 with iPAH, 35 with connective tissue disease, 57 with chronic thromboembolic PAH, 9 anorexigen-related PAH, with mean age at enrollment of 51 years and functional capacity at enrollment of WHO FC II (0%), III (59%), and IV (41%). At trial end, 17% of iloprost-treated patients compared with 4% of placebo-treated patients achieved a primary endpoint; there was a 36-meter difference in 6-minute walk distance between the study groups (Fig. 43–4). This difference was more pronounced in patients with iPAH compared with those with other recognized triggers of PAH. Iloprost is currently FDA approved for patients with PAH and WHO FC III or IV, with estimated cost of treatment $60-70,000/year.

Endothelin Receptor Antagonism

The BREATHE series of trials have assessed the safety and efficacy of a combined endothelin α- and β-receptor antagonist, bosentan, in the treatment of iPAH and other forms of PAH.

The BREATHE-1 (bosentan: combined endothelin α- and β-receptor antagonist) Study[24] was a 16-week, double-

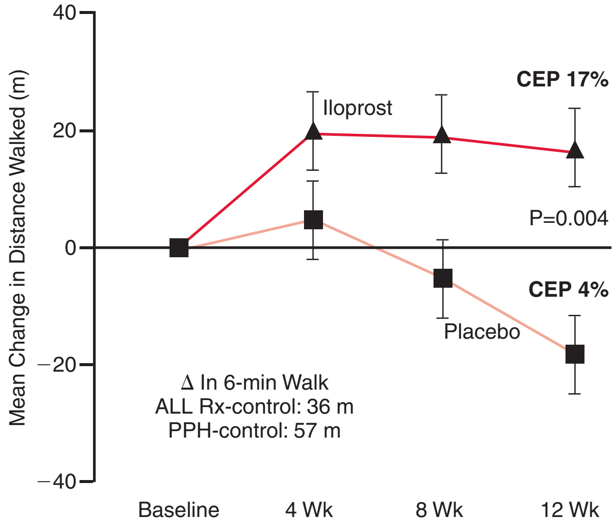

Figure 43–4 Functional capacity in severe PAH: treatment with iloprost. (Modified from Olschewski H, Simonneau G, Galie N, et al: Inhaled iloprost in severe pulmonary hypertension. N Engl J Med 2002;347:322-9.)

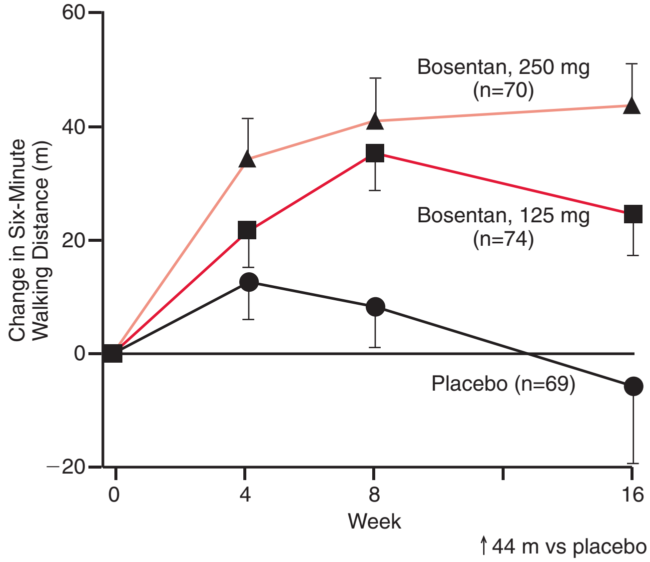

Figure 43–5 Functional capacity in severe PAH: treatment with bosentan. (Modified from Rubin LJ, Badesch DB, Barst RJ, et al: Bosentan therapy for pulmonary arterial hypertension. N Engl J Med 2002;346:896-303.)

blind, randomized trial with enrollment based on a baseline 6-minute walk (mean 335 m). The study drug was started at 62.5 mg bid × 4 weeks with 2 arms of dosage increase to either 125 or 250 mg po bid × 12 weeks. Endpoints were measured at 16 weeks including 6-minute walk and hemodynamic parameters, Borg dyspnea scale, and WHO FC. Of the 213 patients enrolled, 79% were women—151 with iPAH, 62 with connective tissue disease, with mean age at enrollment of 48 years, with functional capacity at enrollment of WHO FC II (0%), III (92%), and IV (8%). At trial end, a 44-m difference in 6-minute walk distance existed between the study groups (Fig. 43–5). Benefits have persisted during long-term follow-up, with the most common side effects being LFT abnormalities (mandating monthly LFT checks) and mild dilutional anemia. The FDA has approved bosentan use in patients with PAH in FC III or IV. The cost per year is $36,000 (Medical Letter—2002).

Phosphodiesterase Inhibition

Phosphodiesterase (PDE) inhibition (in particular, of PDE-5) blocks metabolism of cyclic GMP, enhances cGMP-mediated relaxation and growth inhibition of vascular smooth-muscle cells in the lungs of patient with iPAH, and potentially improves clinical outcomes. Several trials have led to FDA approval of this therapy for patients with iPAH.

The Sildenafil Citrate (phosphodiesterase type 5 inhibitor) Study[25] was a 12-week, double-blind, randomized trial, with enrollment based on baseline 6-minute walk (mean 344 m). The study drug was prescribed at either 20-mg, 40-mg, or 80-mg dosages, each administered three times daily, with endpoints measured at 12 weeks including 6-minute walk and hemodynamic parameters, Borg dyspnea scale, and WHO FC. Of the 277 patients treated, 75% were women—175 with iPAH, 87 with connective tissue disease, and 18 with repaired congenital systemic-pulmonary shunts. The mean age at enrollment was 49 years, with functional capacity at enrollment of WHO FC II (39%), III (58%), and IV (3%). At trial end, there was a 45- to 50-m difference in 6-minute walk distance between the sildenafil-treated groups and placebo, with no statistically significant differences among the different dosage sildenafil-treated arms. Benefits persisted during 1-year follow-up, with most common side effects being flushing, dyspepsia, and diarrhea. The FDA has approved sildenafil use in patients with iPAH. The cost per year is currently approximately $13,000.

Similar trials using sole endothelin A antagonists and combined therapies are under way and remain to be completed or interpreted.

Atrial Septostomy

The rationale for an atrial septostomy as therapy for patients with iPAH is based on the suggestion that the presence of an atrial septal defect or patent foramen ovale appears to confer a benefit in patients with iPAH.[26] It has been suggested that an intra-atrial defect with right-to-left shunting preserves forward cardiac output, at the expense of arterial desaturation, in the setting of severe PHT, right ventricular dysfunction, and low cardiac output. One cohort study reported survival benefit compared with historical control subjects.[27] However, procedure-related morbidity and mortality are high, and randomized studies have not been reported, making such therapy a reasonable option only in centers with considerable expertise, and where alternative therapy as a bridge to transplantation is unavailable.

Transplantation for iPAH

Single-lung, double-lung, and heart-lung transplantation have been used for patients with severe iPAH, with 5-year survival postprocedure still hovering at approximately 50%.

Procedural morbidity and mortality are much higher for transplantation for iPAH, as compared with other forms of lung disease. Until quality of life indices or survival benefit is improved with changes in surgical techniques and medical support, transplantation should be reserved for patients with iPAH refractory to medical therapy. However, in view of variability in individual patient prognosis, and in anticipated waiting times before transplantation, the timing for referral may vary by institution.

MEDICAL THERAPY ALGORITHMS

Prescription of current intravenous and nonparenteral therapies for PAH in the United States focuses on FDA-approved therapies, administered to patients in a particular WHO functional classes in which the approved medications were tested (e.g., epoprostenol or iloprost for FC IV patients; bosentan, treprostinil, iloprost, or sildenafil for patients in FC III). If patients do not respond to initial diagnostic acute vasodilator challenge, we recommend the following therapy (Fig. 43–6):

WHO FC II: United States: sildenafil, bosentan (tested in FC III patients), or treprostinil elsewhere: also short-term Beraprost or long-term iloprost

WHO FC III: United States: bosentan, sildenafil, iloprost, or treprostinil elsewhere: also short-term Beraprost

WHO FC IV: United States: epoprostenol, iloprost (consideration of bosentan or sildenafil, if 4 to 12 weeks from drug start until substantive clinical drug effect is achieved, is believed to be safe)

Patients without improvement to < FC III or 6-minute walk distance ≥ 380 m by several months of therapy, those initiating in FC IV, or those persisting with elevated RA pressure or low systemic cardiac output are typically referred for consideration of multi-drug therapy or organ transplantation (single lung/double lung/heart-lung depending on institutional availability and success).[19a,28] Worsening of FC, new symptoms of neurohormonal activation, or decrement in 6-minute walk time > 10% baseline with worsening dyspnea typically prompt a full reassessment for potential causes of deterioration or to alter therapy.

Therapy designed to support right ventricular contractile function, decrease muscular remodeling, decrease neurohormonal activation, decrease inflammation, or even reduce alveolar hypoxia (e.g., with β-blockade, nesiritide, angiotensin-converting enzyme inhibitors or angiotensin receptor blockade, spironolactone), as shown to be of assistance in left ventricular failure syndromes with increased afterload, have not been adequately studied in patients with PAH. Controlled exercise and respiratory training have been shown to improve both exercise capacity and quality of life for patients with severe chronic pulmonary hypertension.[28a] Effects of exercise training, stress reduction, nutritional support, and therapy of sleep abnormalities have yet to be scientifically examined. How to, and when it is best to, combine or transition therapies, as well as elucidation of markers of responsiveness to such therapies, are topics of current investigation. Use of implanted continuous hemodynamic recording devices of RA, RV, or PA pressures have been described, and although their use remains intriguing, proof of clinical benefit has not been demonstrated.

General patient recommendations to practice are (1) safe airline travel (most commercial airlines pressurize to an equivalent of 1800 to 2400 m, with hypobaric hypoxia typically seen at 1500 to 2000 m) with frequent rests and concomitant oxygen use; (2) budgeting of energy to personal

goals; (3) excellent skin, dental, and overall infection control strategies; (4) episodic laboratory checks (autoimmune tests, renal and hepatic function, complete blood count); (5) vigilance regarding the use of even simple, over-the-counter agents with potential for renal- or hepatic-function alterations; and (6) overall educated consumerism.

NEW PATHOBIOLOGIC AND CARE PARADIGMS?

Evidence is increasing for genetically inherited abnormalities in endothelial cell apoptosis and growth potential, with links of familial and sporadic iPAH to a member of the TGF-B superfamily, bone morphogenetic protein receptor BMPR2 (as well as angiopoietin-1, its specific endothelial cell receptor, BMPR1, and ALK 1, encoding a BMPR receptor). Currently, assays for mutations in these genes are not sufficiently standardized to allow for genetic screening, although there is speculation that specific defects may correlate with more robust PAH phenotypes and improved definitions of susceptibility to PAH.[29-31]

Increasing data suggest that the hallmark lesion of iPAH/PAH, the plexiform lesion, is a response phenomenon to local hypoxia or inflammation and represents a tumor-like proliferation of endothelial cells (monoclonal in iPAH, polyclonal in secondary forms of PAH). To date, the functional significance of these lesions and their components and the temporal control of vascular growth remain elusive.[32]

Markers of cellular inflammation, matrix stimulation and cellular growth, as well as platelet and coagulant activity can now be studied in circulation and in situ, with alterations of fractalkine, RANTES, interleukin 1-B, interleukin-6, soluble IVAM, sVCAM, sP-selectin, S-electin, vW factors, serotonin, PAI-1, fibrinopeptide A, and thrombomodulin noted in biopsy samples and circulation of patients with PAH. To date, there remains a need to further characterize, as well as correlate, changes in these factors with disease severity or progression.[33,34]

Endothelial cell (EC) activation abnormalities have been at the heart of modern understanding and therapies for PAH. Successful use of chronic NO has been demonstrated, while randomized clinical trials remain to be orchestrated. Abnormalities in VEGF have been described in patients with PAH, although where these abnormalities lay in the activation of the overall inflammation/constriction scheme and the effect of modulators of these factors remain unknown.

The role of serotonin as a trigger for development of PAH was highlighted by the fen-Phen epidemic, with direct action on PA sM cell 5HT-2A and 5HT-1B receptors.[35] A unified theory of serotonin activation remains to be clearly defined, and trials of serotonin receptor blockers and serotonin transporters have been suggested. Other abnormalities in sM cell components in patients with PAH may include dysfunctional voltage-dependent potassium channels, which can be altered with anorexigenic agents including aminorex, dexfenfluramine, and phentermine.

Increased extracellular matrix production is a hallmark of PAH, with abnormalities of serine elastase, causing elevation in bFGF leading to changes in MMPs, production of tenascin and phosphorylation of growth factor receptors, and sM cell proliferation.[36] Where such abnormalities in matrix activation lay in the overall inflammation/constriction scheme of PAH and the effect of modulators of these factors remain unknown.

PREGNANCY AND CONTRACEPTION

(see Chapter 41)

The risk of pregnancy-related death for women with PAH is substantial, with mortality in the modern era anecdotally similar to that previously reported as 30% to 50%, despite use of modern pulmonary vasoactive agents.[37] For women who present during pregnancy, maternal and fetal risk of termination may be equally substantial, if not greater, depending on timing of presentation. Warfarin-based teratogenic risk may be substantial at doses typically used in PAH therapy. Any such patient maintaining pregnancy is advised to do so only in regional centers of expertise, with access to all levels of supportive maternal and fetal care. Reliable and educated contraception remains a hallmark of appropriate care, whereas appropriateness and effectiveness of individual therapies (in particular, hormonal contraception) remains untested in this population. Tubal ligation, similar to any noncardiopulmonary surgery, may carry substantial morbid and mortal risk in patients with PAH and should not be undertaken without consideration of alternatives.

Chapter 44

Prevention and Treatment of Endocarditis

Gail E. Peterson and Christopher H. Cabell

CHAPTER CONTENTS

INTRODUCTION

At the time that Sir William Osler eloquently delivered the Gulstonian Lectures in 1885, the understanding of infective endocarditis (IE) was based on clinical observations, autopsy findings, and small case-series. Even today, our knowledge of this disease is primarily based on traditional case-series with relatively small numbers of patients. No randomized trials have been performed to test strategies for prevention, and there are few randomized trials for the treatment of IE. As a result, clinical practice guidelines[1-3] are based largely on expert opinion and practice experience rather than on evidence-based medicine grounded in large-scale trials. The study of IE is hampered further because it is a relatively rare disease, involves diverse underlying risk factors, affects heterogeneous patient populations, and involves a wide array of infecting microorganisms.

DIAGNOSIS

Diagnosis of IE has advanced over the past century with the evolution of standardized diagnostic criteria. In 1994 David Durack and colleagues[4] from Duke University described for the first time new diagnostic criteria that incorporated echocardiographic findings and a history of intravenous drug use.

The clinical utility, sensitivity, and specificity of the Duke criteria have been independently validated and found to have superior performance compared with older criteria that do not use echocardiography.[5-7] As the epidemiology of IE has evolved and basic understanding of the disease process has improved, modifications to the Duke criteria have been proposed. The major criteria have been expanded to include nosocomial *Staphylococcus aureus* (*S. aureus*) bacteremia, and serological criteria for *Coxiella burnetii*.[8] Splenomegaly, elevations in C-reactive protein, elevations in erythrocyte sedimentation rate, and the presence of indwelling intravenous catheters have been added to the minor criteria.[9]

THE USE OF ECHOCARDIOGRAPHY IN THE DIAGNOSIS AND MANAGEMENT OF ENDOCARDITIS

Echocardiography, which provides excellent visualization of cardiac anatomy, has contributed to earlier diagnosis and detection of complications. The hallmark lesion of IE is a vegetation (Fig. 44–1A) that is evident in 67% to 86% of cases of definite IE.[10-12] Vegetations typically occur on the low-pressure side of a high-velocity turbulent jet and are often accompanied by other hemodynamic or anatomic abnormalities. When infection invades contiguous structures, an abscess may result (see Fig. 44–1C). This most commonly involves the aortic root and the anterior mitral annulus and may extend into the ventricular or atrial septum, right ventricular outflow tract, and anterior mitral valve leaflet. Periannular extension may result in tissue necrosis and ultimately result in communication between areas that are external to cardiac chambers. Periannular invasion that occurs in the setting of a prosthetic valve can lead to valve dehiscence and perivalvular regurgitation (see Fig. 44–1B).

Transthoracic echocardiography (TTE) is easily performed, noninvasive, and does not require conscious sedation, but in 10% to 15% of adults sound transmission is compromised, by interfering tissue or air attenuation, or both, and leads to poor spatial resolution. Transesophageal echocardiography (TEE) is more invasive and labor intensive but has an improved ability to detect smaller vegetations and complications of endocarditis. The sensitivity and specificity for TTE and TEE are shown in Table 44–1.

During the initial evaluation of patients with suspected IE, the appropriate mode of echocardiography to use depends, in part, on the prior probability of disease.[13,14] Clinical findings that suggest IE are listed in Table 44–2. In patients with a very low probability for IE based on clinical data, echocardiographic findings are unlikely to change the management of the patient.[15,16] Clinical criteria that suggest a higher likelihood of IE include vasculitic or embolic phenomena, presence of central venous access, presence of prosthetic valve, recent IV

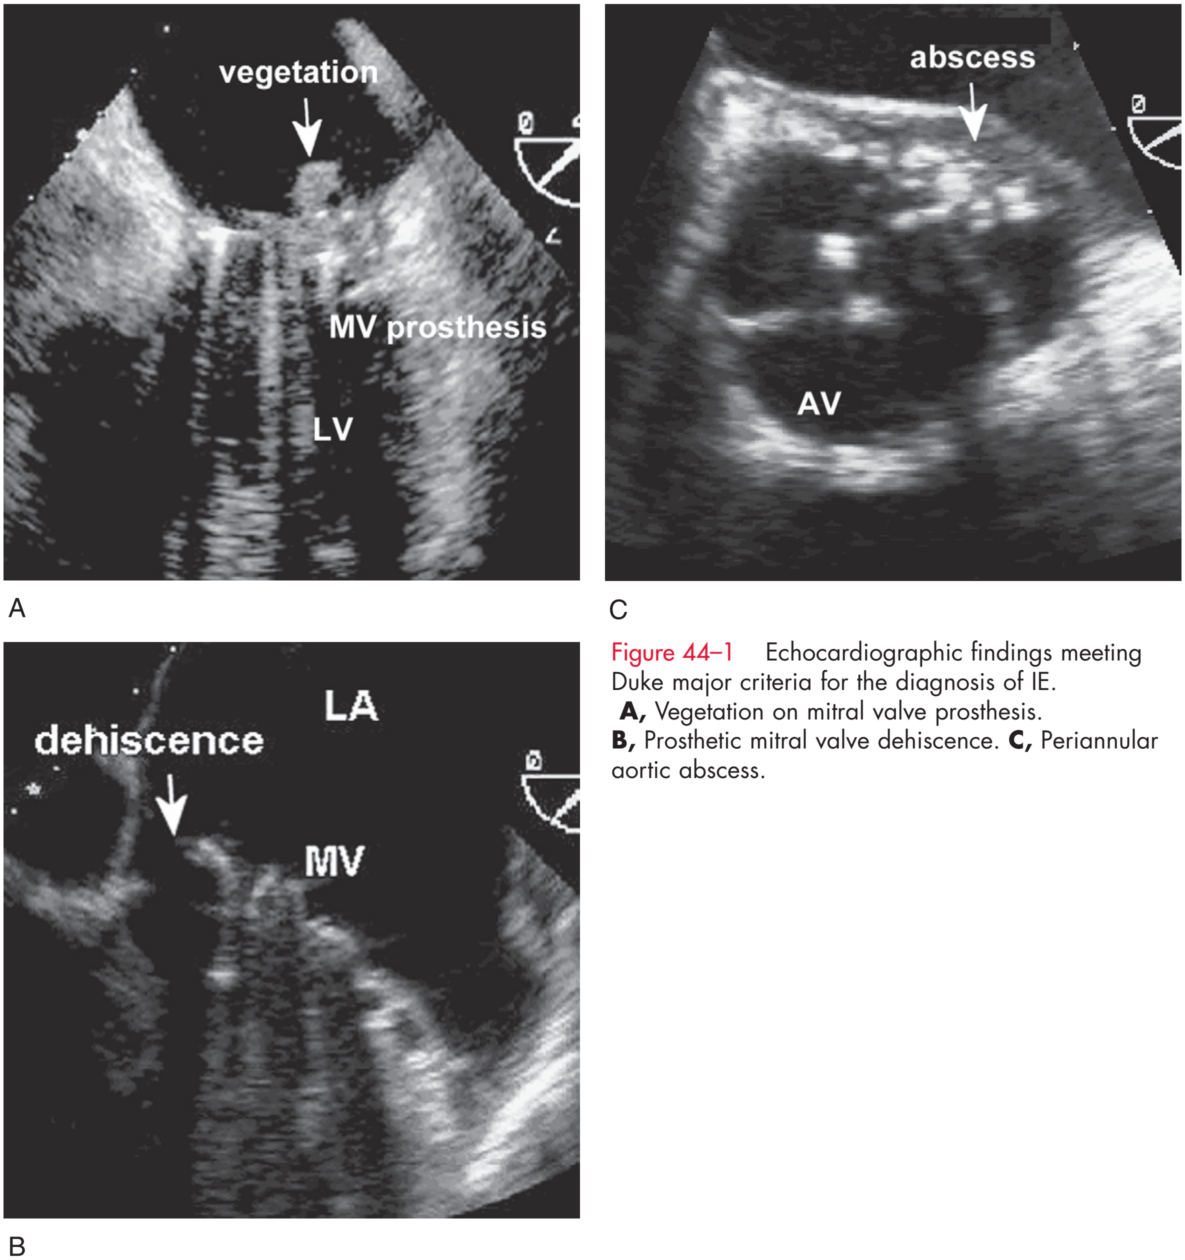

Figure 44–1 Echocardiographic findings meeting Duke major criteria for the diagnosis of IE. **A,** Vegetation on mitral valve prosthesis. **B,** Prosthetic mitral valve dehiscence. **C,** Periannular aortic abscess.

drug use, and positive blood cultures. When these criteria are collectively absent, the likelihood of finding echocardiographic evidence of endocarditis is unlikely.[17] Heidenreich and associates[13] sought to answer the question of which form of echocardiography to select with decision tree analysis and Markov modeling, using published data to simulate costs of care and outcomes of patients suspected of having IE. Based on this analysis, TEE was found to be cost effective for patients with a pretest probability in the intermediate range (i.e., patients with predisposing conditions and bacteremia typical for IE), while TTE was better only for those patients with a very low prior probability of IE. TEE is favored at many institutions for the evaluation of most patients with *S. aureus* bacteremia, and there is supporting evidence that TEE-guided therapy is cost effective for patients with catheter-associated *S. aureus* infections.[14]

Because TEE is more sensitive in detecting complications of IE, such as perivalvular extension and valve perforation, it should be used in patients at risk for these complications. Such patients include those who present with CHF, who develop new heart block, and who have persistent fever or bacteremia during appropriate antimicrobial therapy. TEE should also be used as the initial examination in the setting of the presence of prosthetic valves and intracardiac devices because of the low sensitivity for diagnosing infection in these conditions (≈25%) with TTE. When patients meet the modified Duke criteria for probable IE before imaging, TEE is usually the most rational next step for diagnosis.

In certain clinical situations TEE may be preferable as an initial study over TTE, shown in Table 44–3. The American Heart Association (AHA) recommends that TEE be performed in all patients who have a high clinical suspicion for IE and

Table 44–1 Sensitivity and Specificity of Echocardiography in the Diagnosis of Infective Endocarditis

	TTE		TEE	
	Sn	Sp	Sn	Sp
NVE	50-60%	91-98%	92%	91-98%
PVE	17-36%	100%	82-96%	97%
Abscess	28-36%	99%	76-100%	95%

NVE, native valve endocarditis; PVE, prosthetic valve endocarditis; Sn, sensitivity; Sp, specificity.
Data from NVE,[187-191] PVE,[187,192-195] abscess.[189,196,197]

Table 44–2 Clinical Findings Raising Suspicion for IE (Modified from ESC Guidelines)

New murmur or valvular abnormality
Embolism without known origin
Sepsis without known origin
Hematuria, glomerulonephritis, renal infarct
Fever with any of the following:
- Cardiac device or prosthetic valve in place
- Predisposition for IE
- New conduction disturbance
- New congestive heart failure
- Blood cultures growing organism typical for IE
- Multiple or changing pulmonary infiltrates
- Abscess of the kidney, spleen, or spine without clear origin

ESC, European Society of Cardiology; IE, infective endocarditis.
Data from Horstkotte D, Follath F, Gutschik E, et al: Guidelines on prevention, diagnosis and treatment of infective endocarditis executive summary; the task force on infective endocarditis of the European Society of Cardiology. Eur Heart J 2004;25: 267-76.

who are at high risk for complications. A decision tree to assist in the initial choice of imaging in the setting of suspected IE is shown in Figure 44–2. If the initial TEE is negative or non-diagnostic, a follow-up study is recommended if IE continues to be suspected 7 to 10 days after the first study.

Echocardiographic images should be interpreted only in conjunction with clinical findings. Examining echocardiographic images in isolation may lead to both false-positive and false-negative results. False-negative studies may result from vegetations smaller than the limits of imaging resolution, recent loss of vegetation that has embolized, or acoustic shadowing from a heavily calcified or prosthetic valve. False-positive studies occur in patients with severe myxomatous valvular disease, ruptured chordae, nonbacterial thrombotic (marantic) endocarditis, Libman-Sacks endocarditis, cardiac tumors, or Lambl's excrescences (small tags that occur on 70% to 90% of adult heart valves).

ANTIBIOTIC THERAPY

The cornerstone of antibiotic therapy is the isolation of the appropriate microorganism. Susceptibility testing helps in the appropriate choice and route of antibiotic therapy. Basic principles of antibiotic therapy include the need for bacteriocidal agents, given for an appropriate duration, and in doses that result in predictable and therapeutic serum levels. Most patients with native valve endocarditis (NVE) are treated with a 4-week course of antibiotics. Patients at higher risk for complications and relapse, such as prosthetic valve endocarditis (PVE), are treated for at least 6 weeks, regardless of whether surgery is performed. In selected patients, such as those with highly sensitive viridans group streptococci or uncomplicated right-sided IE due to methicillin-sensitive *S. aureus* (MSSA), a 2-week course of antibiotic therapy results in high cure rates without substantial recurrence.[2,18,19] In the setting of intravenous drug use (IVDU), the choice of antimicrobial therapy may be tailored on the basis of the type of injected drug. *Staphylococcal* species are the most common pathogens in this patient population. However, users of pentazocine are at risk for *Pseudomonas* infections, while those using brown heroin dissolved in lemon juice are at risk for infection with *Candida* species. Patients with IVDU who also have underlying valvular disease or left-sided IE are at risk for streptococcal and enterococcal infections. Details of recommended antibiotic therapy for the most common infecting organisms in IE are discussed in several reviews and are summarized in Tables 44–4 and 44–5.[2,3,20]

The most common cause of culture-negative IE is prior antimicrobial therapy. In the setting of concurrent antimicrobial therapy, discontinuing antibiotics and waiting for 3 days to draw blood cultures during evaluation for suspected IE is more likely to yield the etiological pathogen. However, in certain situations (e.g., CHF, new conduction abnormalities, embolism) empiric antibiotic therapy should be started without delay. Recommended antibiotic therapy for culture-negative endocarditis is found in Table 44–6.

Table 44–3 Situations When TEE is Preferable to TTE

- Prosthetic valves
- Intracardiac devices (pacemaker, ICD)
- Patients at high risk for complications
  - *Staphylococcus aureus*, fungal infection, prior IE, new heart block, cyanotic congenital heart disease, systemic to pulmonary shunts, poor response to antimicrobials
- Intermediate clinical suspicion of IE
  - Unexplained bacteremia with gram-positive cocci, catheter-associated *S. aureus*, IDU with fever or bacteremia
- Meeting modified criteria for possible IE
- When TTE images are inadequate

IE, infective endocarditis; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

IDENTIFYING PATIENTS AT RISK FOR COMPLICATIONS OF ENDOCARDITIS

Despite advances in medical and surgical therapy and better diagnostic methods, mortality rates from IE have not significantly changed since 1950. The reason for the lack in improvement in outcomes is related in large part to changes in

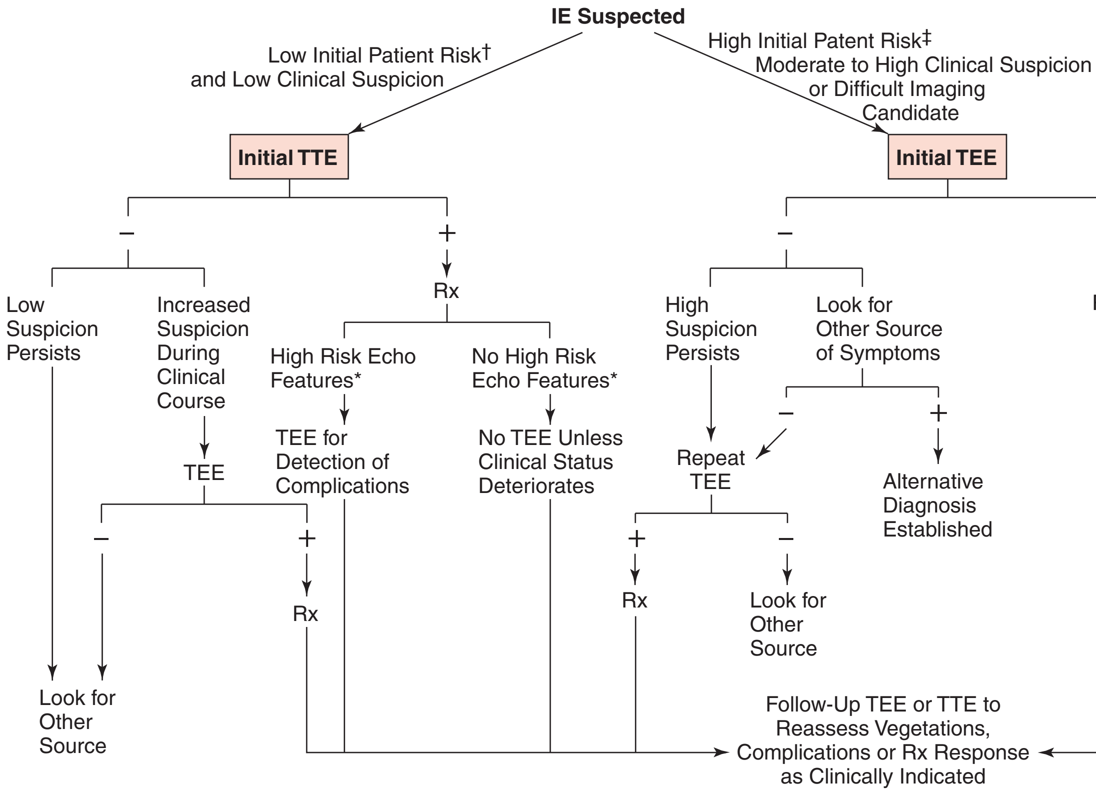

Figure 44–2 An approach to the diagnostic use of echocardiography. *High-risk echocardiographic features include large or mobile vegetations, or both; valvular insufficiency; suggestion of perivalvular extension; or secondary ventricular dysfunction (see text). †For example, a patient with fever and a previously known heart murmur and no other stigmata of IE. ‡High initial patient risks include prosthetic heart valves, many congenital heart diseases, previous endocarditis, new murmur, heart failure, or other stigmata of endocarditis. Rx indicates antibiotic treatment for endocarditis. (Redrawn from Bayer AS, Bolger AF, Taubert KA, et al: Diagnosis and management of infective endocarditis and its complications. Circulation 1998;98:2936.)

the epidemiology of IE. Paradoxically, medical progress has also contributed to an evolution of the spectrum of IE. With advancements in medical technology, endocarditis is shifting from a subacute to an acute, aggressive disease, increasingly involving the elderly, patients receiving hemodialysis, and those with prosthetic cardiac devices.

The U.S. population is aging, and elderly patients constitute a particularly vulnerable group due to the comorbidities associated with medical illness at an advanced age. The incidence of endocarditis in the elderly is 4 to 9 times greater than in the general population and has increased over the past decade.[21-23] Endocarditis in the elderly is associated with a higher mortality rate ranging from 17% to 28%[24-26] and with a higher risk of complications compared with endocarditis in younger patients. This may be related to a greater incidence of comorbid disease in this population, along with more aggressive pathogens. In at least one study, early surgical therapy in elderly patients with IE was independently associated with a lower in-hospital mortality.[26]

The incidence of IE in patients receiving hemodialysis has also increased over the past decade. Patients with hemodialysis have a fivefold increase in the incidence of valve disease,[27] and the incidence of IE in hemodialysis patients is 50- to 70-fold higher than in the general population.[11,28,29] A trend analysis of the Duke IE Database showed that not only did the overall proportion of IE cases occurring in hemodialysis patients increase over a 10-year period, but also that hemodialysis was the best predictor of *S. aureus* as the infecting microorganism.[30] Because of the more aggressive organisms and underlying comorbid disease, the in-hospital and 1-year death rates are high in hemodialysis patients (23% to 52% and 38% to 75%, respectively).[31-35] Factors associated with worse outcome include age, large vegetations, diabetes as a cause for end-stage renal disease (ESRD), fevers on admission, elevated WBC, multivalve IE, mitral annular calcification or severe mitral regurgitation in the setting of mitral valve IE, severe aortic regurgitation in the setting of aortic valve IE, and negative blood cultures.[31,32,34,35] When treating patients medically, one is tempted to use vancomycin even for MSSA because of its ease of administration in the hemodialysis patient. However, vancomycin exerts only a slow bactericidal effect and is less active than β-lactams for MSSA. In addition, there is justifiable concern that overuse of this agent will lead to emergence of vancomycin-resistant microorganisms. When a tunneled or other central catheter is in place, every effort should be taken to remove the catheter because cure is unlikely when catheter salvage is attempted.[36] In a single-center study, valve surgery was found to be an adverse predictor of outcome (75% mortality vs. 40% treated medically), raising concern about using traditional recommendations for surgery in patients receiving hemodialysis.[34]

Although diabetes mellitus is associated with an adverse prognosis in the hemodialysis population, the impact on the mortality rate in patients without end-stage kidney disease is

Table 44–4 Recommended Antimicrobial Therapy for Common Microorganisms in Infective Endocarditis

Microorganism	Native Valve	Prosthetic Valve	Notes
PCN-susceptible viridans streptococci and *S. bovis*, MIC ≤ 0.12 mcg/mL	PCN G 12-18 million U/24 hr IV continuously or in 4-6 divided doses × 4 wk *or* Ceftriaxone 2 g/24 hr IV/IM in 1 dose × 4 wk *or* Vancomycin 30 mg/kg/24 hr IV in 2 divided doses (not to exceed 2 g/24 hr) × 4 wk	PCN G 24 million U/24 hr IV continuously or in 4-6 divided doses × 6 wk *or* Ceftriaxone 2 g/24 hr IV/IM in 1 dose × 6 wk *with or without* Gentamicin 3 mg/kg/24 hr IV/IM in 1 dose × 2 wk *or* Vancomycin 30 mg/kg/24 hr IV in 2 divided doses (not to exceed 2 g/24 hr) × 6 wk	2-wk course of PCN G + gent (3 mg/kg/24 hr in one dose) or ceftriaxone + gent (3 mg/kg/24 hr in one dose) alternative in uncomplicated native valve cases in patients at low risk for gentamicin toxicity. Vancomycin only for patients unable to tolerate PCN or ceftriaxone.
Relative PCN-resistant viridans streptococci and *S. bovis*, MIC > 0.12 mcg/mL and ≤ 0.5 mcg/mL	PCN G 24 million U/24 hr IV continuously or in 4-6 divided doses × 4 wk *or* Ceftriaxone 2 g/24 hr IV/IM in 1 dose × 4 wk *plus* gentamicin 3 mg/kg 24 hr IV/IM in one dose × 2 wk *or* Vancomycin 30 mg/kg/24 hr IV in 2 divided doses (not to exceed 2 g/24 hr)	PCN G 24 million U/24h IV continuously or in 4-6 divided doses x 6 wks *or* Cetriaxone 2 g/24 hr IV/IM in 1 dose × 6 wk *plus* Gentamicin 3 mg/kg/24 hr IV/IM in 1 dose × 6 wk *or* Vancomycin 30 mg/kg/24 hr IV in 2 divided doses (not to exceed 2 g/24 h) × 6 wk	MIC > 0.5 mcg/mL strains treated with regimen recommended for enterococcal endocarditis later. Vancomycin only for patients unable to tolerate PCN or ceftriaxone.
Oxacillin-susceptible staphylococci	Nafcillin or Oxacillin 12 g/24 hr IV in 4-6 divided doses × 6 wk *with (optional)* Gentamicin 3 mg/kg/24 hr IV/IM in 2 or 3 divided doses × 3-5 days	Nafcillin or Oxacillin 12 g/24 hr IV in 6 divided doses ≥ 6 wk *with* Rifampin 900 mg/24 hr IV/po in 3 divided doses ≥ 6 wk *with* Gentamicin 3 mg/kg/24 hr IV/IM in 2 or 3 divided doses × 2 wk	For uncomplicated right-sided IE 2-wk course of nafcillin or oxacillin with gentamicin 3 mg/kg/24 hr in 2-3 divided doses. If history of non–anaphylactoid-type hypersensitivity reactions to β-lactams Cefazolin 6 g/24 hr IV in 3 divided doses × 6 wk *with (optional)* Gentamicin 3 mg/kg/24 hr IV/IM in 2 or 3 divided doses × 3-5 days. If history of anaphylactoid-type hypersensitivity to β-lactams, vancomycin should be used (based on oxacillin-resistant protocol).
Oxacillin-resistant staphylococci	Vancomycin 30 mg/kg/24 hr IV in 2 divided doses × 6 wk	Vancomycin 30 mg/kg/24 hr IV in 2 divided doses ≥ 6 wk *with* Rifampin 900 mg/24 hr IV/po in 3 divided doses ≥ 6 wk *with* Gentamicin 3 mg/kg/24 hr IV/IM in 2 or 3 divided doses × 2 wk	

Continued

Table 44–4 Recommended Antimicrobial Therapy for Common Microorganisms in Infective Endocarditis—cont'd

Microorganism	Native Valve	Prosthetic Valve	Notes
HACEK Microorganisms (*Hemophilus parainfluenzae*, *H. aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*)	Ceftriaxone 2 g/24 hr IV/IM in one dose × 4 wk or Ampicillin-sulbactam 12 g/24 hr IV in 4 divided doses × 4 wk or Ciprofloxacin 1000 mg/24 hr po or 800 mg/24 hr IV in 2 divided doses × 4 wk	Same protocol as native valve HACEK infection but for 6-wk course	May substitute cefotaxime or another third- or fourth-generation cephalosporin Fluoroquinolone therapy recommended only for patients intolerant to cephalosporins and ampicillin.

Vancomycin dose should be adjusted to obtain a peak 1 hr after infusion completed of 30-45 mcg/mL, and a trough of 10-14 mcg/mL. Dose of greater than 2 g/24 hr acceptable if serum concentrations inappropriately low.
Gentamicin dose should be adjusted to obtain peak of 3-4 mcg/mL and trough < 1 mcg/mL when 3 divided doses are used.
Nomogram used for single daily dosing.
See reference for pediatric dosing.
PCN, penicillin.
Data modified from references 200-202.

less clear. Chu and associates[37] found that diabetes, *S. aureus*, and embolic events were independently associated with adverse outcomes after controlling for severity of illness in a large prospectively collected population cohort. In contrast, others have not found diabetes to predict outcomes,[38,39] although these studies have been limited by retrospective identification and collection of cases, small sample size, and single center experiences.

Injection drug use has emerged as an important risk factor for IE, with incidences in this group of 720/100,000 person years[40] compared with 2.4 to 5.9/100,000 person years in the general population.[41,42] In HIV-positive patients, IE is uncommon in the absence of IVDU.[43] However, the combination of HIV and IVDU is associated with an even greater risk for developing IE.[40,44] Patients with IVDU more commonly have right-sided IE, which is associated with a low (<5%) hospital mortality rate.[45] However, left-sided IE in these patients has a mortality rate of 20% to 30%.[45] The presence of HIV itself is not associated with an adverse prognosis from IE,[46] although CD4 levels < 200 are associated with higher mortality rates.[47]

MANAGEMENT OF COMPLICATED INFECTIVE ENDOCARDITIS

Congestive Heart Failure

Congestive heart failure (CHF) is the most common cause of death in IE. The most common cause of CHF is infection-related valvular dysfunction. Endocarditis complicated by acute aortic insufficiency (AI) is associated with particularly high risk because acute AI is poorly tolerated and results in rapid progression of CHF in most cases.[48] The risk of CHF is also increased in the presence of virulent pathogens, such as *S. aureus;* hemolytic streptococci groups A-C, F, and G; and *Streptococcus pneumoniae.*[49]

Heart failure is the most common and accepted indication for surgery. It is the primary indication for surgery in 22% to 71% of cases of surgically treated IE.[50,51] Heart failure carries a worse prognosis with medical therapy alone, but it also increases surgical risks. Operative mortality for IE ranges from 6% to 11% in the absence of CHF compared with 11% to 35% when CHF has developed.[3,48,52] Four observational studies from the 1970s and 1980s compared combined medical and surgical therapy with medical therapy alone in the treatment of IE complicated by CHF and they found mortality rate with surgery ranged from 11% to 35% compared with 56% to 86% with medication alone.[53-56] In more contemporary series the mortality for surgically treated patients with decompensated CHF is 10% versus 20% to 27% in patients treated conservatively.[49,57] Significant treatment bias exists in all of the aforementioned observational studies. For instance, patients selected for surgery may be more acutely ill; conversely, patients who may require surgery can be denied this therapy because of advanced age and other comorbid diseases. Although there are no randomized trials comparing surgical with medical therapy for IE complicated by CHF, the most compelling evidence for the benefit of surgery comes from Vikram and associates.[58] By using propensity scores to reduce selection bias, they concluded that patients with moderate-to-severe CHF had a significant reduction in mortality with surgery compared with conservative therapy (HR 0.22, CI 0.08 to 0.53).[58] In fact, in this study the only group of patients in which surgery appeared to confer a survival advantage was that group with moderate-to-severe CHF.

Surgery should be performed before intractable CHF develops. Postoperative mortality is proportional to the severity of hemodynamic impairment at the time of surgery.[59] The mortality benefit is most apparent when surgery is performed early in the course of disease.[57] There is no evidence that delaying surgery to give additional antibiotics improves outcome. The small (2% to 7%) potential risk of recurrent IE

Table 44–5 Recommended Antimicrobial Therapy for Enterococcal Infective Endocarditis

Microorganism	Native or Prosthetic Valve	Notes
Enterococcus susceptible to PCN, gentamicin, and vancomycin	Ampicillin 12 g/24 hr IV in 6 divided doses *or* PCN G 18-30 million U/24 hr IV continuously or in 6 divided doses × 4-6 wk *plus* Gentamicin 3 mg/kg/24 hr IV/IM in 3 divided doses × 4-6 wk *or* Vancomycin 30 mg/kg/24 hr in 2 divided doses × 6 wk *plus* Gentamicin 3 mg/kg/24 hr IV/IM in 3 divided doses × 6 wk	Native valve: 4-wk dual therapy if ≤ 3 mo of symptoms; 6-wk dual therapy if > 3 mo of symptoms. Prosthetic valve: minimum 6 wk of dual therapy. Vancomycin only for patients intolerant to penicillin or ampicillin.
Enterococcus susceptible to PCN, streptomycin, and vancomycin and resistant to gentamicin	Ampicillin 12 g/24 hr IV in 6 divided doses *or* PCN G 24 million U/24 hr IV continuously or in 6 divided doses × 4-6 wk *plus* Streptomycin 15 mg/kg/24 hr IV/IM in 2 divided doses × 4-6 wk *or* Vancomycin 30 mg/kg/24 hr in 2 divided doses × 6 wk *plus* Streptomycin 15 mg/kg/24 hr IV/IM in 2 divided doses × 6 wk	Native valve: 4-wk dual therapy if ≤ 3 mo of symptoms; 6-wk therapy if > 3 mo of symptoms. Prosthetic valve: minimum 6 wk of dual therapy. Vancomycin only for patients intolerant to penicillin or ampicillin.
Enterococcus resistant to PCN and susceptible to aminoglycoside and vancomycin	Ampicillin-sulbactam 12 g/24 hr IV in 4 divided doses × 6 wk *plus* Gentamicin 3 mg/kg/24 hr IV/IM in 3 divided doses × 6 wk *or* Vancomycin 30 mg/kg/24 hr IV in 2 divided doses × 6 wk *plus* Gentamicin 3 mg/kg/24 hr IV/IM in 3 divided doses × 6 wk	If strain gentamicin resistant, > 6 wk of ampicillin-sulbactam required. Vancomycin only for patients intolerant to ampicillin-sulbactam. If intrinsic penicillin resistance, use vancomycin plus gentamicin dosing; consultation with infectious disease specialist recommended.
Enterococcus resistant to PCN, aminoglycoside, and vancomycin	*E. faecium*: Linezolid 1200 mg/24 hr IV/PO in 2 divided doses ≥ 8 wk *or* Quinupristin-dalfopristin 22.5 mg/kg/24 hr IV in 3 divided doses ≥ 8 wk *E. faecalis*: Imipenem/cilastin 2 g/24 hr IV in 4 divided doses ≥ 8 wk *plus* Ampicillin 12 g/24 hr IV in 6 divided doses ≥ 8 wk *or* Ceftriaxone 4 g/24 hr IV/IM in 2 divided doses *plus* Ampicillin 12 g/24 hr IV in 6 divided doses ≥ 8 wk	Consultation with infectious disease specialist recommended. Cure with antibiotics alone < 50%; valve replacement may be needed for cure.

Vancomycin dose should be adjusted to obtain a peak 1 hour after infusion completed of 30-45 mcg/mL and a trough of 10-14 mcg/mL. Dose of greater than 2 g/24 hr acceptable if serum concentrations inappropriately low.
Gentamicin dose should be adjusted to obtain peak of 3-4 mcg/mL and trough < 1 mcg/mL when 3 divided doses are used. Nomogram used for single daily dosing.
See reference for pediatric dosing.
PCN, penicillin.

after surgery in the acute phase is far less than the mortality rate from uncontrolled CHF.[60-62]

Abscess

Extension beyond the leaflets occurs in 8% to 40% of NVE,[63-66] most commonly in the aortic annular region, and has been reported in 56% to 100% of patients with PVE.[54,66-69] Periannular invasion is more common in bioprosthetic valves during the first postoperative year compared with later, while invasive disease occurs in mechanical valves regardless of time from implantation.[70]

Significant predictors of abscess include aortic valve involvement, IV drug use, and new atrioventricular (AV) or bundle branch block.[66,71,72] The development of new AV or bundle branch block has a positive predictive value of 77% but a relatively low sensitivity (42%) for abscess formation.[66] The presence of intraventricular block (bundle branch or hemiblock) also has poor prognostic implications, with mortality rates of 31% compared with 15% in patients without block.[73] Periannular extension is more common in patients with *S. aureus* IE[74] and should be suspected in patients with NVE with uncontrolled infection or acute hemodynamic deterioration. All patients with PVE involving the aortic valve are at high risk for abscess and should be evaluated aggressively.

Delivery of antibiotics to extravalvular tissue is difficult, and for this reason the mortality rate of medically treated patients with abscess may reach 75% or higher.[74-76] As a result, surgical therapy is preferred in most cases of abscess forma-

tion, with operative mortality rates in many,[77,78] but not all, series[59] not significantly different from patients operated on without abscess. If the surgical procedure is radical, resulting in complete resection of the abscess cavity and restoration of near-normal hemodynamics, presurgical abscess is not a predictor of early surgical mortality or reinfection rate.[79] A small number of patients with abscesses may be treated medically provided they are followed by serial TEE for progression of disease. Contraindications for medical management include heart block, valvular regurgitation, and dehiscence. If any of these conditions occur during medical management, prompt surgical intervention should be pursued.[80]

Embolic Events

The incidence of clinically significant embolic events ranges from 22% to 50%[81-86] and, in prospective targeted evaluations, is closer to 50%.[87] Stroke represents 50% to 65% of these cases and is a major contributor to the morbidity and mortality rates associated with IE.[88] The majority of strokes are diagnosed before antibiotic treatment begins.[88,89] Most "preventable strokes," defined as those occurring after the initiation of treatment, occur early. The frequency of embolism dramatically declines after initiation of antibiotic therapy.[49]

Vegetation size, morphology, and location have been associated with embolic risk. In a meta-analysis of 10 studies involving a total of 738 patients, 37% of the 323 patients with vegetations > 10 mm in diameter experienced embolism, a risk almost 3 times greater than in patients with smaller vegetations.[90] Some investigators found large vegetations independently predicted embolic events only in viridans group streptococcus, whereas infections with *S. aureus* had a high risk of embolism regardless of vegetation size.[81,83]

Evidence indicates that vegetations on the mitral valve (particularly the anterior leaflet) are associated with the highest risk for embolism and stroke (21% to 32% with mitral valve IE vs. 11% to 15% with aortic valve IE).[11,89] The degree of vegetation mobility may also predict embolic risk.[83,91] When the incidences of both silent emboli (as assessed by cerebral and thoracoabdominal CT scans) and clinically apparent emboli are included, the rate of embolic events is particularly high (83%) in the setting of vegetations that are large (>15 mm) and mobile.[83]

Developing risk models that allow appropriate stratification of patients with endocarditis is important. Clinical risk factors that increase the risk for embolization are shown in Table 44–7. Novel factors that may influence risk include circulating adhesion molecules, which may be stronger predictors of thromboembolism in endocarditis than echocardiographic features.[92] In addition, coagulation parameters, antiphospholipid antibodies, and endothelial cell activation have also been associated with thromboembolic events.[93] Elevation in serum CRP levels also appears to be associated with major embolic events,[86] and there is evidence that CRP plays a role in activating the coagulation cascade by inducing monocyte production of tissue factor.[94] Identifying risk factors associated with embolism may be useful in selecting patients who might benefit from early surgical therapy.

Although current practice suggests that surgery be performed after 2 or more embolic events occur on antibiotic therapy, many experts advocate earlier surgical intervention; however, evidence to support this position is limited. If the patient has another indication for surgical therapy, such as significant valvular regurgitation or CHF, the decision is easier because surgery will achieve a twofold objective. Likewise, surgery may be considered following a single embolic episode in patients with a persistent vegetation when the risk of repeat embolism, based on clinical, microbiologic, or echocardiographic parameters, is believed to be high. Whether surgery is warranted in the presence of a large mobile vegetation without evidence of embolism is unclear. However, when the goal is to prevent embolic events, surgery is best performed early because the rate of embolism decreases significantly after the first 1 to 2 weeks of medical treatment.[86]

Table 44–7 Risk Factors for Stroke/Embolism

Clinical	Microbiology	Echocardiography
Prior embolism Short symptom duration Older age PVE Atrial fibrillation	*S. aureus* *Candida* species Abiotrophia HACEK	MV infection Perivalvular extension Increase in size during Rx Vegetation number mobility size > 10 mm

Mycotic Aneurysms

Occurring in 1.2% to 5% of IE, mycotic aneurysms (MAs) result from embolization to the vasa vasorum with spread of infection into the intima and through the vessel wall.[95,96] They are associated with an increased mortality rate that ranges from 30% for unruptured to 80% for ruptured aneurysms.[97] The most common location is in the branch points of cerebral arteries, but visceral arteries and arteries of the extremities may also be involved. In the absence of signs or symptoms, routine screening for MA is not indicated. When symptoms that suggest MA are present (focal neurologic deficits or localized severe headaches), an MRI is often performed as the initial step. However, angiography is the diagnostic procedure of choice.[95]

Once the diagnosis of an intracranial MA is established, monitoring with serial angiograms is recommended, with prompt repair if the aneurysm is enlarging in size or is bleeding. Endovascular therapy is less invasive and is a viable alternative to surgical clipping or ligation. Intracranial MAs will often heal with medical therapy. However, extracranial mycotic aneurysms usually rupture if left untreated and preemptive repair is recommended. The diagnosis is often an incidental finding; for example, symptoms of extracranial MA rupturing include massive diarrhea (rupture of an MA into the bowel) or hematuria and increased blood pressure (rupture of a renal MA).

Prosthetic Valve Infections

Prosthetic valve IE can be devastating. The increased frequency of paravalvular invasion, particularly in early PVE, results in a greater incidence of complications such as heart failure, persistent fever, or new conduction abnormalities when compared with NVE. The reported mortality rates for PVE range

from 5% to 69%, with most studies suggesting a rate of 20% to 30%.[12,98-106] Early PVE (defined as occurring within the first postoperative year) is associated with a particularly high mortality rate[12] and is more likely to be associated with paravalvular invasion and hemodynamically significant valvular lesions.

The frequency of PVE is highest during the initial 3 months following implantation, remains high through the sixth month, and declines gradually to a relatively constant rate of 0.3% to 0.8% per year at 12 months and thereafter.[107-109] The infection risk may be higher for mechanical valves during the initial year following implantation, but over time the risk of infection for a bioprosthetic valve increases such that there is no overall difference in infection rates between the two valve types 5 years postoperatively.[108,109] Patients with prosthetic valves who develop nosocomial bacteremia are at high risk for developing PVE, with an incidence rate of 11%.[110]

The use of anticoagulation therapy is controversial. Experts agree that there is no role for the introduction of anticoagulation for patients who otherwise do not require it. Most experienced clinicians continue administration of anticoagulation during therapy for mechanical valve IE. This approach has been questioned, particularly in patient populations who are at high risk for embolism (e.g., *S. aureus* infection) during the first 1 to 2 weeks of therapy.[111] In patients with *S. aureus* PVE with embolism, discontinuation of anticoagulation for a period of 2 weeks is recommended.[20] Although aspirin has been shown to reduce vegetation size and embolism in some animal models, a randomized clinical trial did not show any reduction in embolization in patients receiving aspirin therapy. Notably, in that trial patients receiving aspirin therapy had a high rate of bleeding complications.[112] Therefore, the routine use of aspirin is not recommended for the purpose of preventing embolic events.[20]

Certain clinical findings help to identify patients who are at high risk for complications and death when they are treated with medical therapy alone. Patients who develop any of the following are at high risk for significant complications (including death) and unlikely to respond to medical therapy alone: pathologic murmurs or moderate-to-severe heart failure as a result of valve dysfunction, fever more than 10 days despite appropriate medical therapy, new-onset heart block, or echocardiographic evidence of abscess or valve dehiscence.[113,114] The addition of surgery to the treatment plan for high-risk patients results in greater survival rates, fewer relapses, and fewer rehospitalizations for valve surgery.[113,115,116] *S. aureus* PVE is associated with a particularly grave prognosis, with the mortality rate ranging from 28% to 82%.[113,114,117-119] Surgery appears to improve outcomes in *S. aureus* IE, regardless of the presence of cardiac complications.[117] Indications for surgical therapy of PVE are not absolute and should be implemented with careful attention to the relative risks and benefits for a given patient. For instance, there is observational evidence that supports medical therapy alone for patients with late-onset PVE caused by viridans streptococci, HACEK group, or enterococci without evidence of paravalvular invasion or valve dysfunction.[120] If medical therapy alone is pursued, frequent follow-up is required.

Table 44–8 Indications for Surgical Therapy

Moderate to severe CHF due to valve dysfunction
Extension of infection into adjacent structures
Fistula formation
Rupture into pericardium
New conduction disturbance
Abscess
Unstable prosthesis in PVE
Persistent bacteremia or fever despite appropriate antimicrobial therapy
No available effective antibiotic treatment
NVE with difficult to treat organisms
Coxiella burnetii, Brucella, left-sided *Pseudomonas aeruginosa*, fungal infections
PVE caused by *S. aureus*, multidrug resistant enterococci, fungi, *Pseudomonas* aeruginosa, *Brucella* species, *Coxiella burnetii*
Destructive microorganisms (*S. lugdunensis*)
Culture-negative PVE with unexplained fever > 10 days duration
PVE with relapse despite optimal therapy
Very large (>10 mm), very mobile vegetations
Increasing size of vegetation on antimicrobial therapy
Large (>20 mm) vegetation on tricuspid valve with septic pulmonary emboli

Data from references 203-208.

WHEN TO REFER FOR SURGICAL THERAPY

Surgical therapy is required during the early phase of IE in 20% to 40% of patients overall and in an even greater percentage of cases of patients with mitral valve IE.[42,49,60,98,121,122] Published experiences of surgery during active IE show operative mortality rates ranging from 5% to 16%, with actuarial 5- and 10-year survival rates of 75% and 61%, respectively.[48,50,51,57,59,79,121,123] By comparison, mortality rates for the same operative procedures are lower when performed for reasons other than IE.[50,121] Commonly accepted indications for surgery are shown in Table 44–8.

The decision for surgical therapy should not be based on absolute indications but rather on serial clinical evaluations, microbiologic results (including surveillance blood cultures on appropriate therapy), and echocardiographic findings (Fig. 44–3). Treatment failure should generally not be assumed unless (1) fever persists for more than 7 days or (2) blood cultures remain positive after 7 days of appropriate antibiotic therapy and a search for metastatic infection is negative.

Results of surgery depend on many factors including the preoperative condition of the patient, timing of the surgery, surgical techniques, and postoperative management. Preoperative predictors of mortality include NYHA classification, age, and the presence of renal failure.[51,57,59,79,123,124] Aggressive disease of a shorter duration, as occurs with *S. aureus,* is also associated with increased mortality.[23]

Early surgical intervention in the acute phase, particularly in the presence of uncontrolled infection, may seem risky due to concerns about placing prosthetic material into a highly infected field with the potential for failure and recurrence of IE. Some investigators have reported that surgical inter-

vention during the acute phase of IE was associated with increased risk for persistent or early recurrent PVE.[50,118,125] In contrast, others did not find this to be true,[60,62,119,126,127] particularly for mitral valve disease.[118,121] With increasing experience and good results, there is a trend for earlier operation in patients with IE. The final surgical outcome appears to have little relation to the duration and intensity of antibiotic therapy before surgery.[57,59,60,123,128-130] However, it is important that adequate bactericidal concentrations of antibiotics be present to kill bacteria entering the circulation during surgical débridement. In general, when surgery is indicated, prognosis is improved if surgery is performed early before the general condition of the patient has deteriorated.[60,68,98]

No randomized trials have shown a benefit with surgical therapy. When patients who undergo surgery are carefully matched using propensity scoring to reduce treatment bias, surgery in a diverse group of patients with IE is associated with a 50% reduction in the 6-month mortality rate versus medical therapy alone, although almost all of this benefit occurred in patients who had moderate-to-severe CHF.[58]

All patients with neurologic symptoms should undergo CT of the brain to clarify the nature and extent of disease and to identify hemorrhage before they undergo surgical therapy for IE. Cerebral angiography is recommended for patients with CT evidence of hemorrhage because 10% to 50% of these patients will have a ruptured MA.[131,132] A ruptured MA should be resected, clipped, or embolized before valve surgery occurs.[131]

After a stroke has occurred, the patient's risk for possible further neurologic damage during cardiopulmonary bypass becomes a concern. Some authors assert that valve replacement can be performed 72 hours or later after an ischemic cerebral infarct with a low risk of perioperative stroke in the absence of hemorrhage.[133] However, in a multicenter retrospective study involving 181 patients with cerebral complications, who underwent surgery for IE, the risk for exacerbation of neurologic events persisted for weeks.[134] This risk decreased with time regardless of the type of stroke; 15 and 28 days after stroke, the rates of exacerbation were 10% and 2.3%, respectively. Most investigators recommend allowing a 2- to 3-week interval between neurologic events and the cardiac operation.[131,135]

The choice of surgical technique plays a role in short- and long-term outcomes. Mitral valve repair and the use of homografts in the aortic position, even in the presence of active infection, may reduce the incidence of infective recurrence.[51,67,136,137] In the setting of mitral valve IE, valve repair should be performed whenever possible because it is associated with a lower mortality rate (0% to 9%) compared with mitral valve replacement (5% to 25%) and low rates of

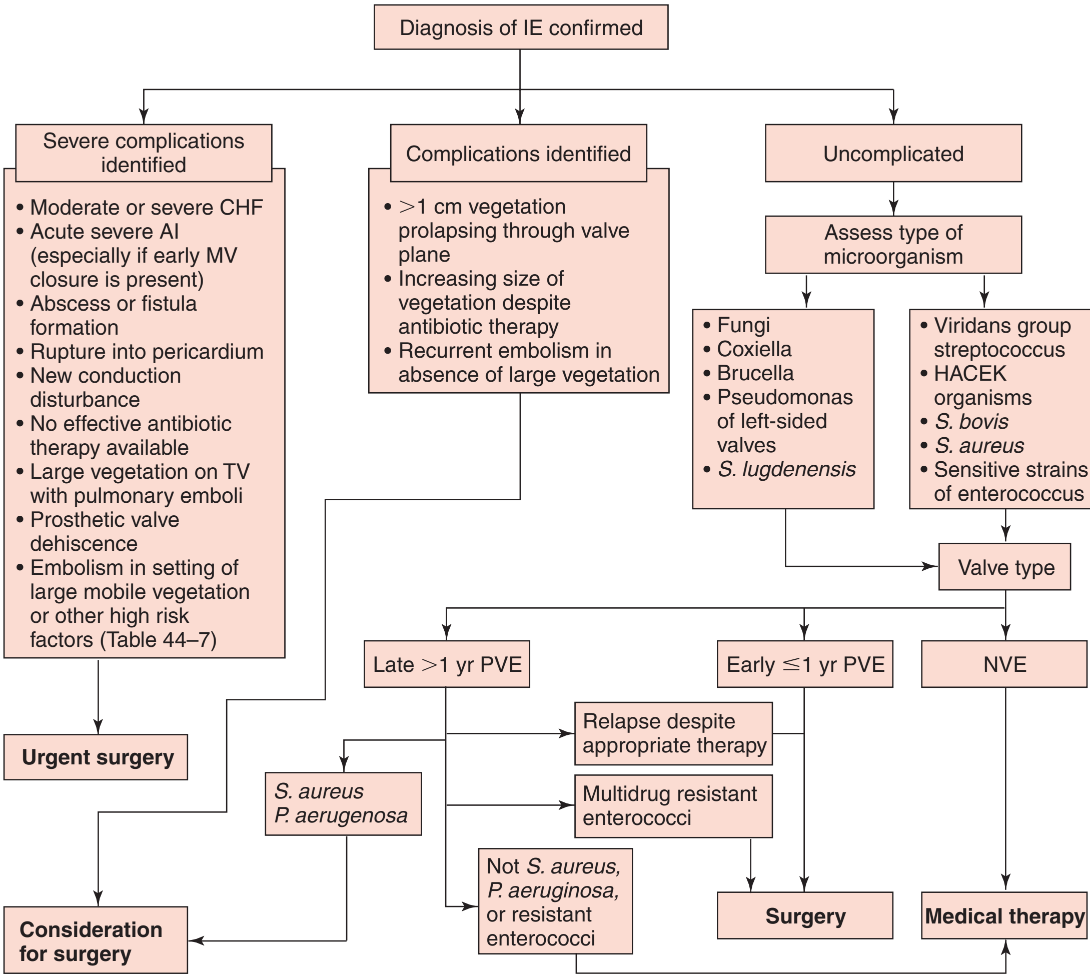

Figure 44–3 Decision tree for surgical therapy.

recurrent infection.[68,138-141] Ten-year survival rates in the setting of mitral valve repair are 80%,[141] compared with 61% after mitral valve replacement.[59]

For aortic valve IE, homograft replacement may be a better option in terms of reducing recurrent IE.[51] Homografts are also an advantage in the setting of extensive periannular destruction by infection.[137,142,143]

DEVICE-RELATED INFECTIONS

Cardiac device-related infections (CDIs) are becoming increasingly important because they represent a leading cause of death and disability after device implantation. The published incidence varies from 0.6% to 5.6% in recent series,[144-147] with 10% to 15% of all CDIs having involvement of an intracardiac lead. The risk of pacemaker-associated infection among high-risk populations, such as those with *S. aureus* bacteremia, may be as high as 45%.[148] Reported internal cardiac defibrillator (ICD) infection rates, although not studied systematically, appear to be at least 0.8% to 1.5% in nonthoracotomy devices.[144,145,149] The past decade has seen an exponential increase in placement of cardiac devices. In the Medicare population, CDIs have outpaced the increase in implantations, with an increase from 0.94 to 2.11 infections per 1000. Medicare beneficiaries have experienced a 124% relative increase, which may represent both an increase in the absolute number of patients with intracardiac devices, as well as an increase in the at-risk years for those patients.[150]

With contemporary data expanding the indications for defibrillators and biventricular pacemakers,[151-154] rates of device infections can be expected to keep increasing. The importance of CDI is further underscored when one considers that the cost of standard therapy includes removal of the entire device; intravenous antibiotics; and, in most instances, reimplantation of the device.[155]

TEE outperforms TTE in the detection of device IE and has a high concordance with surgical findings. The sensitivity of TTE ranges from 22% to 30% versus 95% for TEE.[147,156,157] Once a device infection is confirmed, a total of 4 to 6 weeks of appropriate antibiotic therapy is recommended on the basis of microorganism susceptibilities. *Staphylococcus epidermidis* and *S. aureus* are the most common infecting organisms,[147,155,157,158] and empiric therapy should be based accordingly on coverage. Because of unacceptably high relapse and death rates in patients whose device removal was incomplete, it is recommended that, in addition to antibiotic therapy, complete system removal be performed.[147,155] Removal can be performed using excimer laser with a complete extraction success rate of 95%.[159] Percutaneous removal has been described even for patients with large vegetations and is associated with a low complication rate.[156,160] We recommend an echocardiogram with contrast before percutaneous removal of an intracardiac lead to rule out a right-to-left cardiac shunt, particularly when large vegetation is evident. At the time of device removal, cultures from the device pocket and from all lead tips and mesh should be performed. Surgical removal is required in the setting of epicardial leads or in the presence of a right-to-left shunt and may be considered in the setting of a large mobile vegetation on the lead. In pacemaker-dependent patients, temporary pacing will be required, with leads placed on the ipsilateral side of infection proximal to the infected site.[161] Most authors recommend waiting at least 7 to 10 days before device replacement, after serial blood cultures are sterile and signs of infection are absent.

Preventive measures can reduce cardiac device infections. Preimplantation fever, the use of a temporary pacing wire before implantation, and early reintervention increase the risk for infection.[162]

Infections are often acquired at the time of device placement or during subsequent manipulation and are often latent. A meta-analysis of antibiotic prophylaxis before pacer placement in 2023 patients who were randomized to antibiotics versus placebo showed a consistent protective effect that decreased subsequent pocket and pacemaker infections by a magnitude of 40 over a mean follow-up of 2 years.[163]

LONG-TERM OUTCOMES—MANAGEMENT OF HOSPITAL SURVIVORS

Patients who survive the initial hospitalization are subject to long-term complications that are related to the predisposing factors that led to the initial infection, new valvular damage, or the prosthetic heart valve placed during the initial hospitalization. Relapse, defined as resumption of IE within 6 months of treatment with the same microorganism, occurs in approximately 3% of patients.[119,127,164] Recurrence, infection with a different organism, or infection more than 6 months after the initial episode occurs in 2.5% to 12.3% of hospital survivors.[12,119,164-166] The probability of recurrence-free survival is lower in men and in the elderly.

Between 19.7% and 47% of patients with IE who are treated medically will eventually require valve replacement, most frequently in the first 2 years of follow-up.[119,127,164,167] Patients who receive valve replacements during the acute episode of IE or during the follow-up period are at risk for all the complications that are associated with prosthetic heart valves including valve degeneration, thromboembolic events, bleeding, and recurrent infection.[168] In published series, the long-term mortality rate in hospital survivors varies greatly, most reporting a 10-year survival rate from 48% to 80%.[50,121,127,140,169] Age and recurrent endocarditis are significant predictors of mortality in the follow-up period.[164]

After the patient has completed the antibiotic course, any indwelling lines used for therapy should be removed promptly.[20] Surveillance blood cultures should be performed 5 to 7 days after discontinuation of antibiotics to confirm the effectiveness of therapy. A repeat TTE should be obtained after therapy to document the extent of residual valvular abnormalities and to reestablish baseline hemodynamics after valve repair or replacement surgery. The patients should be educated regarding antibiotic prophylaxis because they represent a high-risk group for recurrent IE. In addition, the patient should be referred for dental treatment if necessary. He or she should be scheduled for regular follow-up to assess for CHF and evidence for progression of valve disease.[20]

PREVENTION

Historically, endocarditis has been a disease associated with underlying valvular abnormalities, particularly rheumatic

Table 44–9 Underlying Cardiac Disease at Risk for Adverse Outcomes in Setting of IE

High Risk	Moderate Risk
Prosthetic valves	Most other congenital heart disease (excluding secundum ASD)
Prior IE	Acquired valvular heart disease
Cyanotic congenital heart disease	Hypertrophic obstructive cardiomyopathy
Surgically constructed systemic to pulmonary shunts	MVP with thickened leaflets or regurgitation

ASD, atrial septal defect; IE, infective endocarditis; MVP, mitral valve prolapse.

heart disease, and with community-acquired bacteremia. Approximately two thirds (53% to 70%) of patients with endocarditis have preexisting cardiac disease.[11,49,170] Few studies have quantified the actual risk for the development of IE on the basis of predisposing cardiac risk factors. Therefore, organizations such as the American Heart Association (AHA) and the European Society of Cardiology (ESC) base their recommendations for prophylaxis not only on the risk for the development of IE, but also on the risk for an adverse outcome if IE were to occur (Table 44–9*).* Patients with acquired valvular dysfunction are said to be at moderate risk for IE, although guidelines for antibiotic prophylaxis are not specific about which valvular abnormalities are included in this entity. Some authors have suggested using the U.S. Department of Health and Human Services (DHHS) criteria for valvular abnormalities: moderate or greater mitral, tricuspid, or pulmonary regurgitation; mild or greater aortic regurgitation; mild or greater mitral regurgitation with a thickened or redundant mitral valve; and any valvular stenosis of mild or greater degree.[171]

Because there have been no randomized, controlled trials in humans with underlying heart disease to determine whether antibiotic administration prevents IE, there has been controversy regarding the effectiveness of antibiotic prophylaxis for prevention of IE. Therefore, recommendations are based on in vitro susceptibilities of microorganisms known to cause IE, as well as on animal models of endocarditis. Four small case control studies have focused on antibiotic prophylaxis: One showed a benefit (although only eight cases of IE occurred),[172] and the other three found no significant protective effect.[173-175] Amoxicillin has been proven to have a significant impact on the incidence and duration of bacteremia after dental procedures.[176] However, the cost-effectiveness of amoxicillin for the prevention of IE has come into question.[177]

Despite the lack of convincing evidence for efficacy, antibiotic prophylaxis remains a class I recommendation by both AHA and ESC. Prophylaxis is primarily directed toward viridans group streptococcus and HACEK organisms before oral, respiratory, and upper gastrointestinal (GI) procedures and against *Streptococcus bovis* and enterococcus before GI and genitourinary (GU) procedures. Procedures likely to produce bacteremia and recommended antibiotic prophylaxis regimens are shown in Table 44–10.

With an age-related increase in the prevalence of valvular pathology[171,178] and the advancing age of the U.S. population, there is an increasing prevalence of cardiac valve disease that may warrant prophylaxis to prevent IE on the basis of current guidelines. This may lead to greater financial cost, development of antibiotic resistance, and adverse drug reactions, emphasizing the need for further study to determine which patients actually benefit from prophylaxis.

FUTURE DIRECTIONS

Future directions in therapy for IE include treatment with novel therapeutic agents. Bacterial adherence is central to initiation of infection and metastatic spread, and the MSCRAMM (Microbial Surface Components Recognizing Adhesive Matrix Molecules) family of bacterial surface adhesion proteins has been a target for the development of new immunotherapies. *S. aureus* Human Immune Globulin (SA-IGIV, Inhibitex, Inc.), a purified IgG derived from pooled human plasma selected for high antibody titers to the *S. aureus* MSCRAMM protein clumping factor A (ClfA), interferes with *S. aureus* adherence to extracellular matrix proteins in vitro and may also enhance opsonization and phagocytosis of *S. aureus* by PMNs.[179] In an animal model of *S. aureus* IE, combination therapy with SA-IGIV and vancomycin significantly increased clearance of bacteremia when compared with the use of vancomycin alone.[180] Aurexis is a humanized monoclonal antibody against ClfA; a phase 1 open-label trial in humans has been completed, and a phase 2 study of Aurexis in patients with MRSA IE is currently under way.[181,182]

The development and testing of vaccines to target high-risk groups may reduce adverse outcomes and the costs associated with this disease. Immunizations with fibronectin binding proteins or FimA proteins protect against experimental IE (with *S. aureus* and streptococcal species, respectively) in animal models.[183-185] StaphVax (Nabi, Inc.) is a vaccine with *S. aureus* type 5 and type 8 capsular polysaccharides, the strains accounting for more than 80% of *S. aureus* infections. In a double-blind, placebo-controlled trial StaphVax resulted in a significant 57% relative reduction in *S. aureus* bacteremia at 40 weeks in hemodialysis patients.[186] Such vaccines could have important clinical applications among patients with indwelling intravascular catheters or prostheses at high risk for *S. aureus* infections.

A shift in approach is necessary to further our understanding of IE. To develop the high-quality evidence necessary to make therapeutic decisions that improve the outcomes of our patients, we must take advantage of recent advances in technology and information systems. International collaboration in this area has led to opportunities to share data and conduct large-scale prospective cohort studies through the creation of the International Collaboration of Endocarditis (ICE) investigation. The first phase of this collaborative effort was to merge all existing databases into a single analysis database from which retrospective and descriptive studies are being performed. The second phase involved the development of a large global database of IE patients whose clinical, echocardiographic, and microbiologic findings have been characterized with standardized, predefined methods.

Since the inception of the prospective database in June 2000, 2739 patients who meet Duke criteria for definite IE have been enrolled from 59 sites in 27 countries. The multinational aspect of this study provides a global view of IE in

Table 44–10 Procedures Likely to Produce Bacteremia and Recommended Antibiotic Prophylaxis Regimens

Procedure	Antibiotic Prophylactic Regimen	Prophylactic Regimen for PCN-Allergic Patients	Notes
Dental procedures with risk of gingival/ mucosal trauma • Dental extractions • Periodontal procedures • Dental implants • Endodontic (root canal) instrumentation • Subgingival placement of antibiotic fibers or strips • Initial placement of orthodontic bands • Intraligamentary local anesthetic injections • Prophylactic cleaning of teeth **Respiratory tract and esophageal procedures** • Tonsillectomy or adenoidectomy • Surgical operations involving respiratory mucosa • Bronchoscopy with a rigid bronchoscope • Esophageal sclerotherapy or dilation	Amoxicillin 2 g PO 1 hr before procedure Unable to take PO: Ampicillin 2 g IM/IV 30 min before procedure	Clindamycin 600 mg PO 1 hr before procedure *or* Cephalexin or cefadroxil 2 g 1 hr before procedure *or* Azithromycin or clarithromycin 500 mg PO 1 hour before procedure Unable to take PO: Clindamycin 600 mg IV 30 min before procedure *or* Cefazolin 1 g IV 30 min before procedure	Avoid cephalosporins in patients with immediate-type hypersensitivity reactions to penicillins. See full reference for pediatric dosing.
Genitourinary Procedures • Lithotripsy • Cystoscopy • Prostate surgery • Urethral dilation • Gynecologic procedures in presence of infection • Biopsy urinary tract, prostate **Gastrointestinal procedures** • Surgical operations involving intestinal mucosa • ERCP with biliary obstruction • Biliary tract surgery	**High-risk patients:** ampicillin 2 g IM/IV *plus* gentamicin 1.5 mg/kg within 30 min of starting procedure *and* ampicillin 1 g IM/IV or amoxicillin 1 g PO 6 hr later **Moderate-risk patients:** Amoxicillin 2 g PO 1 hr before procedure *or* ampicillin 2 g IM/IV within 30 min of starting procedure	**High-risk patients:** Vancomycin 1 g IV over 1-2 hr plus gentamicin 1.5 mg/kg IV/IM to complete infusion within 30 min of starting procedure **Moderate-risk patients:** Vancomycin 1 g IV over 1-2 hr to complete infusion within 30 min of starting procedure	For definition of high- and moderate-risk patients, refer to Table 44–9. No second dose of vancomycin and gentamicin recommended in PCN-allergic patients Total dose of gentamicin should not exceed 120 mg. See full reference for pediatric dosing.

ERCP, endoscopic retrograde cholangiopancreatography; PCN, penicillin.
Data modified from Dajani AS, Taubert KA, Wilson W, et al: Prevention of bacterial endocarditis. Recommendations by the American Heart Association. Circulation 1997;96:358-66.

contrast to the relatively small case series largely from single centers. Identifying patients at high risk for complications and targeting this population for preventive therapy are among the potential benefits. The information gained from these efforts will be used to design and conduct randomized, controlled trials of treatment strategies that may then provide the definitive evidence necessary to assist with therapeutic decision-making.

CONCLUSION

Despite improved understanding of the pathogenesis of IE and despite the development of better diagnostic and therapeutic methods, the overall death rate for IE has changed little over the past 40 years. The use of global databases, such as ICE, can improve knowledge about this heterogeneous disease, identify populations at risk for IE and its complications, and create collaborations among investigators that will lead to new treatment and preventive strategies.

Chapter 45

Treatment of Pericardial Disease

Brian D. Hoit

CHAPTER CONTENTS

The treatment of pericardial disease is often simple and rewarding; however, it may offer unexpected challenges and frustrations to both clinician and patient for a number of reasons. First, the presence of pericardial heart disease may elude detection, often remaining clinically silent, being apparent only during the evaluation of unrelated complaints. Moreover, although pericardial disease may present as an isolated phenomenon, it may complicate a number of systemic disorders (and indeed may be overshadowed by extracardiac manifestations). Second, although the European Society of Cardiology published guidelines for the diagnosis and management of pericardial diseases,[1] there is a paucity of randomized, placebo-controlled trials (level of evidence A) from which appropriate therapy may be selected and important clinical decisions assisted (Table 45–1). Thus the physician often must rely heavily on clinical judgment because most data originate from small, uncontrolled trials and anecdotal experience. Finally, therapeutic options in most cases are limited to nonspecific anti-inflammatory agents, drainage of pericardial fluid, and pericardiectomy. Although there is general agreement on how these measures should be applied in the patient with either mild or severe disease, there is little consensus on how the large number of cases encountered with clinical manifestations between these two extremes should be managed. Recognizing the subjective nature of many of the therapeutic recommendations, this chapter reviews the options available for treating pericardial heart disease.

ACUTE PERICARDITIS

Acute fibrinous (or "dry") pericarditis is a syndrome characterized by typical chest pain, a pathognomonic pericardial friction rub, and specific electrocardiographic changes. Hospitalization is warranted for many patients who present with an initial episode of acute pericarditis (particularly with moderate or large effusions) in order to determine an etiology and to observe for the development of cardiac tamponade; close, early follow-up is important in the remainder. Establishing the exact cause of acute pericarditis is an important part of management, but considerable judgment must be exercised when deciding whether and how to investigate the possibility of concomitant systemic disease. For example, an extensive evaluation is generally unnecessary in a young, previously healthy adult who presents with a viral syndrome, typical pericardial chest pain, and a pericardial friction rub. Despite the availability of polymerase chain reaction (PCR) and histochemistry for etiolopathogenetic classification,[2] most cases of viral pericarditis are recognized long after the period of viral activity, making a specific etiologic diagnosis and the need for antiviral chemotherapy unnecessary.

Acute pericarditis usually responds to oral nonsteroidal anti-inflammatory agents (NSAIDs), such as acetylsalicylic acid (ASA) 650 mg every 3 to 4 hours or ibuprofen 300 to 800 mg every 6 hours. Indomethacin reduces coronary blood flow and should be avoided. Prophylaxis against gastrointestinal bleeding with H2 blockers or proton pump inhibitors is warranted, particularly in those at high risk or who require longer durations of treatment. Selective COX-2 inhibitors are NSAIDs with few adverse gastrointestinal effects, but they have been implicated in adverse cardiovascular events[3]; moreover, they have not been tested in acute pericarditis. Cumulative anecdotal data suggest that colchicine (1 mg/day, with or without a 2 mg loading dose), either as a supplement to the use of NSAIDs or as monotherapy, is effective for the acute episode, is well-tolerated, and may prevent recurrences.[4] Side effects (diarrhea and nausea) are usually mild and most often do not necessitate withdrawal of the drug; long-term toxicity (azoospermia and chromosomal abnormalities) is reported in patients treated with colchicines for gout and familial Mediterranean fever.[5]

Chest pain is alleviated in 1 to 2 days, and the friction rub and ST-segment elevation resolve shortly thereafter. Most mild cases of idiopathic and viral pericarditis are adequately treated with 1 to 4 days of treatment[6]; the duration of therapy is variable, however, and patients should be treated until an effusion, if present, has resolved.[1] The intensity of therapy is dictated by the distress of the patient, and narcotics may be required for severe pain. Some cases necessitate steroid therapy (prednisone 60 to 80 mg/day) for a week to control pain, with the dosage tapered carefully on an individual basis thereafter. However, corticosteroids should be avoided unless there are specific indications (e.g., connective tissue disease, autoreactive or uremic pericarditis) because they enhance viral multiplication and may result in recurrences when the dosage is tapered; colchicine may be particularly useful in this situation. Importantly, tuberculous and pyogenic pericarditis should be excluded before steroid therapy is initiated. Intrapericardial instillation of triamcinolone (300 mg/m^2) avoids systemic side effects and is highly effective.[2] Patients in whom pericarditis

Table 45–1 Summary of the European Society of Cardiology Guidelines on the Diagnosis and Management of Pericardial Heart Disease[1]

	Indication	Evidence
Acute Pericarditis		
NSAIDs	Class I	level B
Colchicine*	Class IIa	level B
Systemic corticosteroids†	Class IIa	level B
Chronic Pericarditis		
Balloon pericardiotomy or pericardiectomy‡	Class IIb	level B
Recurrent Pericarditis		
Colchicine	Class I	level B
Systemic corticosteroids§	Class IIa	level C
Pericardiectomy¶	Class IIa	level B
Pericardial Effusion		
Pericardiocentesis for cardiac tamponade	Class I	level B
Pericardiocentesis for smaller effusions	Class IIa	level B
Analysis of Pericardial Fluid		
Pericardial fluid and blood for bacteria	Class I	level B
PCR, ADA, IFγ, lysozyme for tuberculosis	Class I	level B
PCR, in situ hybridization for virus	Class IIa	level B
Serum viral titers	Class IIb	level B
Pericardial chemistry (specific gravity, protein, LDH, glucose)	Class IIb	level B
Specific Forms of Pericarditis		
Corticosteroids for TB pericarditis	Class IIb	level A
Pericardiocentesis for tamponade and large effusions unresponsive to dialysis	Class IIa	level B
Pericardiocentesis for large neoplastic effusions	Class I	level B
Diagnostic pericardiocentesis in suspected neoplastic effusion	Class IIa	level B
Intrapericardial instillation of cytotoxic/sclerosing agent for neoplastic pericarditis	Class IIa	level B
Radiation Rx for control of effusions in patients with radiosensitive tumors	Class IIa	level B
Percutaneous balloon pericardiotomy for malignant effusions	Class IIa	level B
Pleuropericardiotomy to drain malignant effusions	Class IIb	level C
Surgical therapy of chylous effusion resistant to diet and pericardiocentesis	Class I	level B
Thyroid hormone for effusion secondary to myxedema	Class I	level B

*For initial attack and prevention of recurrences.
†For connective tissue disease–associated, autoreactive, and uremic effusions.
‡For frequent and symptomatic recurrences.
§For recurrent pericarditis in patients in poor general condition or in frequent crises.
¶For frequent, highly symptomatic recurrences resistant to medical therapy.
ADA, adenosine deaminase; IFγ, interferon gamma; LDH, lactate dehydrogenase; PCR, polymerase chain reaction.

represents one manifestation of systemic illness (e.g., sepsis, uremia, connective tissue disease, neoplasia) should, in addition to palliative and supportive treatment, also receive therapy directed toward the primary disorder.

RECURRENT PERICARDITIS

Recurrent or relapsing acute pericarditis is one of the most distressing disorders of the pericardium for both patient and physician. It may occur with or without pericardial effusion and occasionally is associated with pleural effusion or parenchymal pulmonary lesions. Atypical features, such as the absence of physical findings, offer challenges for diagnosis and management and often necessitate close follow-up and rigorous emotional support. Recurrences occur with highly variable frequency over a course of many years; although they may be spontaneous, occurring at varying intervals after discontinuation of drug (i.e., "recurrent"), they are more commonly associated with either discontinuation or tapering of anti-inflammatory drugs (i.e., "incessant").

Painful recurrences of pericarditis may respond to NSAIDs but commonly require corticosteroids. Once steroids are administered, dependency and the development of steroid-induced abnormalities are potential perils. Prednisone is begun at a high dose (1 to 1.5 mg/kg/day) for at least 4 weeks and tapered slowly over the next 3 months.[7] Tapering to the lowest possible dose, using alternate day therapy, or combinations with NSAIDs should minimize the risks associated with long-term steroids. In the most difficult cases, relapse occurs each time the dose of prednisone is reduced to less than 5 to 20 mg/day. When this occurs, the patient should be maintained for several weeks on the lowest suppressive dose before the next taper commences. A recent multicenter trial of 51 patients followed for up to 10 years suggests that colchicine is both efficacious and safe for the prevention of recurrences.[8]

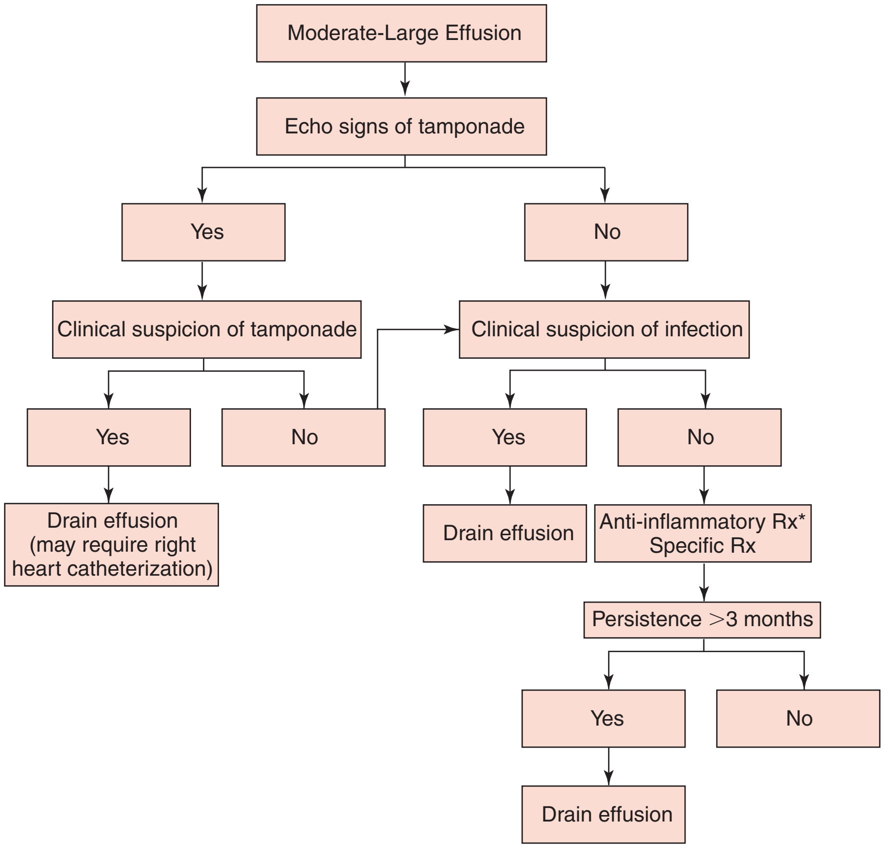

Figure 45–1 Algorithm for the management of moderate to large pericardial effusions. *Anti-inflammatory treatment if there are signs of pericarditis. (Redrawn with permission from Hoit BD: Management of effusive and constrictive pericardial heart disease. Circulation 2002;105:2939-42.)

Most authors recommend 1 mg/day p.o. for at least 1 year with a gradual taper; the need for a loading dose of 2 to 3 p.o. mg is unsettled. Azathioprine and cyclophosphamide have been used to prevent recurrent episodes in patients who fail to respond to high-dose corticosteroids or who experience severe corticosteroid side effects.[7] Although encouraging results have been reported in a series of patients who underwent surgery for recurrent pericarditis, pericardiectomy may simply abbreviate, rather than terminate, the painful recurrences. Therefore, pericardiectomy should be considered only when repeated attempts at medical treatment have clearly failed, especially when there is evidence (or at least well-grounded suspicion) of steroid-induced complications.

PERICARDIAL EFFUSION AND TAMPONADE

In the absence of tamponade or suspected purulent pericarditis, there are few indications for pericardial drainage. Persistent large and unexplained effusions (especially when tuberculosis is suspected or present for more than 3 months) may warrant pericardiocentesis. Occasionally, suspected malignancy or systemic disease may necessitate pericardial drainage and biopsy. However, *routine* drainage of large effusions (20-mm, echo-free space in diastole) has a low diagnostic yield (7%) and no therapeutic benefit.[9] Figure 45–1 presents an approach to the management of moderate and large pericardial effusions.

Remembering that clinically significant tamponade is a clinical diagnosis and "echocardiographic signs of tamponade" are not by themselves an indication for pericardiocentesis is important. Although the absence of any cardiac chamber collapse has a high negative predictive value (92%), the positive predictive value is reduced (58%); and although positive and negative predictive values were high (82% and 88%, respectively) for abnormal right-sided venous flows (i.e., systolic predominance and expiratory diastolic reversal), they could not be evaluated in more than one third of patients.[10]

Removal of small amounts of tamponading pericardial fluid (≈50 mL) produces considerable symptomatic and hemodynamic improvement because of the steep pericardial pressure-volume relation. Unless there is concomitant cardiac disease or coexisting constriction (i.e., effusive-constrictive pericarditis), removal of all of the pericardial fluid normalizes pericardial, atrial, ventricular diastolic and arterial pressures, and cardiac output (see Fig. 45–1). Mild or low pressure tamponade (i.e., when the venous pressure is < 10 cm of water, arterial blood pressure is normal, and pulsus paradoxus is absent), particularly when the etiology is idiopathic, viral, or when responsive to specific therapy (e.g., thyroid hormone), does not require pericardiocentesis. At the other extreme, hyperacute tamponade (usually resulting from cardiac trauma) necessitates immediate pericardiocentesis as an initial triage measure. However, most patients fall between these two extremes and will require pericardial drainage. Either surgical means (via subxiphoid incision, video-assisted thoracoscopy, or thoracotomy) or percutaneous means (with a needle or balloon catheter) accomplishes pericardial drainage.

Unless the situation is immediately life threatening, experienced staff should perform pericardiocentesis in a facility equipped with radiographic, echocardiographic, and hemodynamic monitoring to optimize the success and safety

Table 45–2 Advantages and Disadvantages of Pericardial Drainage Methods

Method	Advantages	Disadvantages
Pericardiocentesis	Acquisition of hemodynamic data Provides effective relief, particularly if no clots Less postoperative pain than other methods	No biopsy material available Effusion may recur Drainage may not be adequate, particularly if effusion is loculated
Pericardiotomy (subxiphoid or balloon)	Clots and loculations removed "Minor" surgical procedure	Evacuation may not be complete Frequent pericardial-pleural window closure
Open Surgical Drainage	Complete drainage Less reaccumulation, constriction (if total pericardiectomy) Access to pericardial tissue Avoidance of "blind" trauma to pericardium	Surgical procedure Hemodynamics not readily available Longer hospitalization, more postoperative pain

of the procedure. Monitoring the cardiac rhythm and systemic blood pressure is a minimum requirement. Invasive hemodynamics and measurement of pericardial pressures are useful for the diagnosis, particularly in questionable cases. Monitoring the local electrocardiogram from the needle tip is not recommended by all authors, and if such monitoring is employed, it is essential that the apparatus have equipotential grounding. The advantages of needle pericardiocentesis include the ability to perform careful hemodynamic measurements and relatively simple logistic and personnel requirements (Table 45–2). The safety of the procedure has been increased by using 2-D echo guidance (Fig. 45–2).[11]

The patient's back should be elevated at an approximately 30-degree angle to assist anterior and inferior pooling of the effusion. The subxiphoid approach is preferred because of its extrapleural and relatively avascular location. Echocardiographic or computed tomographic guidance assists pericardial drainage using alternative sites on the chest wall. Except in the most desperate measures, a short beveled needle, 5 to 8 cm long (unless the patient is morbidly obese) should be used. The needle track is anesthetized with 1% lidocaine, and the skin is pierced with a blade approximately 5 mm below and to the left of the subxiphoid process. The needle is attached via a three-way stopcock to a pressure transducer and an aspiration syringe containing 1% lidocaine and is advanced at an approximately 90-degree angle to the skin until the inner aspect of the rib cage is reached. The hub of the needle is then depressed and angled toward the left shoulder, and the needle is advanced cautiously with a 15-degree posterior tilt using a "worm gear" turning action. Deeper tissues are anesthetized with small injections of lidocaine that follow attempts to aspirate fluid. Upon puncturing the parietal pericardium, a slight "give" may be appreciated. Unsuccessful aspiration (or epicardial contact, which may be indicated by a current of injury, ventricular ectopic beats, or transmission of a "tickling" sensation in the fingers) calls for posterior reorientation of the hub or the redirection of the needle toward the right shoulder.[6] Injection of agitated saline or small quantities of radiographic contrast and imaging can make confirmation of pericardial puncture with echocardiography or fluoroscopy, respectively (Fig. 45–3). Unless there has been massive intrapericardial hemorrhage, bloody fluid originating from the pericardium does not clot.

A 6- to 8-cm French catheter may be placed over a guidewire when pericardial fluid can be freely withdrawn, and the catheter left in place for continued drainage (using only slight negative pressure). Drainage of the pericardial fluid using a catheter minimizes trauma, allows measurement of pericardial pressure and instillation of drugs into the pericardium, and helps prevent (but does not guarantee) reaccumulation of pericardial fluid. Extended (3 ± 2 days) catheter drainage is associated with a trend toward lower recurrence rates over a nearly 4-year follow-up.[12] Generally speaking, drainage should continue until the volume of the aspirated volume is less than 25 mL/day. The site of skin puncture should be covered with antiseptic ointment and a sterile dressing during catheter drainage.

Although pericardiocentesis is usually well tolerated, pulmonary edema, circulatory collapse, and acute right and left ventricular dysfunction have been reported after drainage.[13-15] Patients should be monitored for recurrent tamponade, particularly those with hemorrhagic effusions, which may occur despite the presence of an intrapericardial catheter. Dilute heparin or fibrinolytic agents may be instilled in the catheter to prevent clotting. Patients generally should be observed for 24 hours in an intensive care unit.

Major complications of pericardiocentesis include laceration of a coronary vessel, perforation of the myocardium (the thin-walled coronary veins and right heart chambers are particularly prone to brisk bleeding), hypotension (often reflex in origin), arrhythmia (both atrial and ventricular), perforation of a lung, or gastrointestinal viscus.

Although pericardiocentesis may provide effective relief, percutaneous balloon pericardiotomy, subxiphoid pericardiotomy, or the surgical creation of a pleuropericardial or a peritoneal-pericardial window[16,17] may be required. In a retrospective review, pericardiocentesis with intrapericardial sclerotherapy was as effective as an open surgical drainage procedure in patients with malignant pericardial effusion.[18] However, the safety and efficacy of subxiphoid pericardiostomy was found to be superior to percutaneous drainage in both benign and malignant effusions. The authors of the latter study recommended that percutaneous needle drainage be reserved for patients with hemodynamic instability.[16]

Open surgical procedures offer several advantages including complete drainage, access to pericardial tissue for histopathologic and microbiologic diagnoses, the ability to evacuate loculated effusions, and the absence of traumatic injury owing to the blind placement of a needle into the pericardial space. The choice between needle pericardiocentesis

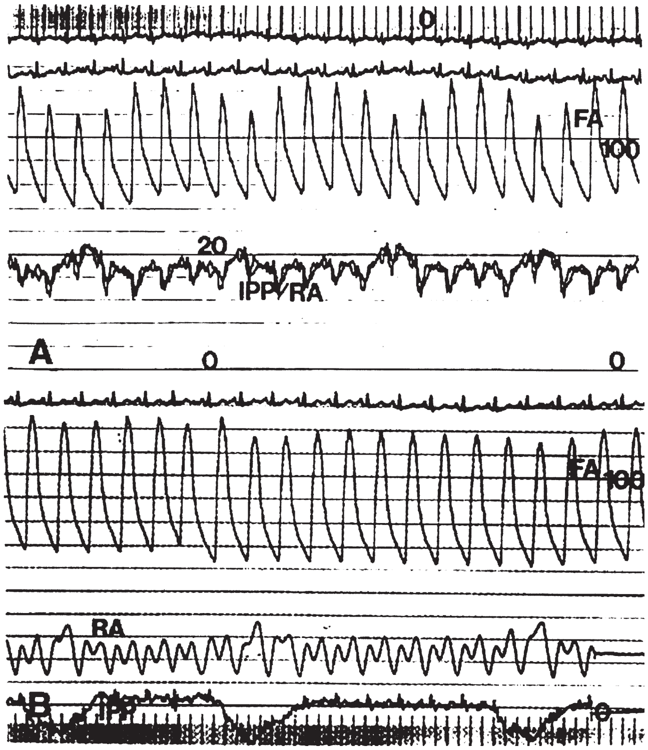

Figure 45–2 Hemodynamic record from a patient with cardiac tamponade before *(A)* and after *(B)* pericardiocentesis. **A**. Pulsus paradoxus is evident from the femoral artery *(FA)* pressure tracing. Note the absent Y descent on the right atrial *(RA)* tracing and the equal and elevated RA and pericardial *(IPP)* pressures. **B**. After removal of pericardial fluid, pericardial and right atrial pressures decrease and the pulsus paradoxus disappears. (Courtesy Noble O. Fowler, MD. From Hoit BD: Pericardial disease and pericardial heart disease. In O'Rourke RA (ed): Steins's Internal Medicine, 5th ed. St. Louis, Mosby–Year Book, 1998, p 273.)

and surgical drainage depends on institutional resources and physician experience, the etiology of the effusion, the need for diagnostic tissue samples, and the prognosis of the patient. Needle pericardiocentesis is often the best option when the etiology is known or the diagnosis of tamponade is in question, or both, and surgical drainage is optimal when the presence of tamponade is certain but the etiology is unclear. Pericardiocentesis is ill-advised when there is less than 1 cm of effusion, loculation, or evidence of fibrin and adhesion (Fig. 45–4). It should be recognized that surgical approaches (subxiphoid pericardiotomy or thoracoscopic drainage) can be performed using local anesthesia with little attendant morbidity. Irrespective of the method of retrieval, pericardial fluid should be sent for hematocrit and cell count; glucose; Gram, Ziehl-Nielsen, and fungal smears; viral, bacterial, and fungal culture; and cytology. Depending on the clinical circumstances, cytology; tumor markers and carbohydrate antigens (for suspected malignant disease); and adenosine deaminase, interferon gamma, pericardial lysozyme, and PCR analysis (for suspected tuberculosis) should be obtained.

IV saline solution should be given to patients with cardiac tamponade awaiting pericardial drainage in an effort to expand the intravascular volume. However, volume expansion may only be of value in hypovolemic patients.[19] Dobutamine or nitroprusside may be used to increase cardiac output after the blood volume has been expanded, but only as a temporizing measure. Vagal reflexes complicating tamponade or pericardiocentesis are treated with atropine (1 mg IV). Positive pressure breathing should be avoided because it reduces venous return, right ventricular transmural pressure, and cardiac output.

Recurrent effusions may be treated by either repeat pericardiocentesis, sclerotherapy with tetracycline, surgical creation of a pericardial window, or pericardiectomy. Subtotal pericardiectomy is preferred when the patient is expected to survive more than 1 year. A pleuropericardial window provides a large area for fluid to be reabsorbed and is often performed in patients with malignant effusions. Pericardiectomy may be required for recurrent effusions in dialysis patients. In critically ill patients, a pericardial window may be created percutaneously with a balloon catheter.[20,21]

CONSTRICTIVE PERICARDITIS

Constrictive pericarditis is a condition in which a thickened, scarred, and often calcified pericardium limits diastolic filling of the ventricles. Although acute pericarditis from most causes may eventuate in constrictive pericarditis, the most common

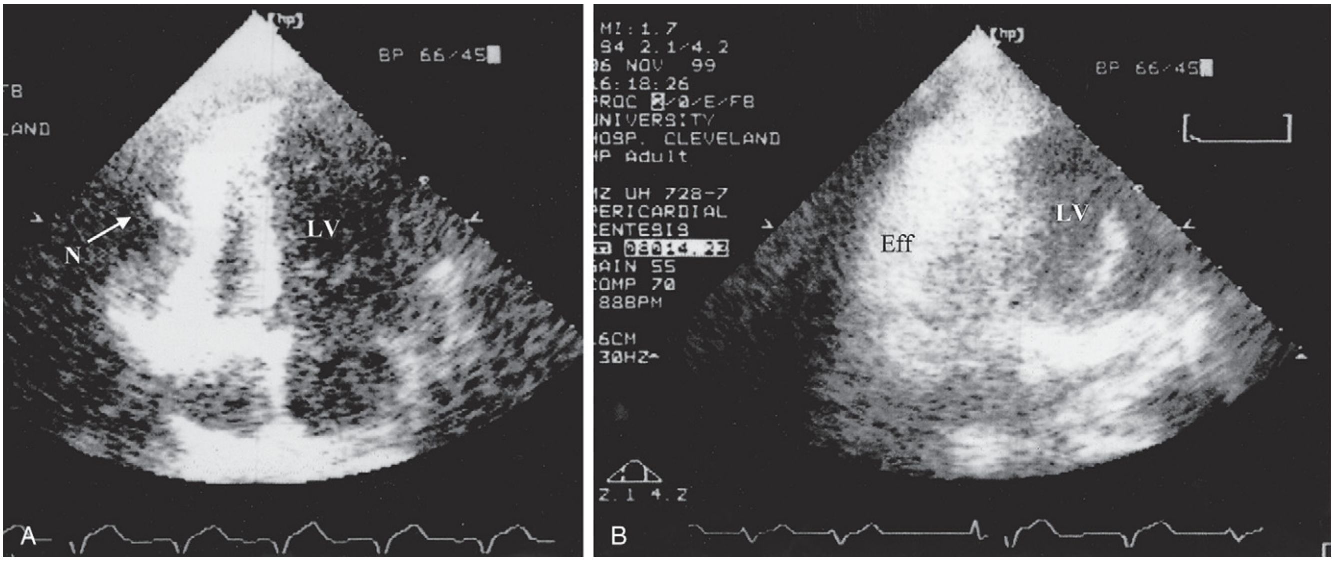

Figure 45–4 Echocardiographic imaging can be used to verify the intrapericardial location of the needle *(N)* by either direct imaging **(A),** or by the production of an intrapericardial contrast effect *(Eff)* after injection of agitated saline **(B).** LV, left ventricle.

antecedents are idiopathic pericarditis, cardiac trauma and surgery, mediastinal irradiation, tuberculosis (particularly common in nonindustrialized countries) and other infectious diseases, neoplasms (particularly lung and breast), renal failure, and connective tissue diseases. Although it is commonly thought that a normal pericardial thickness excludes the diagnosis of constrictive pericarditis, 28% of 143 surgically confirmed cases had normal pericardial thickness on CT scan and 18% had normal thickness on histopathologic examination.[22]

Classic *chronic constrictive pericarditis* is less frequently encountered than in the past, whereas *subacute constrictive pericarditis* (weeks to months after the inciting injury, such as after cardiac surgery) is becoming more common. In this latter group of patients, constriction may be transitory, with a course that may span a matter of weeks to a few months. Not surprisingly, pericardial calcification is uncommon. Doppler-detected constrictive physiology resolved without pericardiectomy in 36 of 212 patients studied retrospectively at Mayo Clinic after an average of approximately 8 weeks.[23] In asymptomatic patients *(occult constrictive pericarditis)*, exercise testing and, if available, maximal O_2 consumption should be quantified, jugular venous pressure carefully estimated, and liver function tests measured. Increasing jugular venous pressure, the need for diuretic therapy, evidence of hepatic insufficiency, and reduced exercise tolerance indicate the need for surgery.

Pericardiectomy is the definitive treatment for constrictive pericarditis but is unwarranted either in early constriction (occult and functional class I) or in severe, advanced disease (functional class IV), when the risk of surgery is excessive (operative mortality 30% to 40% versus 6% to 19%) and the benefits are diminished.[24,25] Because some cases of constriction resolve spontaneously, it is prudent that patients with subacute constrictive pericarditis who are hemodynamically stable be given a trial of conservative management for 2 to 3 months until it is clear that the constrictive process is permanent before pericardiectomy is recommended. After pericardiectomy, symptomatic relief and normalization of cardiac pressures may take several months, occurring sooner when the operation is carried out before the disease becomes too chronic (calcification may correlate with disease chronicity in populations with a low incidence of tuberculous pericarditis[26]) and when the pericardiectomy is almost complete. Complete or extensive pericardial resection is desirable. In one study, the long-term outcome was predicted by three variables in a stepwise logistic regression analysis. Specifically, the prognosis was worse with increasing age and New York Heart Association class and a postirradiation etiology.[25] In another study, age, renal dysfunction, pulmonary hypertension, left ventricular dysfunction, and hyponatremia were independent adverse predictors.[27]

Pericardiectomy is commonly carried out via a median sternotomy, although some surgeons prefer access through a thoracotomy. Despite a decline, the risk of mortality remains approximately 6% to 19%. The risk is increased by heavy calcification and involvement of the visceral pericardium. Left ventricular systolic dysfunction may occur after decortication of a severely constricted heart. Although the left ventricular dysfunction may require treatment for several months, it usually resolves completely. In highly selected patients, orthotopic transplantation may be considered.[25]

Medical therapy of constrictive pericarditis has a small but important role. In some patients constrictive pericarditis resolves either spontaneously or in response to various combinations of nonsteroidal anti-inflammatory agents, steroids, and antibiotics[23]; in the remaining patients medical therapy is adjunctive. Specific antibiotic (e.g., antituberculous) therapy should be initiated before surgery and continued afterward. Preoperative diuretics should be used sparingly with the goal of reducing, not eliminating, elevated jugular pressure, edema, and ascites. Postoperatively, diuretics should be given if spontaneous diuresis does not occur. The central venous pressure may take weeks to months to return to normal after pericardiectomy. The left ventricular ejection fraction may decrease postoperatively, only to return to normal months later. In the interim, digoxin, diuretics, and vasodilators may

be useful. Diuretics and digoxin (in the presence of atrial fibrillation) are useful in patients who are not candidates for pericardiectomy because of their high surgical risk.

Prevention of pericardial constriction consists of appropriate therapy of acute pericarditis and adequate pericardial drainage. Although instillation of fibrinolytics (urokinase 400,000 U per instillation to 1,600,000 U; streptokinase 250,000 IU per instillation to 1,000,000 IU) is promising, corticosteroid instillation is often ineffective.[28-29]

TREATMENT OF SPECIFIC CAUSES OF PERICARDITIS

Purulent Pericarditis

The incidence and bacterial spectrum of purulent pericarditis have changed because of the increasing frequency of cardiac surgery and instrumentation, selection-induced changes in the flora responsible for hospital-acquired infections, and the prolonged survival of immunocompromised hosts. Bacterial pericarditis is treated with surgical exploration and drainage (pericardiectomy is preferable) and appropriate systemic antibiotics, which should be considered adjuvant. A high index of suspicion is critical because in the appropriate setting, pericardial involvement is often unrecognized when it complicates systemic infection, and the characteristic features of acute pericarditis are frequently absent. The threshold for echocardiography in the septic patient should be low, and whenever purulent pericarditis is suspected, the pericardial space should be explored. Iodine-containing irrigants may provoke constriction and should be avoided. Fibrinolytics (see earlier) may be used to lyse fibrous adhesions, liquefy purulent exudate, and prevent constrictive pericarditis.[28-29]

Mycobacterial and Fungal Pericarditis

Tuberculosis is a major cause of pericarditis in nonindustrialized countries but is an uncommon cause of pericarditis in the United States. Nevertheless, its incidence is increasing because of HIV infection.[30] Tuberculous pericarditis results from hematogenous spread of primary tuberculosis or from breakdown of infected mediastinal lymph nodes, and therefore typical symptoms and signs and radiologic evidence of pulmonary tuberculosis are usually absent. Fibrinous pericarditis with caseating necrosis and mononuclear infiltrate gives rise to an effusive phase, which is often voluminous and hemodynamically significant. An adhesive phase follows resolution of the effusion and eventuates in dense, calcific adhesions with clinical constriction in nearly one half of patients.

The diagnosis of tuberculous pericarditis is based on (1) histologic identification, (2) culture of *Mycobacterium tuberculosis*, (3) pericarditis with proven extracardiac tuberculosis, or (4) pericardial effusion responsive to antituberculosis therapy. PCR-detected *M. tuberculosis* DNA, high adenosine deaminase activity, and interferon gamma concentration in the pericardial fluid are also diagnostic.[1] Fluid should be removed and cultured, and antituberculous therapy should begin. Depending on the echocardiographic appearance, subxiphoid drainage may be necessary. Early pericardiectomy has been recommended by some in all cases of tuberculosis pericarditis, but the long-term (16 years) prognosis of patients without cardiac compression during the acute illness who are treated with medical therapy alone is excellent.[31] Multiple drug therapy and corticosteroids are effective in tuberculous pericarditis, whereas atypical mycobacterial infections (especially *M. avium-intracellulare*) may be resistant to treatment. Patients with tuberculous pericarditis should receive triple drug therapy (isoniazid 5 mg/kg to a maximum of 300 mg, rifampin 10 mg/kg to a maximum of 600 mg, and either streptomycin 15 mg/kg to a maximum of 1 g or ethambutol 5 to 25 mg/kg to a maximum of 2.5 g) for a minimum of 9 months. Corticosteroids (prednisone 1 to 2 mg/kg/day) may be useful if pericardial effusion persists or recurs during therapy and are beneficial acutely in reducing morbidity and mortality, but definitive data supporting their use to prevent constriction in primary pericardial effusion are lacking.[32] Pericardiectomy may be necessary for recurrent cardiac tamponade.

Patients should be observed for constriction because up to half of them will require pericardiectomy.[33] Failure to improve or worsening over 1 to 2 months, pericardial thickening, or evidence of constriction require urgent pericardiectomy.[6] For patients with hemodynamics consistent with effusive-constrictive pericarditis, plans for visceral and parietal pericardiectomy after a few weeks of chemotherapy should be made. Persistent hypotension may signify tuberculous adrenal insufficiency.

Pericarditis complicating deep fungal infection with *Histoplasma* or *Coccidioides* immitis may be immunologic, resolve spontaneously, and not require specific therapy. Amphotericin B (up to 2.5 g total), itraconazole (200 to 400 mg/day), ketoconazole (200 to 400 mg/day), and fluconazole (200 to 400 mg/day) are rarely required. Tamponading effusion and constriction require decompression.

Surgical decompression and specific antifungal or antimicrobial therapy may be necessary for disseminated infection with *Candida, Aspergillus, Actinomycetes,* and *Nocardia.*

HIV-Associated Pericarditis

Human immunodeficiency virus (HIV) is an important cause of pericardial heart disease. Typically, pericardial effusions are small and asymptomatic in outpatients, but large effusions and tamponade are common in hospitalized patients with late-stage AIDS. Large, symptomatic pericardial effusion in patients with HIV infection should be aggressively investigated, as two thirds of these cases have an identifiable cause.[34] Tamponade in patients with HIV is mycobacterial (*M. tuberculosis* or *avium-intracellulare*) in origin in approximately one third of patients.[34]

Neoplastic Pericarditis

Metastatic neoplasia remains the leading cause of pericardial disease in hospitalized patients, most often in patients with lung or breast cancer, melanoma, lymphoma, and acute leukemia. Many cases are asymptomatic and are found only incidentally at autopsy, but others cause symptoms and may progress to cardiac tamponade. The pericardium may be thickened and cause constriction; less commonly, effusive-constrictive pericarditis occurs.

In almost all cases, fluid should be removed if large effusions are refractory or if tamponade ensues.[35] The specific

approach depends on the patient's expected longevity and medical condition. Pericardiocentesis is associated with a high recurrence rate and does not provide tissue for biopsy. Sclerosing agents, such as tetracycline (500 to 1000 mg in 20 mL of sterile saline), reduce recurrences and their use can be considered for patients with a poor prognosis. However, sclerosis is painful, does not improve prognosis, and may not be superior to an indwelling catheter alone. Subtotal pericardiectomy is most effective but should only be performed in carefully selected patients. Balloon pericardiotomy avoids the discomfort and risk of surgery and will likely replace surgical subxiphoid pericardiotomy in critically ill patients with predictably limited survival.[36] Radiation therapy and intrapericardial instillation of P32-colloid (a colloidal suspension of radioactive phosphorus) are effective strategies to control pericardial effusion but are not without significant practical difficulties and toxicities.[35,37]

Pericarditis Complicating Myocardial Infarction

Pericarditis is common in the first few days after myocardial infarction, occurring in up to 28% to 43% of fatal infarctions, but is clinically apparent in 7% of cases[38] (see Chapter 47 of *Heart Disease,* 7th edition). Pericardial involvement is related to infarct size and is associated with a poor prognosis.[39] An important clinical issue is the extent to which acute pericarditis in myocardial infarction influences management with anticoagulants. A pericardial friction rub that occurs in the first 2 or 3 days without an associated pericardial effusion should not influence clinical decisions, but pericarditis that occurs later in the course or is accompanied by pericardial effusion or tamponade is a contraindication to anticoagulant therapy. Cardiac tamponade seldom occurs, except in patients who receive systemic anticoagulants or who have cardiac rupture.

Treatment of infarct pericarditis is seldom indicated, but when symptomatic, infarct pericarditis responds to ASA (up to 650 mg every 4 hours by mouth for 5 to 10 days); corticosteroids should be avoided because of concerns with impaired infarct healing, steroid dependency, and toxic side effects.

Reperfusion therapy almost invariably precedes the development of pericarditis; therefore clinical decision making is not usually affected. Reperfusion therapy reduces the incidence of postinfarction pericarditis by approximately one half,[40] and for reasons not entirely clear, has helped render late postmyocardial infarction pericarditis nearly obsolete.[41] When it occurs, Dressler's syndrome is treated similarly to idiopathic acute effusive pericarditis.

Radiation-Induced Pericardial Disease

Acute pericarditis that occurs early during radiation therapy is uncommon and is most likely the result of radiation-induced effects on the tumor rather than a direct toxic effect of radiation on the pericardium.[42] In this instance, therapy should not be disrupted, although a reduction in dose may be necessary. A delayed (usually less than 1 year, but highly variable) form of pericardial injury may present as acute pericarditis or effusion (often with some degree of cardiac compression). The reaction of the pericardium to radiation is fibrinous inflammation,[43] often with an effusion. Although the acute lesion usually subsides within 2 years without sequelae, constrictive and effusive-constrictive pericarditis may manifest only after many years.

In the effusive stage the differential diagnosis includes recurrence of the neoplasm; examination of pericardial fluid is then helpful because the fluid frequently shows evidence of malignancy.[44,45] When the diagnosis remains in doubt, biopsy, particularly epicardial biopsy, may be necessary.[46] Effusion may be due to a radiation therapy–induced hypothyroid state.

Acute radiation-induced pericarditis can be managed symptomatically as acute idiopathic pericarditis. Hemodynamically insignificant pericardial effusion can also be managed conservatively, as spontaneous resolution is the rule; however, pericardiectomy should be offered to symptomatic patients with large, recurrent pericardial effusions. Constrictive pericarditis requires pericardiectomy unless a biopsy (obtained to distinguish constriction versus restrictive cardiomyopathy secondary to radiation) reveals significant endomyocardial fibrosis.

Traumatic Pericardial Disease

Blunt and penetrating trauma are important causes of pericarditis, particularly among young males. Chronic constrictive pericarditis, recurrent pericardial effusion, and recurrent acute pericarditis are well-recognized complications of such trauma. Although traumatic pericarditis is often overshadowed by associated injuries and usually resolves uneventfully, pericardial involvement may be life threatening. Echocardiography used in the trauma unit rapidly and accurately diagnoses hemopericardium in patients with potentially penetrating cardiac wounds.[47] Failure to repair the injury responsible for tamponade is associated with a poor clinical outcome.[48] Constrictive pericarditis occasionally occurs and may be delayed, presenting for weeks or years after the injury.[49]

Chylopericardium

Chylous pericardial effusions generally follow traumatic or surgical injury to the thoracic duct but may result from neoplastic obstruction of the thoracic duct (secondary chylopericardium); less commonly, they may be idiopathic (primary). Failure to respond to a diet rich in medium chain triglycerides and pericardiocentesis warrants ligation of the thoracic duct and pericardiectomy.[50] In cases deemed inappropriate for aggressive therapy, a valved pericardioperitoneal conduit can be implanted.[51]

Pericardial Disease in Patients with Renal Failure

Pericarditis complicates both uremia and dialytic therapy (hemoperitoneal and peritoneal) and may be clinically silent. The clinical manifestation of nephrogenic pericardial disease may be acute fibrinous pericarditis, pericardial effusion, or cardiac tamponade; classic constrictive pericarditis is rare.

Although intensification of dialysis is an accepted treatment modality for hemodynamically insignificant disease, considerable controversy exists regarding the optimal management of large, persistent, or recurrent pericardial effusion. Tamponade is an indication for pericardial drainage, and

large, resistant chronic effusion warrants pericardiocentesis. A conservative approach, such as intensification of dialysis and NSAIDs, may suffice in less severe cases. The instillation of nonabsorbable steroids (triamcinolone 50 mg every 6 hours for 2 to 3 days) directly into the pericardial space has been advocated,[52] but randomized controlled data about this form of therapy are absent. If needle drainage is necessary, an indwelling catheter should be left in the pericardial space for at least 2 to 3 days. Dialysis-associated effusive pericarditis usually responds to an intensification of dialysis and regional heparinization or by changing to peritoneal dialysis. Pericardiectomy may be necessary for intractable effusions.

Myxedema Pericardial Disease

Pericarditis with effusion (sometimes containing cholesterol) occurs in about one third of patients with myxedema. Effusions develop slowly and may reach prodigious size; slow resolution usually follows institution of thyroid replacement therapy. Pericardial drainage is generally not indicated because myxedema effusions seldom cause tamponade.

Connective Tissue Disease–Related Pericardial Disease

Pericarditis may accompany virtually any connective tissue disease and present as either acute or chronic pericarditis with or without an effusion.[53] Although tamponade, effusive-constrictive disease, and constrictive pericarditis are recognized complications, most cases are subclinical and in many instances are recognized only at autopsy. In the absence of tamponade or secondarily infected effusions, NSAIDs and corticosteroids are useful.

Pericardial Disease and Pregnancy

Small- to moderate-sized effusions occur in the last trimester of approximately 40% of healthy pregnancies, whereas larger accumulations should raise concern of another disorder.[54] Most pericardial diseases in pregnancy are managed as for the nonpregnant patient. However, colchicine is contraindicated and high-dose ASA may prematurely close the ductus.[54] Pericardiocentesis should be reserved for large, tamponading effusions and suspected infection; echocardiographic guidance avoids fetal irradiation.

Drug-Induced and Iatrogenic Pericardial Disease

A wide variety of drugs and toxins may cause pericardial heart disease (Table 45–3), by producing either drug-induced lupus, a hypersensitivity or idiosyncratic reaction, pericardial irritation, or hemorrhage. Cardiac tamponade after thrombolysis with tPA given for stroke was recently reported.[55]

Iatrogenic pericardial disease results from both the calculated complications and the unanticipated misadventures of diagnostic and therapeutic procedures. Specific management depends on the particular procedure; for example, although

Table 45–3 Drugs and Toxins Implicated as Causing Pericardial Heart Disease

Drug-induced Lupus	Hypersensitivity or Idiosyncratic Reaction	Pericardial Irritation/Hemorrhage
Procainamide	Penicillins, sulfas	Anticoagulants
Tocainide	Cephalosporins	Thrombolytics

transeptal punctures may require rescue pericardiocentesis, perforation of a coronary artery by a guidewire may require only withdrawal of the wire and watchful waiting. Coronary artery transections during coronary interventional procedures are treated with either a covered stent or perfusion balloon. Routine echocardiography is recommended after myocardial biopsy and pacemaker lead implantation.[1]

Anticoagulation in Pericarditis

The management of anticoagulation in patients with acute pericarditis and effusion requires analysis of the competing risks and benefits; few objective data are available for decision-making. In a study of seven patients with recent anterior wall myocardial infarction and pericarditis (small effusion in five, moderate in two), apical LV thrombi were successfully treated with parenteral heparin and long-term oral anticoagulation.[56] Acute pericarditis generally responds to NSAIDs within a few days, during which time anticoagulants may be withheld in low-risk patients; patients at higher thromboembolic risk can be switched to heparin while awaiting a clinical response. Unexplained effusions should be thoroughly evaluated to exclude hemorrhage.

Optimal Timing of Surgical and Mechanical Intervention in Native Valvular Heart Disease

Edmund A. Bermudez and William H. Gaasch

CHAPTER CONTENTS

INTRODUCTION

The timing of surgical intervention in the management of isolated native valvular dysfunction depends on several elements. The presence of symptoms is important and often reflects the hemodynamic burden that lesions place on ventricular size and function. When lesions are mild in severity, ventricular systolic function remains largely unchanged and the patient remains asymptomatic. However, as lesions progress in severity, their hemodynamic impact may begin to emerge as ventricular geometry and function change. Cardiovascular symptoms may eventually follow, and if then left untreated, persistent ventricular dysfunction and circulatory compromise may ensue. It is therefore a triad of lesion severity, ventricular function, and symptomatology that largely guides the timing of intervention in an effort to avoid irreversible ventricular dysfunction and cardiovascular morbidity and mortality.[1]

Advances in technology have enabled the accurate noninvasive detection and assessment of valvular dysfunction. In particular, echocardiography has become the cornerstone of assessment of valvular lesions. The hemodynamic impact of valvular heart disease can be readily assessed and quantified using multiparametric analyses that include an assessment of ventricular size and function.[2] In some cases, however, the severity of valvular disease may be ambiguous or disparate from other clinical findings, leaving the diagnosis of severity in doubt. In these cases, invasive hemodynamics can be obtained at cardiac catheterization and used to help clarify lesion severity. Still, the severity of the lesion alone does not necessarily mandate surgical correction.

Corrective therapy for valvular heart disease is mechanical and absolute. The decision process in arriving at a referral for surgical correction is often complex and requires consideration of the risk of the procedure itself and the risks of prosthetic heart valves in relation to patient-specific conditions. Therefore the type of mechanical intervention (percutaneous or surgical, repair versus replacement) is a factor in the timing of intervention.

AORTIC STENOSIS

Assessing Stenosis Severity

The severity of aortic stenosis can be assessed noninvasively through echocardiography or invasively during cardiac catheterization.[3] Both methods can provide an accurate assessment of valve area and transaortic gradients. However, because of its ease and accuracy, echocardiography remains the primary modality for the assessment and follow-up of aortic stenosis. In virtually all patients, transthoracic evaluation provides adequate hemodynamic information in the assessment of stenosis severity so that management strategies can be well formulated. Morphologic information (e.g., pattern and degree of calcification, number of cusps), as well as an assessment of ventricular function and hypertrophy, can readily be obtained.

Lesion severity can usually be categorized by the calculation of the aortic valve area and measurement of the mean transvalvular pressure gradient.[4] By echocardiography, the continuity equation can readily be applied to determine valve area with mean gradients measured by Doppler techniques.

$$\mathrm{AVA} = \prod (\mathrm{D}/2)^2 \times \frac{\mathrm{V_{lvot}}}{\mathrm{V_{AV}}}$$

where *AVA* = aortic valve area, *D* = diameter of the left ventricular outflow tract, V_{lvot} is the velocity of blood through the left ventricular outflow tract (LVOT) measured by pulse wave Doppler, and V_{AV} is the maximum velocity across the aortic valve measured by continuous wave Doppler. Accuracy in determining valve area by echocardiography depends on the accuracy of measuring these elements. Calcification can present problems in accurately measuring LVOT diameter. Multiple windows of interrogation that are optimally aligned with blood flow ensure a more precise determination of maximum velocity. Direct planimetry of the aortic valve can be performed through transesophageal echocardiography and correlates well with the Doppler-derived valve area.

If cardiac catheterization is performed, the formula derived by Gorlin and Gorlin[5] is applied to calculate the orifice area.

$$AVA = \frac{CO/SEP(HR)}{44.3(C)\sqrt{MG}}$$

where *AVA* = aortic valve area (cm^2), *CO* = cardiac output (mL/min), *SEP* = systolic ejection period (sec), *HR* = ventricular rate (bpm), and *MG* = mean transvalvular gradient. An accurate cardiac output calculation depends on the appropriate use of thermodilution (which is less accurate with low flow states, significant tricuspid insufficiency, or irregular rhythm); Fick (which requires accurate measurement of oxygen consumption); or angiographic technique.[5] Transducer placement and timing of measurements are important variables in calculating accurate valve areas.

Both techniques to assess valve area depend on flow, so calculated valve areas may be relatively small in the presence of low flow (i.e., low cardiac output) and low pressure gradients. During catheterization, calculation of valve resistance may be helpful in these situations.[6] Aortic valve resistance can be calculated as follows:

$$R_{AV} = [(MG) \times (HR) \times (SEP)] \times 1.33$$

where R_{AV} = aortic valve resistance (dyne-sec-cm^{-5}), *HR* = ventricular rate (bpm), *MG* = mean transvalvular gradient (mm Hg), and *SEP* = systolic ejection period (sec). Because resistance may be less sensitive to changes in flow, higher valve resistance (>250 dyne-sec-cm^{-5}) is generally seen with truly severe aortic stenosis. The use of dobutamine either at cardiac catheterization or coupled with echocardiography may be of benefit in these conditions to help differentiate "pseudo" from true stenosis[7] and is discussed later.

Assuming normal cardiac output, severe aortic stenosis is usually present when mean gradients exceed 40 mm Hg. By echocardiography, this usually corresponds to a peak transaortic velocity that exceeds 4.0 to 4.5 meters per second.[8] Aortic stenosis is considered severe when these values are present or the calculated valve area is less than 1.0 cm.[2] Table 46–1 provides definitions of mild, moderate, and severe aortic stenosis.

Occasionally, noninvasive and invasive measures provide differing results with regard to severity. Aside from technical fidelity in measurement, the phenomenon of pressure recovery may explain some differences. Distal to the stenosis, some of the blood flow kinetic energy may be recovered in pressure, a phenomenon that is more apparent when the ascending aorta is small. In these cases, echocardiographic velocity may be higher and the valve area may appear smaller than that determined at cardiac catheterization. Calculation of an energy loss coefficient echocardiographically by accounting for the size of the proximal ascending aorta may be helpful to reconcile calculated differences.[9,10]

Table 46–1 Measures of Severity in Aortic Stenosis

Severity of Aortic Stenosis	Mild	Moderate	Severe
Doppler jet velocity	<3.0	3.0-4.0	>4.0
Mean gradient (mm Hg)	<25	25-40	>40
Aortic valve area (cm^2)	>1.5	1.0-1.5	<1.0

Overall, pressure gradients and valve areas by echocardiography and cardiac catheterization correlate well with one another such that in most cases, only echocardiography is necessary to define the severity of aortic stenosis. Therefore, unless noninvasive evaluation is ambiguous, cardiac catheterization is used only for the identification of coronary artery disease before aortic valve surgery.

Symptomatic Patients

The timing of surgical intervention in severe aortic stenosis is clear from its natural history. Once symptoms of heart failure, angina, or syncope develop, the prognosis abruptly changes; the 2-year survival of patients presenting with heart failure approaches 50% without surgical correction.[11] No randomized clinical trials are available that compare outcome with medical therapy versus surgical correction in symptomatic patients, but observational data consistently demonstrate that aortic valve replacement is associated with a substantial improvement in overall survival and symptomatology.[12-15] Therefore, it is universally recommended that symptomatic patients with severe aortic stenosis undergo surgical correction.

The outcome and risk of surgery is in part related to left ventricular function.[16] In patients with mild or moderate left ventricular dysfunction, aortic valve replacement confers a similar favorable outcome as do those with normal left ventricular function. Excessive afterload, also called *afterload mismatch,* is the prime cause of the dysfunction in many, if not most, of these patients and is promptly corrected after valve replacement.[17] In those with severely reduced left ventricular function, complete resolution of symptoms and left ventricular dysfunction may not ensue.[18] Despite this, the operative risk of aortic valve replacement appears acceptable and the majority of patients experience improved functional status.[19-23] The presence of coronary artery disease is associated with increased mortality after surgery in patients with severely decreased LVEF[24]; this suggests that afterload mismatch is not the primary cause of ventricular dysfunction in these patients.

Low-Gradient Aortic Stenosis

Patients with severe aortic stenosis (AVA < 1.0 cm^2) may present with low transvalvular pressure gradients (mean gradient < 30 mm Hg) in the setting of severe left ventricular dysfunction.[25] This nominal discrepancy, occurring in the presence of low transvalvular flow, may be seen in patients with primary contractile dysfunction or excessive afterload, or some combination of the two. In those with truly severe stenosis, the use of low-dose dobutamine infusion generally produces an increase in flow and an increase in the transvalvular pressure gradient with little or no change in the valve area. By contrast, a "pseudostenosis" may be related to the reduced valve-opening force that is caused by the weakened ventricle. In this situation dobutamine infusion augments valve opening; there is an increase in transvalvular flow with little or no change in the pressure gradients, and the calculated effective valve area increases. Dobutamine infusion also provides important information about left ventricular contractile reserve. Thus, a limited contractile reserve (i.e., stroke volume

increment is < 25% during dobutamine infusion) identifies the patient with a severe contractile deficiency and a poor prognosis, regardless of medical or surgical treatment.[26]

Elderly Patients

Calcific aortic stenosis is the most common valvular lesion seen in elderly patients. The indications for surgery are the same as for younger patients. Although advanced age has been shown to be a determinant of outcome, it does not preclude surgery because the majority of elderly patients have a good outcome following surgery. For example, in a large retrospective study of 1100 patients aged older than 80 years undergoing aortic valve replacement, 30-day cardiac and all-cause mortality rates were 4% and 6.6%, respectively.[27] Overall, elderly patients experience an improvement in function and quality of life to a degree that is similar to age-matched controls.[28-32]

Elderly patients may present with anatomic features that may necessitate further surgical consideration.[28,33] For example, elderly women may have narrow outflow tracts and smaller aortic annular dimensions. This may require annular dilatation to allow for a larger prosthesis or occasionally require a composite graft. In addition, heavy calcification is not uncommon and may require extensive débridement. Comorbidities and the patient's wishes and expectations must be considered.

Role of Percutaneous Intervention

Percutaneous balloon dilatation of the stenotic aortic valve plays a pivotal role in the very young with congenital lesions.[34] However, aortic balloon valvotomy plays a limited role in adult patients with severe calcific disease.[35] In adults the morbidity and mortality rates are high, with reported in-hospital mortality rates between 3.5% and 13.5%.[36] Furthermore, the durability of the procedure is limited because most patients experience recurrence within 6 months to 1 year.[37] Although the procedure has been used as a bridge to surgery, data supporting this are limited; under most circumstances, direct operative replacement is more appropriate.

Asymptomatic Patients

Aortic valve replacement in asymptomatic patients with severe stenosis is controversial. Despite limited data, some experts advocate earlier surgery, arguing that irreversible myocardial damage and fibrosis may ensue during the absence of symptoms, and that a finite risk for sudden death exists during this time period.[38] However, the risk of sudden death in an asymptomatic patient is < 1% per year.[39] Several factors identify asymptomatic patients who may be at particular risk without surgical correction.[39] These include patients with an abnormal response to exercise, abnormal systolic function, ventricular arrhythmias, or marked hypertrophy with hyperdynamic function, and those with a combination of marked valvular calcification, a peak jet velocity of > 4 m/sec and evidence of rapid progression (i.e., an increase in jet velocity > 0.3 m/sec within 1 year).[40-43] With this approach, the risk of surgery and the attendant long-term prosthesis risks must be weighed. Apart from perioperative complications, implantation of a prosthesis is associated with a significant annual complication rate.[44] Therefore, the risk of valve replacement likely exceeds benefit in those who are truly asymptomatic with normal left ventricular function. Many, if not most, patients with the previously mentioned risk factors will develop symptoms after a brief period and will then qualify for prompt surgical correction.

Progression to symptomatic disease is common in patients with severe stenosis, with a reported incidence of 14% at 1 year and 38% at 2 years.[45] In addition, faster progression of disease is more likely in those with concomitant coronary disease, significant calcification of the valve, and in those older than 50 years of age.[42] The rate of progression has been linked to adverse outcomes, particularly in those with an increase in Doppler velocities > 0.3 m/sec or a decrease in valve area greater than 0.1 cm^2 per annum.[40] Thus, regular monitoring is warranted in asymptomatic patients with severe stenosis. Regardless of symptoms, patients who undergo other valve surgery or coronary bypass generally undergo aortic valve replacement at the same time.

Role of Exercise Testing

Exercise testing has been proposed as a method of risk stratification in patients with severe aortic stenosis but without clear symptomatology.[46] It should not be performed in those whose symptoms are attributable to aortic stenosis. However, with close physician supervision, exercise testing can be considered and may uncover exercise-induced symptoms and intolerance. The presence of exercise-induced hypotension portends a poor prognosis. In a study of 66 asymptomatic patients with severe aortic stenosis but without angiographic coronary artery disease followed for a mean of 15 months, four patients died suddenly, with all four having an abnormal test.[47,48]

Overall Approach

Surgical correction should be performed in all patients with symptomatic severe aortic stenosis (Table 46–2). Aortic valve replacement has been associated with marked improvements in morbidity and mortality rates across numerous symptomatic subgroups. In general, patients with only moderate aortic stenosis and symptoms resembling those of aortic stenosis do not require surgical intervention; other causes for symptoms should be sought. With rare exception, valve replacement should not be performed in truly asymptomatic patients. Asymptomatic patients with high-risk features require close monitoring. Figure 46–1 provides an algorithmic approach incorporating these recommendations.[25]

MITRAL STENOSIS

Assessment of Severity

Echocardiography is the preferred modality to assess for the presence and severity of mitral stenosis.[49] Classic doming of the anterior leaflet is readily identified from 2-D images, as are other morphologic features important in the assessment of mitral stenosis. Doppler techniques are used to measure the transmitral pressure gradients using the modified Bernoulli equation, as well as to calculate the mitral valve area (MVA)

using the diastolic pressure half-time method or the continuity equation. These measures correlate well with valve areas that are derived at cardiac catheterization.[50] The pressure half-time method should not be used when significant aortic regurgitation is present or immediately after mitral valvotomy because abnormalities of atrial or ventricular compliance can affect MVA calculation.[51] Other techniques may be used to calculate MVA including the proximal isovolumetric surface area (PISA) method, as well as direct planimetry.[52] Importantly, pulmonary artery pressures should be determined to aid in the hemodynamic assessment.

Morphologic assessment of the mitral apparatus provides important information that may help guide the type of mechanical intervention (i.e., percutaneous balloon mitral valvuloplasty, surgical commissurotomy, or valve replacement). Echocardiography provides an assessment of leaflet mobility, thickness, calcification, and subvalvular thickening. When leaflets are relatively mobile, noncalcified, and with little subvalvular involvement, percutaneous mitral balloon valvuloplasty (PMBV) is generally successful and provides a safe and effective nonsurgical approach.[53] An echocardiographic scoring system described by Wilkins[54] combines these factors into a useful approach to predict procedural success (Table 46–3). The degree of commissural calcification has also been used to help identify the most appropriate candidates for PMBV.[55,56] Higher scores indicate more severe disease and predict a lower likelihood of procedural success of PMBV. A similar scoring system has been described to predict the likelihood of postprocedural severe mitral regurgitation.[57] When patients have significant mitral abnormalities (score > 10), the sensitivity and specificity for predicting severe mitral regurgitation is 82% and 91%, respectively. Finally, higher echocardiographic morphologic scores have been related to higher inpatient costs.[58]

Hemodynamic measurements during cardiac catheterization can be performed when noninvasive findings are ambiguous or discordant with clinical findings. Transmitral pressure gradients can be measured, and the MVA can be calculated using the Gorlin hydraulic formula.[59] Pulmonary pressures and resistance are routinely obtained to assess the hemodynamic effect of the stenosis on the pulmonary circulation. When pulmonary artery balloon occlusion or wedge pressure is used as a surrogate for left atrial pressure, the transmitral pressure gradient may be overestimated despite adjustment for phase delay. Transseptal puncture is therefore more appropriate in determining the pressure gradient, especially if the accuracy of the wedge pressure is questioned.[60] Left ventriculography is used to assess for the presence of significant mitral insufficiency, and coronary angiography is performed if intervention is contemplated.

The resting mitral valve area and mean pressure gradient are used to categorize the severity of mitral stenosis (Table 46–4). Not infrequently, however, the patient's symptoms may be out of proportion to the severity of the stenosis in the basal or resting state. In these cases assessment of hemodynamics with exercise at catheterization or coupled with

Table 46–2 Recommendations for use of Aortic Valve Replacement in Patients with Aortic Stenosis

Aortic Valve Replacement Indicated

- Patients with severe aortic stenosis and symptoms (angina, syncope, or heart failure)
- Patients with severe or moderate aortic stenosis who are undergoing coronary artery bypass graft surgery or surgery on the aorta or other heart valves

Aortic Valve Replacement Possibly Indicated

- Asymptomatic patients with severe aortic stenosis and at least one of the following:
  - Ejection fraction < 50%
  - Hemodynamic instability during exercise (e.g., hypotension)
  - Ventricular arrhythmia

*Aortic valve replacement is not indicated to prevent sudden death in asymptomatic patients with none of the findings listed. Modified from Carabello BA: Clinical practice. Aortic stenosis. N Engl J Med 2002;346:677-82.

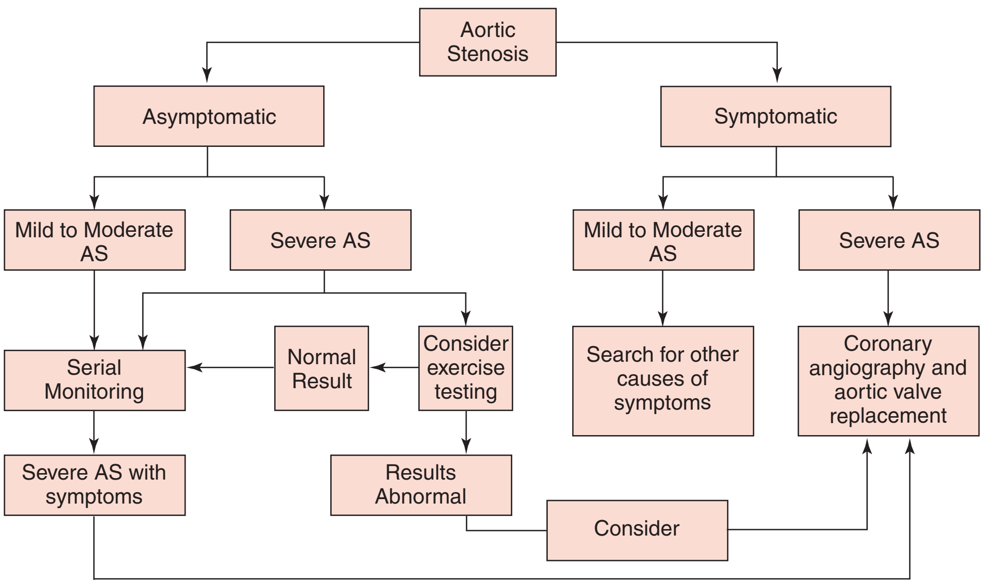

Figure 46–1 Algorithm for the timing of surgery in patients with aortic stenosis.

echocardiography can help clarify the physiologic burden of mitral stenosis.[61] If a significant rise in mean transmitral pressure gradient (>15 mm Hg) or pulmonary capillary wedge pressure (> 25 mm Hg) is observed or if pulmonary hypertension results (systolic pressure > 60 mm Hg), then percutaneous intervention should be considered if valve morphology is appropriate.[62] Therefore, an assessment of severity with exercise can help resolve clinical discrepancies in severity, as well as aid in planning for mechanical intervention.

Table 46–3 Echocardiographic Classification of Mitral Valve Anatomy

Leaflet Mobility
1. Highly mobile valve with restriction confined to the leaflet tips
2. Middle portion and base of leaflets with reduced mobility
3. Valve leaflets move forward in diastole mainly at the base
4. No or minimal forward movement of the leaflets in diastole

Valvular Thickening
1. Leaflets near normal (4-5 mm)
2. Midleaflet thickening, marked thickening of the margins
3. Thickening extends through the entire leaflets (5-8 mm)
4. Marked thickening of all leaflet tissue (>8-10 mm)

Subvalvular Thickening
1. Minimal thickening of chordal structures just below the valve
2. Thickening of chordae extending up to one third of chordal length
3. Thickening extending to the distal third of the chordae
4. Extensive thickening and shortening of all chordae extending down to the papillary muscle

Valvular Calcification
1. A single area of increased echo brightness
2. Scattered areas of brightness confined to leaflet margins
3. Brightness extending into the midportion of leaflets
4. Extensive brightness through most of the leaflet tissue

From Vahanian A, Palacios IF: Percutaneous approaches to valvular disease. Circulation 2004;109:1572-9.

Percutaneous Mitral Balloon Valvuloplasty

Percutaneous mitral balloon valvuloplasty (PMBV) was first used approximately 20 years ago using a double balloon technique.[63] Today most centers use a single balloon (Inoue balloon) that is advanced across the interatrial septum into the left atrium and across the mitral valve.[64] The balloon is inflated across the stenotic valve and produces separation of the fused commissures, as well as fracture of calcific leaflet tissue similar to surgical commissurotomy. A retrograde non-transseptal technique and a metallic valvotomy technique have also been used with acceptable results.[65,66] The procedure is performed in many centers with concomitant transesophageal or intracardiac echocardiography to guide the procedure and monitor for complications.[2]

Patients are selected for PMBV on the basis of hemodynamic and echocardiographic parameters. PMBV should be considered only in those without significant mitral insufficiency or evidence of left atrial appendage thrombus. These can readily be excluded by transesophageal echocardiography before catheterization.[67] Those with low echocardiographic scores are the most appropriate candidates for the procedure because these low scores have been shown to predict procedural success and complications.[68]

The efficacy of PMBV appears to be good and is comparable with surgical open commissurotomy.[69,70] Acutely, PMBV produces a significant increase in MVA and significant decreases in left atrial pressure and transmitral gradient. The morphology of the mitral apparatus is the most important factor in determining outcome, with postprocedural hemodynamics being important predictors of longer-term clinical outcome.[71] Complications include severe mitral insufficiency; residual atrial septal defect; and, less frequently, left ventricular perforation and embolism.[36] In experienced centers the mortality rate is reported to be less than 1%.[72] Given the safety and efficacy of this nonsurgical technique, it is the preferred method of mechanical correction of mitral stenosis.

PMBV is appropriate in symptomatic patients with moderate-to-severe mitral stenosis or asymptomatic patients

Table 46–4 Grades of Mitral Stenosis Severity

Severity	MVA, cm^2	Gradient, mm Hg	PAP	Symptoms	Signs	Therapy
Mild	>1.8	2-4	Normal	Usually absent	S_2-OS >120 ms; normal P_2	IE prophylaxis
Moderate	1.2-1.6	4-9	Normal	Class I-II	S_2-OS 100-120 ms; normal P_2	IE prophylaxis; diuretics
Moderate to severe	1.0-1.2	10-15	Mild pulmonary HTN	Class II-III	S_2-OS 80-100 ms; P_2 increase	IE prophylaxis; BMV if applicable or surgery
Severe	<1.0	>15	Mild-to-severe pulmonary HTN	Class II-IV	S_2-OS < 80 ms; P_2 increase; RV lift Sx if R heart fails	IE prophylaxis; BMV or surgery

with resting pulmonary hypertension or adverse hemodynamics on exercise. It should also be considered in asymptomatic women planning on childbearing to obviate complications during pregnancy.[73] Contraindications for PMBV have been published (Table 46–5).

Overall Approach

In asymptomatic patients, percutaneous mechanical intervention is not generally entertained unless hemodynamic abnormalities coexist with at least moderate stenosis (Fig. 46–2).[74] Thus, if resting pulmonary hypertension exists (>50 mm Hg) or exercise testing reveals exercise intolerance, induced pulmonary hypertension (>60 mm Hg), or high pulmonary artery wedge pressures (>25 mm Hg), then PMBV should be considered, although confirmatory data supporting this approach are not available.

Symptomatic patients with moderate or severe mitral stenosis (MVA < 1.5 cm^2) are generally considered for PMBV if valve morphology is favorable and significant mitral insufficiency and left atrial thrombus are excluded (Figs. 46–3 and 46–4).[75] If hemodynamically mild mitral stenosis is present at rest in the presence of symptoms, then exercise testing should be employed to assess for adverse hemodynamics during stress. If pulmonary hypertension or high pulmonary artery wedge pressure is observed, other problems (e.g., left ventricular dysfunction) should be considered. If a significant increase in transmitral gradient is observed, then PMBV is considered. When patients are severely symptomatic (New York Heart Association [NYHA] class III-IV) and conditions are not favorable for percutaneous intervention, then referral for mitral valve surgery is recommended. These include patients with significant mitral insufficiency (3 to 4+) or heavily calcified valves that would predict adverse periprocedural and clinical outcomes.

If left atrial or left atrial appendage thrombus is present, but conditions otherwise favor PMBV, a period of anticoagulation can be advocated in order to assist a later attempt at PMBV.[76] Percutaneous intervention may be feasible after several months of anticoagulation as long as thrombus resolution or organization is confirmed by echocardiography.

Surgical approaches to mitral stenosis are used when PMBV is not favorable or is unavailable. Mitral valve replacement or open commissurotomy is usually employed (see Table 46–5). Patients at high risk for surgery can be considered for PMBV even though they may not be optimal candidates for the percutaneous procedure.[77] Recurrent stenosis can either be managed with repeat PMBV or mitral valve replacement.[78,79] The risks of each should be considered given patient comorbidities and valve morphology.

AORTIC INSUFFICIENCY

Assessment of Severity

The severity of aortic insufficiency can be assessed by Doppler echocardiography. Color flow and spectral Doppler imaging provide the foundation for the determination of the severity of insufficiency. An integrative approach is usually applied using all information from the echocardiography study to arrive at a coherent assessment. This should routinely include a 2-D assessment of the aortic valve, aorta, and left ventricular chamber size and function.

Color flow imaging of the regurgitant jet provides important clues to severity. The length alone of the color jet in the left ventricle during diastole is a limited measure of severity; its width and area in the parasternal views are more reliable indicators of regurgitant severity. In addition, the size of the vena contracta provides a useful measure of severity when its size exceeds 6 mm.[80] The vena contracta is the narrowest central flow portion of any color flow jet. It is essentially the smallest jet size measured at the level of the aortic valve in aortic regurgitation. With these measures, the larger the width or area, the greater the severity of regurgitation. Supportive signs of severe aortic regurgitation include a short pressure half-time of the aortic regurgitant signal, holodiastolic flow reversal in the descending thoracic aorta, and at least

J Am Coll Cardiol 1998;32:1486-588.)

moderate LV enlargement.[81] Parameters for the diagnosis of severe aortic regurgitation by echocardiography have been published (Table 46–6).

The aforementioned measures provide a qualitative or semiquantitative measure of severity. The flow convergence method or proximal isovelocity surface area (PISA) can be applied, but there is considerably less experience with PISA in aortic regurgitation compared with its use in mitral insufficiency.[82] Using this method, the size of the regurgitant orifice can be calculated and an assessment of regurgitant volumes and severity can be made. A similar volumetric assessment[83] can be made by comparing aortic stroke volume (i.e., TVI of LV outflow) with that of another uninvolved valve (usually mitral or pulmonic valve).

Hemodynamic assessment at cardiac catheterization is used when noninvasive techniques fail to provide confident results.[59] Qualitative assessment of severity is made by assessing the persistence of opacification of the left ventricle during diastole and comparing this with aortic opacification (Table 46–7). Quantitative left ventriculography can be employed to calculate regurgitant volumes and regurgitant fraction. Total stroke volume can be obtained by a careful angiographic assessment of end diastolic and end systolic volumes. When forward stroke volume (obtained from thermodilution or Fick cardiac output techniques) is subtracted from total stroke volume, regurgitant volume is derived.

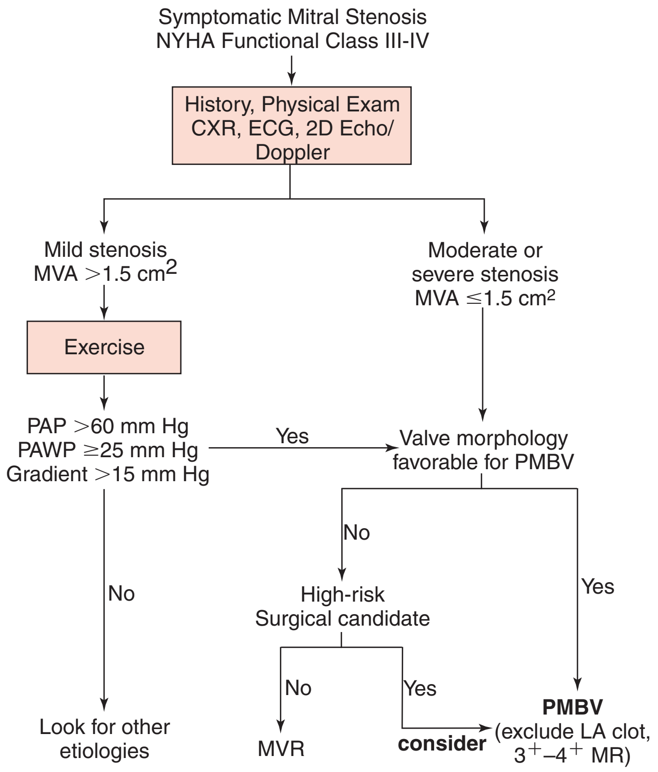

Figure 46–4 Management strategy for patients with mitral stenosis and moderate to severe symptoms. CXR, Chest x-ray; LA, left atrial; MVA mitral valve area; PAP, pulmonary artery pressure; PAWP, pulmonary artery wedge pressure; PMBV, percutaneous mitral balloon valvuloplasty. J Am Coll Cardiol 1998;32:1486-588.)

Further division by the total stroke volume results in the regurgitant fraction. A regurgitant fraction exceeding 50% is consistent with severe aortic insufficiency. Coronary angiography is performed to assess the status of the coronary arteries in those at risk before surgical intervention.

Timing of Surgical Intervention

As with other cardiac valves, recommendations are largely based on observational data in relatively small populations because prospective and adequately powered clinical trials have not been performed. Despite this, robust data are available that favor surgical intervention on the basis of the presence of severe insufficiency, symptoms, and the size and function of the left ventricle. The vast majority of patients with aortic insufficiency undergo valve replacement, although experience with valve repair is accumulating in selected patient populations.

Symptomatic Patients with Normal Left Ventricular Function

The prognosis of patients with significant aortic insufficiency has been shown to be related to the presence of heart failure symptoms. In a study encompassing 246 patients followed conservatively with severe or moderately severe insufficiency, those with NYHA class III or IV heart failure had an annual mortality rate of 25%, whereas those with class II heart failure had an annual mortality rate of 6%.[84] Surgery significantly reduced the overall cardiovascular mortality rate. The presence of significant symptoms of heart failure or angina in other studies indicates high annual mortality rates (>10%) in those treated conservatively.[85,86]

Aortic valve surgery is indicated in patients with normal left ventricular function when NYHA class III or IV heart failure symptoms are present.[87] However, when milder symptoms are present, it is often unclear whether symptoms are cardiac in origin. Exercise stress testing may provide helpful information in such patients.[88] However, when marked left ventricular enlargement (exceeding 75 mm at end-diastole) is present or when ejection fraction (EF) is borderline (EF 50% to 55%), the presence of even mild symptoms should prompt a consideration of surgical correction.

The aforementioned applies chiefly to patients with chronic aortic insufficiency. Patients with acute severe insufficiency invariably present with advanced symptomatology (pulmonary edema or cardiogenic shock, or both) and often have normal left ventricular systolic function, tachycardia, and normal left ventricular chamber sizes. In these settings, compensatory mechanisms are often inadequate, and poor outcomes are seen without prompt surgical intervention. Therefore nearly all patients with symptomatic severe aortic insufficiency, whether chronic or acute, should be considered candidates for surgical correction.[89]

Symptomatic Patients with Left Ventricular Dysfunction

Surgical correction of symptomatic severe aortic insufficiency usually produces improvement in symptoms irrespective of the state of the left ventricle. In a small study of symptomatic patients with a mean preoperative EF of 45%, the majority had a decrease in symptoms and a postoperative increase in left ventricular function (mean postoperative EF 59%).[90] Likewise, symptomatic patients with mild or moderate left ventricular dysfunction also benefit from corrective aortic valve surgery. Patients with severe LV dysfunction and/or class IV symptoms have increased mortality rates and less chance of complete functional recovery postoperatively.[91] These patients often present difficult management issues as irreversible ventricular dysfunction may be present. Although perioperative risk is high in such patients, aortic valve surgery often provides a better alternative than medical therapy alone. In a study from the Mayo Clinic involving 450 patients who underwent aortic valve surgery for chronic aortic insufficiency, approximately 10% had left ventricular ejection fractions below 35%. In such patients, operative mortality was 14%. However, the LVEF increased by 4.9 percentage units after surgery and most patients had prolonged survival without progression to heart failure. Thus, even though a controlled trial has not been performed, it can be recommended that

Table 46–6 Echocardiographic Grading of Aortic Regurgitation

	Mild	Moderate		Severe
Specific signs for AR severity	Central jet width < 25% of LVOT Vena contracta < 0.3 cm* No or brief early diastolic flow reversal in descending aorta	Signs of AR > mild present, but no criteria for severe AR		Central jet width ≥ 65% of LVOT Vena contracta >0.6 cm*

Table 46–7 Qualitative Grading of Aortic Regurgitation at Cardiac Catheterization

Grade	Description
1+	Incomplete, faint left ventricular opacification that clears with systole
2+	Faint, complete left ventricular opacification not completely cleared with each systole
3+	Progressive opacification such that the left ventricle equals the density of aortic root
4+	Left ventricular opacification on the first or second diastole greater than aortic root

such patients should not be denied the potential benefits of surgery.[92] A period of intense medical treatment to relieve the signs and symptoms of heart failure is warranted prior to surgical correction.

Asymptomatic Patients

Some controversy exists regarding surgery for severe aortic regurgitation among asymptomatic individuals, particularly when left ventricular systolic function is normal. Left ventricular size by echocardiography at end diastole and end systole has been recommended as a guide for recommending surgical intervention. Severe LV dilatation (LV end diastolic dimension > 75 mm) or systolic dysfunction (LV end systolic dimension > 55 mm) appears to represent high-risk patients with an increased incidence of adverse outcomes without intervention.[93,94] Despite the lack of large-scale studies evaluating patients with asymptomatic severe aortic insufficiency, conventional wisdom indicates that LV ejection fraction and end systolic dimension are important predictors of survival and left ventricular function following surgical correction.[94] Thus, an EF < 50% or an ESD > 55 mm, or both, can be considered an indication for AVR in an asymptomatic patient. However, patients with moderately severe dilatation (LV end diastolic dimension > 70 to 75 mm) have been shown to have acceptable outcomes with conservative management.[95] This suggests that end-diastolic size alone is not a strong indication for aortic valve replacement.

Serial monitoring is required in patients with severe aortic insufficiency who do not yet meet criteria for surgical correction and remain asymptomatic.[96] Patients with a declining ejection fraction represent a subgroup at higher risk, and regular monitoring is mandatory.[97] In addition, some patients who develop systolic dysfunction do so without premonitory symptom development.[98] Therefore, in addition to serial follow-up for symptom evaluation, objective evidence by echocardiography is invaluable to identify asymptomatic patients with left ventricular dysfunction when surgical intervention is appropriate.

Overall Approach

An algorithm to guide timing of surgery in severe chronic aortic insufficiency has been developed (Fig. 46–5).[93] In essence, all patients with symptoms (functional class III or IV) or with LV dysfunction irrespective of symptoms should undergo corrective aortic valve surgery. Serial noninvasive

monitoring is mandatory for those asymptomatic patients without resting ventricular dysfunction or who are not yet candidates for correction.

MITRAL INSUFFICIENCY

Assessment of Severity

An integrative approach is recommended when using echocardiography to assess the severity of mitral regurgitation.[81] The combination of 2-D, color, and spectral Doppler measurements, as well as quantitative parameters, will aid in identifying severe mitral regurgitation in a more accurate and reproducible fashion. An application of specific and supportive parameters in mitral regurgitation is shown in Table 46–8. It should be recognized that chronic severe mitral insufficiency rarely exists without left ventricular enlargement, and therefore the presence of severe chronic mitral insufficiency should be questioned if the left ventricle is not enlarged. Likewise, the diagnosis of chronic severe mitral insufficiency should be questioned if left atrial enlargement is not present.

Color flow Doppler parameters can help to identify severe mitral insufficiency. As a guide to severity, regurgitant jet area lacks accuracy, especially when the jet is eccentric, and should

Table 46–8 Echocardiographic Grading of Mitral Regurgitation

	Mild	Moderate		Severe
Specific signs of severity	Small central jet < 4 cm^2 or < 20% of LA area*	Signs of MR > mild present, but no criteria for severe MR		Vena contracta width > 7 cm with large central MR jet (area > 40% of LA) or with a wall-impinging jet of any size, swirling in LA*
	Vena contracta width < 0.3 cm			Large flow convergence†

*At a Nyquist limit of 50-60 cm/sec.
†Minimal and large flow convergence defined as a flow convergence radius of < 0.4 cm and ≤ 0.9 cm for central jets, respectively, with a baseline shift at a Nyquist of 40 cm/sec; cut-offs for eccentric jets are higher and should be angle corrected.
‡Usually older than 50 years of age or in conditions of impaired relaxation, in the absence of mitral stenosis or other causes of elevated LA pressure.
§In the absence of other etiologies of LV and LA dilatation and acute MR.
¶¶LV size applied only to chronic lesions. Normal 2-D measurements: LV minor axis ≤ 2.8 cm/m^2, LV end-diastolic volume ≤ 82 mL/m^2, maximal LA antero-posterior diameter ≤ 2.8 cm/m^2, maximal LA volume ≤ 36 mL/m^2.
¶Quantitative parameters can help subclassify the moderate regurgitation group into mild-to-moderate and moderate-to-severe as shown. Caution should be used when interpreting non-normalized volumes in isolation.
**Consider body surface area (BSA).
CW, continuous wave; EROA, effective regurgitant orifice area; LA, left atrium; LV, left ventricle; MR, mitral regurgitation; RF, regurgitant fraction; R Vol, regurgitant volume.
Modified from Zoghbi WA, Enriquez-Sarano M, Foster E, et al: Recommendations for evaluation of the severity of native valvular regurgitation with two-dimensional and Doppler echocardiography. J Am Soc Echocardiogr 2003;16:777-802.

not be used as a single measure of severity.[99] However, significant MR is likely present when large jets penetrate the pulmonary veins and systolic flow reversal is seen. Measurement of the vena contracta may provide a more specific sign of severity, especially when measurements exceed 0.6 to 0.8 cm in long axis views.[100,101] Clinicians should avoid making this measurement in the apical two-chamber view, as the vena contracta may be erroneously wide along the coaptation margins. Although measurement of the vena contracta works well with central or eccentric jets, multiple jets create fundamental problems with this technique.

Spectral Doppler measurements provide important adjunctive information to indicate severe mitral regurgitation. Pulmonary vein systolic flow reversal is a specific sign of hemodynamically severe regurgitation when seen in more than one pulmonary vein.[102] This finding is more reliable in acute or subacute than in chronic mitral insufficiency (it depends on left atrial compliance and other factors). The height of the mitral E velocity is greater than the A wave velocity in severe MR and is usually greater than 1.2 cm/sec. An A wave dominant pattern virtually excludes severe mitral insufficiency.[103] Other supportive information of severe insufficiency is a dense, triangular, early peaking, mitral-insufficient envelope on continuous wave Doppler sampling.

Quantitative methods can be used to assess the severity of mitral insufficiency. Calculation of stroke volumes in a similar manner as described earlier for aortic regurgitation enable one to calculate regurgitant volume, regurgitant fraction, and regurgitant orifice area. Studies confirm the validity of this method to assess the severity of mitral insufficiency.[104] The proximal isovelocity surface area (PISA) method has been validated and appears to be most accurate with central jets arising from circular orifices.[104] Regurgitant flow and an effective regurgitant area (EROA) can be derived. An EROA > 0.4 cm^2 is consistent with severe mitral insufficiency.

Hemodynamic evaluation at cardiac catheterization is used when clinical and noninvasive measures are disparate or inconclusive. Semiquantitative and quantitative measures are

Table 46–9 Qualitative Grading of Mitral Regurgitation at Cardiac Catheterization

Grade	Description
1+	Contrast enters the left atrium without complete chamber opacification
2+	Compete opacification of left atrium; not as dense at left ventricle
3+	Progressive and complete opacification of the left atrium equal in density to left ventricle
4+	Early opacification with the left atrium denser than left ventricle, often with opacification of the pulmonary veins

used to assess for severe insufficiency.[59] A qualitative scheme is shown in Table 46–9. In a manner similar to that described for aortic insufficiency, regurgitant volumes and fraction can be derived with regurgitant fractions exceeding 50%, signifying severe mitral insufficiency.

Timing of Intervention

As with other valvular lesions, there is a paucity of large-scale randomized trials, and recommendations regarding the optimal time of surgery have been largely based on observational data regarding predictors of outcome. Several factors predicting adverse outcomes have been borne out of these data and include end-systolic dimension, ejection fraction, and the presence of atrial fibrillation.[41] Other measures of severe mitral insufficiency (i.e., effective regurgitant orifice area) have been prospectively evaluated and may help refine the definition of an optimal time for surgery.[105]

The etiology of severe mitral insufficiency appears to affect prognosis. Those having primary leaflet abnormalities appear to have a more favorable outcome with surgical intervention. By contrast, those with secondary insufficiency tend to have a prognosis that primarily depends on the underlying process. For example, ischemic or functional mitral insufficiency is associated with higher operative mortality, decreased survival, and a higher incidence of heart failure postsurgery.[106] Here, our discussion centers on chronic mitral insufficiency originating from organic leaflet dysfunction.

Surgical Intervention

Modern surgical methods generally involve either mitral valve replacement with preservation of the subvalvular apparatus or mitral valve repair (see Chapter 47).[107] When mitral valve replacement is performed, removal of the chordal apparatus is no longer performed, if at all possible. When the subvalvular apparatus is preserved during surgical replacement, postoperative left ventricular function and survival are significantly improved compared with the result obtained when the mitral apparatus is disrupted.[108,109] It appears that preservation of the mitral apparatus may assist in the maintenance of a favorable left ventricular geometry in order to favorably affect postoperative ventricular function.

Mitral valve repair is favored in almost all cases when feasible because a prosthesis and its attendant potential problems are avoided. Therefore, the issue of anticoagulation can be avoided, as well as the potential for future prosthetic failure. Furthermore, mitral repair preserves the entire mitral apparatus, which is associated with superior postoperative survival and left ventricular function.[107] The reoperation rates for mitral valve replacement and repair appear to be similar with a reoperation rate approaching 10% by 10 years for those undergoing repair.[110,111]

The feasibility of repair versus replacement can be assessed echocardiographically, either with transthoracic or transesophageal methods.[106] Repair is usually feasible when limited calcification of the leaflets or annulus is present, limited prolapse of only one leaflet exists, or when pure annular dilatation or valvular perforation is present. On the other hand, replacement may be required if extensive calcification, severe prolapse, infection, or subvalvular involvement is seen.[112,113]

Symptomatic Patients

Symptomatic patients with severe chronic mitral insufficiency should be considered candidates for surgical intervention.[114] Patients with normal left ventricular function and little or no chamber enlargement can be candidates for surgery even if only mild symptoms are present, particularly if mitral valve repair is feasible.[115] Mitral valve surgery is also recommended when mild-to-moderate left ventricular dysfunction is present (EF 30% to 55%) or when end-systolic dimension exceeds 45 mm.[116] Suboptimal outcome is more likely when severe left ventricular dysfunction is present (EF < 30% or end-systolic dimension > 55 mm).[117] Still, surgery is reasonable, particularly if repair is feasible, whether a primary leaflet abnormality is present or functional insufficiency is present.[91]

Asymptomatic Patients

Despite the absence of symptoms, patients with chronic severe mitral regurgitation and echocardiographic indicators of left ventricular dysfunction are candidates for mitral valve surgery.[118] Indicators of ventricular dysfunction include a reduction in EF less than 55% to 60% and an end-systolic dimension exceeding 45 mm.[94,118] Although mitral valve repair is preferred, a survival advantage can be expected whether repair or replacement is performed.[115,119]

Some lack of agreement exists regarding surgical intervention in those without indicators of left ventricular dysfunction (EF > 60% or ESD < 40 mm). However, when atrial fibrillation or pulmonary hypertension (pulmonary artery systolic pressure > 50 mm Hg at rest or > 60 mm Hg with exercise) is present, early surgery is considered, especially if repair is feasible.[41,120] This recommendation is supported by evidence suggesting that atrial fibrillation independently predicts cardiac death and that a concomitant surgical Maze procedure may prevent future events with the restoration of normal sinus rhythm.[121-123] In the absence of these factors, asymptomatic patients with normal left ventricular function should be followed closely with noninvasive studies. Subsequently, prospective studies suggested that asymptomatic patients with effective regurgitant orifice areas exceeding 0.4 cm^2 have a more favorable outcome with mitral valve surgery despite the absence of indicators for left ventricular dysfunction because increasing EROA has implications for decreased survival with medical management.[105] Although these data are interesting, use of a single measurement to base referral for surgery is not advocated.

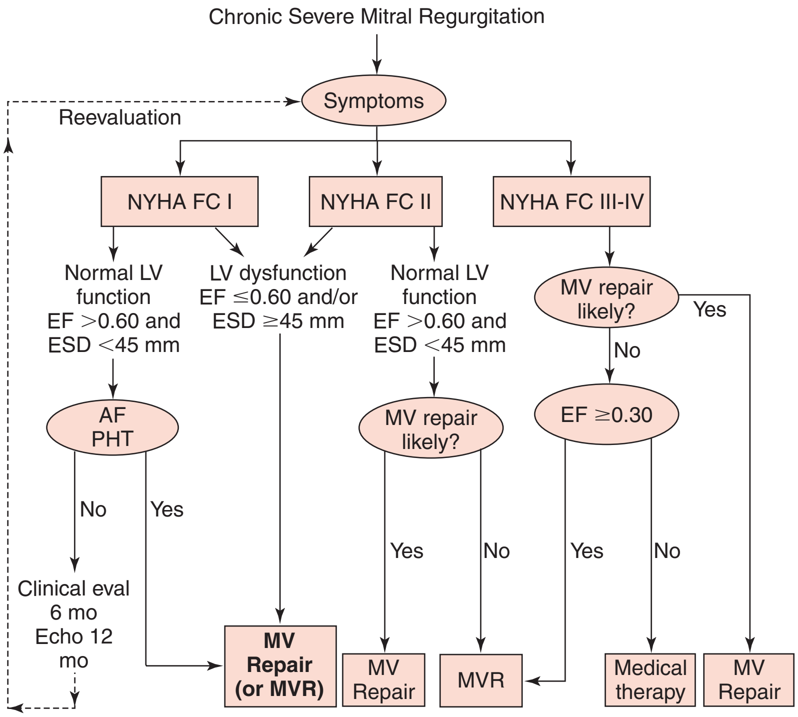

Figure 46–6 Management strategy and timing of surgery in patients with mitral regurgitation. (Redrawn from ACC/AHA guidelines for the management of patients with valvular heart disease. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee on Management of Patients with Valvular Heart Disease]. J Am Coll Cardiol 1998;32: 1486-588.)

Overall Approach

The decision for surgery is based largely on the presence or absence of symptoms and size and function of the left ventricle. If surgery is performed, valve repair is preferred over replacement, and if replacement is performed, chordal preservation is always preferred. Patients with echocardiographic indicators of left ventricular dysfunction are candidates for surgery irrespective of symptomatology. When severe left ventricular dysfunction is present, mitral valve surgery is reasonable when repair is feasible but can be problematic when valve replacement is attempted. When atrial fibrillation or pulmonary hypertension is present in asymptomatic individuals, early surgery should be considered, especially when repair is likely. Otherwise, close monitoring is usually advocated with noninvasive measures (Fig. 46–6).

RIGHT-SIDED VALVE DISEASE

Tricuspid Valve Disease

In adults, severe tricuspid insufficiency can result from a host of primary leaflet abnormalities or secondary dysfunction. Primary leaflet abnormalities include bacterial endocarditis, carcinoid disease, and trauma. Tricuspid insufficiency may also result from right ventricular failure or from annular dilatation.[124] A dense, triangular, early-peaking tricuspid regurgitant envelope seen on spectral Doppler, systolic reversal of hepatic vein flow, and a large vena contracta width (>0.7 cm) are echocardiographic indicators of severe tricuspid insufficiency.[81,125]

Severe tricuspid insufficiency may be a marker for poor outcomes when present in combination with other valve disease.[126] When right ventricular failure and tricuspid insufficiency result from reversible left-sided cardiac disease, particularly mitral stenosis, an improvement in tricuspid insufficiency may result with surgical correction of the mitral stenosis. However, balloon valvuloplasty for mitral stenosis alone may not completely resolve tricuspid insufficiency.[127] Therefore, tricuspid annuloplasty at the time of surgical correction for mitral stenosis may be appropriate.[128]

Timing of surgical intervention in severe isolated tricuspid insufficiency is controversial. However, when symptoms are refractory to medical therapy, surgical intervention is reasonable. When surgical intervention is contemplated, tricuspid annuloplasty is usually performed. However, when the leaflets are abnormal or severely diseased, valve replacement may be necessary.

Significant tricuspid stenosis is a relatively rare entity but when present is usually the result of rheumatic involvement. Both stenosis and regurgitation may be present. The clinical status of the patient usually determines the treatment strategy. Although balloon valvuloplasty has been attempted,[129] significant TR may result. Therefore, bioprosthetic valve replacement is often necessary.[130,131]

Pulmonary Valve Disease

Acquired pulmonic valve disease in adults is rare, with the vast majority of lesions originating from congenital malformation of the valve itself. Pulmonic stenosis in adolescents and young adults is often approached percutaneously and is often performed when peak transpulmonic gradients exceed 30 mm Hg at catheterization in symptomatic patients.[132] Significant pulmonic insufficiency can result following surgical repair of tetralogy of Fallot.[133] The timing of pulmonary valve replacement with a bioprosthesis is controversial but optimally should be performed before irreversible right ventricular dysfunction.[134,135]

FUTURE DIRECTIONS

Although surgical correction for valvular heart disease has been largely based on the presence of symptoms and results of noninvasive imaging, increasing clinical data suggest a role for the measurement of circulating biomarkers. Natriuretic peptides have not only been shown to help in the diagnosis of heart failure[136] but also to be independent predictors of outcome.[137] In valvular disease, natriuretic peptides may be a reflection of left ventricular wall stress.[138] Clinically, plasma levels of B-type natriuretic peptide (BNP) have been shown to parallel the severity of valvular disease and NYHA class among patients with aortic stenosis and mitral insufficiency.[139,140] Further clinical data suggest that BNP measurement may be helpful in discerning symptom onset[141] or clinical deterioration[142] in aortic stenosis and appear to predict symptom-free survival and postoperative outcome among such patients.[143] Although clinical data are still emerging, measurement of natriuretic peptides may soon complement our current strategies in timing surgical intervention in valvular heart disease.

Chapter 47

Surgery for Valvular Heart Disease

Lishan Aklog and Anelechi Anyanwu

CHAPTER CONTENTS

INTRODUCTION

Although medical therapy can ameliorate symptoms and, in some instances, slow the progression of early-stage valvular heart disease, surgical intervention has been, and remains, the primary and only definitive therapy for nearly all patients with advanced valvular heart disease.

Before the introduction of closed mitral commissurotomy by Elliot Cutler at the Peter Bent Brigham Hospital in 1923, the natural history of most forms of valvular heart disease was progressive cardiopulmonary dysfunction and death. Although his subsequent results were poor, he showed for the first time that surgical manipulation of the diseased valve could correct the physiologic dysfunction, alleviate symptoms, and alter the natural history of disease. Twenty-five years later his successor Dwight Harken, Charles Bailey, and others perfected the technique and demonstrated that surgical correction of valvular heart disease could be routine and durable.

Not until the clinical introduction of the heart-lung machine (John Gibbons, 1953) and the successful deployment of valvular prostheses, first in the descending aorta (Charles Hufnagel, 1952) and then intracardiac (Nina Braunwald, 1960), could the full spectrum of valvular lesions be approached surgically.[1,2] The modern era of valvular heart surgery began soon after with the introduction of the first widely used and highly successful prosthesis, the Starr-Edwards caged-ball mechanical valve (Albert Starr, 1961).[3]

Other milestones in surgical therapy for valvular heart disease (Table 47–1) include the introduction of xenograft bioprostheses, valved-conduit replacement of the aortic root, the development of reproducible techniques for mitral valve repair by Alain Carpentier,[4,5] and the introduction of minimally invasive techniques in the late 1990s.

Currently, the vast majority of patients with advanced valvular heart disease can be offered surgical therapy with very good short- and long-term results including those with severe ventricular dysfunction, advanced age, significant pulmonary hypertension, and other comorbidities. Operative mortality rates have declined despite a higher-risk patient profile, presumably as a result of refined surgical techniques and technologies, improved myocardial protection, and advances in perioperative care. Recent advances in less-invasive surgical approaches and accelerated postoperative care plans have decreased hospital stays and recovery times. Finally, refined repair techniques and improved prostheses have improved longer-term outcomes including reoperation rates and thromboembolic complications.

GENERAL CONSIDERATIONS

Epidemiology

Approximately 100,000 patients in the United States undergo valvular heart surgery each year. The overall volume of valvular surgery appears to be growing (Fig. 47–1A). As expanding percutaneous interventions erode into isolated coronary surgery volume, most centers are reporting an increasing share of valvular surgery (see Fig. 47–1B). The most commonly performed procedure is aortic valve replacement with or without concomitant coronary bypass grafting (see Fig. 47–1C). Mitral valve repair, although still underused,[6] is growing steadily. There has also been a greater appreciation of the importance of correcting tricuspid regurgitation, usually concomitant with mitral valve surgery. Pulmonic valve surgery is quite rare in adults and is usually performed in the context of long-standing congenital heart disease or carcinoid heart disease. Pulmonic valve surgery is not discussed in this chapter.

Indications

The specific indications for surgical intervention vary from valve to valve and are discussed separately. Generally, however, the indications can be primary or secondary. Traditionally, the primary indication for surgery has been the onset of symptoms, most notably symptoms of left or right heart failure, or both, but also angina, syncope, and arrhythmias. With wider utilization of echocardiography and improved surgical outcomes, echocardiographic evidence of ventricular strain (dilatation or dysfunction, or both) has become the primary indication for surgery in an increasing number of asymptomatic or mildly symptomatic patients. Most recently, the primary indications for mitral valve repair have been broadened to include some asymptomatic patients with normal ventricular function and dimensions.[7]

Many patients without a primary indication for intervention on a particular valve will undergo valve surgery at the time of another cardiac surgery procedure, such as coronary bypass surgery, other valve surgery, or aortic surgery. The

AVR, aortic valve replacement; MVR, mitral valve replacement.

threshold for intervention as a concomitant procedure is usually lower than as a primary procedure, and valve repair or replacement may be indicated for moderate or even mild degrees of stenosis or regurgitation. The decision to intervene is based on an understanding of the natural history of these valvular lesions and is primarily aimed at preventing subsequent progression of heart failure symptoms or the need for late reoperation.

Preoperative Evaluation and Optimization

Patients undergoing valvular surgery require thorough preoperative evaluation and optimization to assure the best possible outcomes.

History and Physical

A detailed history and physical examination is fundamental. In addition to carefully characterizing the symptom profile of the valve disease, it is important to determine if there is a history of palpitations or known arrhythmia; risk factors for or known coronary artery disease; stroke or transient ischemic attacks (TIAs); lung, liver, or renal disease; GI bleeding; peripheral vascular disease; bleeding or hypercoagulable conditions; and recent infections. In addition to careful cardiopulmonary auscultation, key elements of the physical examination include a good dental examination, assessment of jugular venous pressures, carotid bruits and peripheral pulses, hepatomegaly, and availability of venous or arterial conduits for possible concomitant bypass grafting.

Documenting the baseline rhythm, any bundle branch blocks, and baseline ST and T-wave changes is important for intraoperative and postoperative management. In addition to identifying unsuspected cardiopulmonary pathology, the chest x-ray provides a plethora of useful preoperative information including chest wall anatomic details (useful for planning less-invasive surgical incisions) and the presence of pathologic calcification (aorta, valves, annuli). Each of these elements can have a significant impact on surgical decision-making, timing, and choice of prosthesis.

Echocardiography

Nearly all patients referred for surgery will have undergone a transthoracic echocardiogram to make the diagnosis, and this will often be supplemented by a transesophageal study. Careful characterization of the primary valve lesion is important and can be invaluable for surgical planning and counseling the patient on the likely intraoperative events. In addition to measuring the degree of stenosis or regurgitation, or both, the specific etiology can often be determined. The use of quantitative methods for measuring mitral regurgitation (PISA, ERO, and RV) should be encouraged. The other valves should be carefully interrogated to rule out multivalve disease. Estimation of biventricular function is obviously critical, but so are ventricular dimensions, hypertrophy, any ventricular outflow tract obstruction and TR-jet derived estimates of pulmonary artery pressure. Other important findings include atrial dilatation, thrombus, patent foramen ovale, and occasional rare anomalies such as a persistent left-sided superior vena cava (SVC). In young patients in whom coronary arteri-

ography may be deferred, echocardiographic identification of the coronary ostia may be important.

Even if the primary valve lesion was well characterized on a series of older echocardiograms, it is advisable to repeat the study within a month or so of surgery to reassess ventricular and other valvular function, which can sometimes progress rather rapidly. In some patients in whom the decision to proceed with surgery is equivocal (e.g., low-gradient aortic stenosis [AS] with poor left ventricular [LV] function), stress echocardiography may provide useful information.

Cardiac Catheterization

In the majority of patients about to undergo valvular surgery, the complete hemodynamic picture can be obtained with echocardiography alone. Occasionally, however, right or left heart catheterization, or both, may be indicated to more precisely delineate the hemodynamic picture, especially stenotic gradients and the severity of pulmonary hypertension. Angiographic assessment of valvular regurgitation does not add much to the echocardiogram and can frequently underestimate eccentric jets.

As echocardiography has improved, the primary indication for preoperative catheterization is now coronary angiography, which is indicated in patients with known CAD or significant CAD risk factors. The age threshold for coronary angiography in patients without risk factors is usually 40 years for men and 50 years for women, although some would recommend routine coronary angiography in men as young as 35 years. The likelihood of CAD in preoperative valve patients varies from about 1% in degenerative mitral valve disease to more than 50% in calcific AS.

The specific question of whether a stenotic aortic valve should be crossed to confirm hemodynamics is controversial. Most surgeons are comfortable proceeding on the basis of a good echocardiogram with catheter-based hemodynamic assessment only in equivocal cases. A contemporary study highlighted the real risk of embolism during attempts to cross a stenotic valve and encouraged a selective approach.[8]

Other Preoperative Testing

Although echocardiography remains the mainstay of preoperative testing, cardiac magnetic resonance imaging provides

excellent outstanding anatomic and physiologic data in patients with valve disease. The specific indications for its use in this setting, however, have not been established. Other imaging may be indicated in specific clinical scenarios. A head CT scan may be useful in patients with prior CVA or to rule out mycotic aneurysms in patients with endocarditis. Preoperative carotid ultrasound is frequently performed if carotid stenoses are suspected. A chest CT scan may be useful to more precisely determine the relationship between the heart and chest wall structures to plan minimally invasive incisions.

Holter monitoring may be useful in patients with suspected atrial arrhythmia to determine whether concomitant arrhythmia surgery should be considered. If indicated, formal electrophysiologic testing for ventricular arrhythmias is typically performed postoperatively because the substrate may be altered by surgical intervention.

In patients with dyspnea as a primary symptom, it may be difficult to determine the relative cardiac and pulmonary contributions to their symptoms and the degree to which correcting the cardiac lesion will improve their symptoms. Pulmonary function tests can help clarify this and allow the physician to provide the patient with realistic expectations from surgery.

Medical Therapy

Whether a patient presents for urgent aortic valve replacement for acute AR secondary to endocarditis or for purely elective mitral valve repair, the potential for preoperative medical optimization should be considered. Such efforts, however minor they might appear, may significantly assist intraoperative care and improve postoperative outcomes, especially in high-risk patients. Even in the most urgent settings, such as a patient in shock with acute MR from papillary muscle rupture, the time until the operating room is ready can be used to stabilize the hemodynamics with inotropic agents and an intraaortic balloon pump if not contraindicated.

In less urgent settings every effort should be made to optimize the patient for surgery, remaining careful not to miss the opportunity to intervene by trying to make the patient "perfect." Patients with decompensated heart failure may benefit from aggressive outpatient or inpatient diuresis and titration of other cardiac medications. Elderly or debilitated patients may benefit from preoperative physical therapy or nutritional support. Efforts to improve rate control or even cardioversion may be indicated in patients with supraventricular arrhythmias including atrial fibrillation. Smoking cessation programs or formal pulmonary rehabilitation may be helpful. Patients on hemodialysis are often admitted a few days preoperatively for more aggressive dialysis runs. Patients on warfarin should stop at least 4 to 5 days before surgery, and those with strong indications for anticoagulation are usually admitted for IV heparin or treated as an outpatient with low-molecular-weight heparin. On the other hand, the current practice is to continue aspirin for patients with coronary disease through surgery.

Preoperative optimization of high-risk patients undergoing mitral valve surgery may be particularly important, especially those with significant pulmonary hypertension and ventricular dysfunction. Our group recently reported on a preoperative regimen including nesiritide, which decreased PA pressures and operative mortality relative to predicted in high-risk mitral valve surgery patients (0% versus 23%).[8a]

Surgical Approaches

Median Sternotomy

The median sternotomy remains the primary approach for most patients undergoing valve surgery. Median sternotomy is the only viable approach for those undergoing concomitant bypass grafting. It provides direct access to all important cardiovascular structures, and valve exposure is usually excellent. A full sternotomy can be performed through a fairly limited skin incision (12 to 18 cm) in patients with a favorable body habitus who desire a better cosmetic result. After pericardiotomy, the heart and great vessels are inspected and, increasingly, the ascending aorta is scanned to rule out significant plaque or atheroma, which might alter cannulation or aortic clamping techniques.

Minimally Invasive Approaches

Over the past decade surgeons have explored alternative incisions for accessing heart valves that aim to reduce surgical invasiveness and also yield a more cosmetic result. The primary incisions (Fig. 47–2) are typically 5 to 10 cm and include mini-thoracotomies (anterior, lateral, and axillary) and partial sternotomies (upper, lower). The approaches can be categorized as direct access, videoscopic, or robotic assisted. With *direct access* approaches, surgical manipulation is performed under direct vision through the primary incision. Cannulation for cardiopulmonary bypass can be performed centrally through this incision or peripherally. *Videoscopic* mitral valve surgery is performed through a small working incision and one or more additional endoscopic ports. Cannulation for cardiopulmonary bypass is usually performed peripherally. The valve is viewed on a monitor, and the tissues are manipulated using specialized endoscopic instruments. *Robotic* mitral valve surgery is similar, but the imaging and instruments are integrated into a robotic surgical device (da Vinci, Intuitive Surgical) which is manipulated remotely from a separate console. Some surgeons have used this technology to perform truly endoscopic mitral valve surgery.

The major advantage of minimal access approaches is cosmetic. Other potential advantages include less pain (because of less tissue retraction) and less bleeding (because of less dissection). All minimal access approaches leave at least part of the sternum intact, thereby preserving chest wall integrity (and possibly resulting in less wound dehiscence and less respiratory morbidity). Minimally invasive approaches are more technically demanding, require more surgical skill, and pose unique surgical challenges (e.g., reduced tactile feedback, modification of cannulation techniques, difficulties in myocardial protection, and de-airing). There is a learning curve to the procedure, and the procedures generally take longer to perform. With adequate training and experience, minimally invasive valve surgery can be undertaken with comparable or superior results to conventional technique.

Minimally invasive aortic valve replacement through a partial upper sternotomy is now widely practiced and has become the standard approach for isolated aortic valve replacement at many centers. Although published data support the safety and efficacy of this approach, they are mixed on whether real clinical advantages beyond cosmesis exist.[9-14] Videoscopic and robotic mitral valve surgery is being performed mostly at

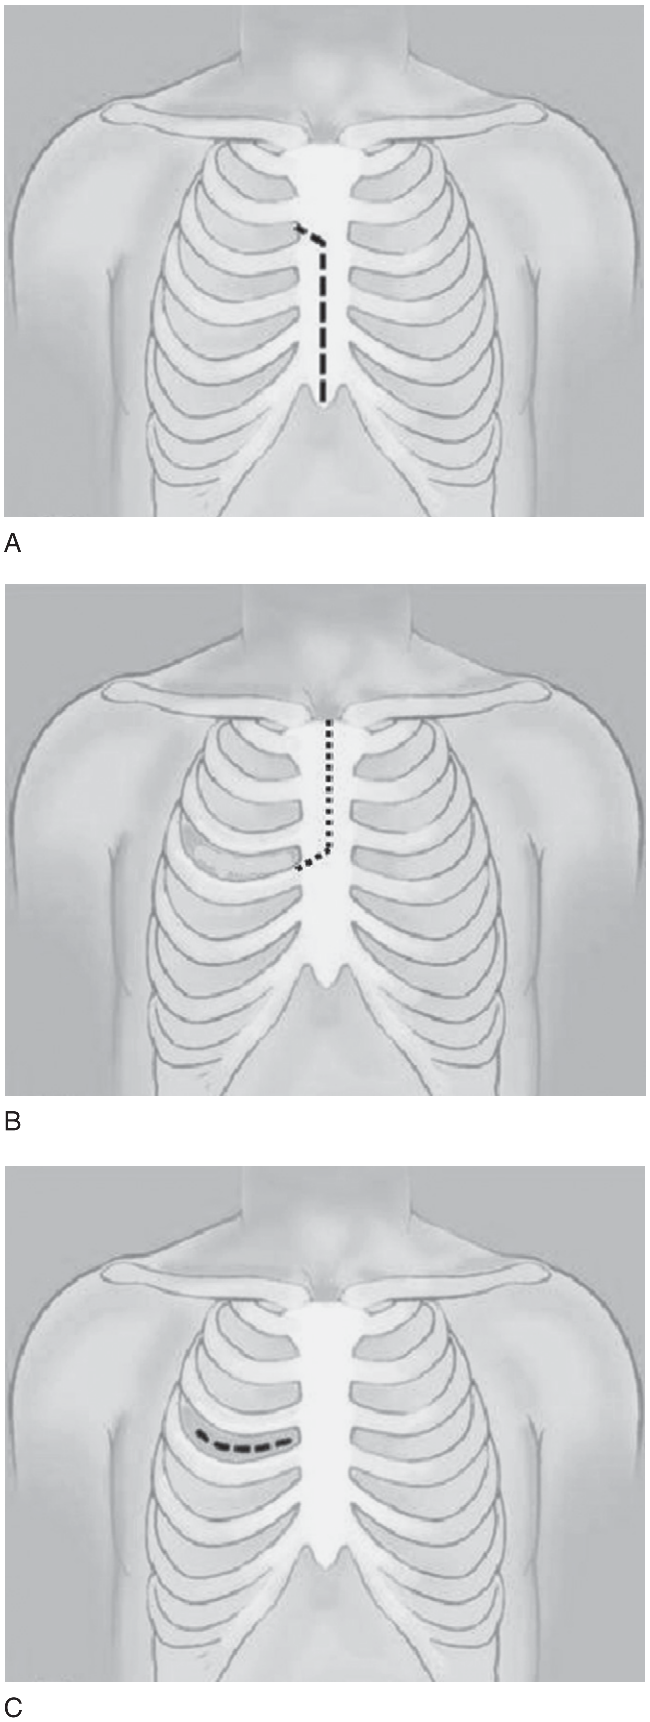

Figure 47–2 (*See also Color Plate 47–2.*) Minimally invasive valve surgery incisions. **A,** Lower partial sternotomy. **B,** Upper partial sternotomy. **C,** Right mini-thoracotomy.

specialized centers. Again, published data support its safety and efficacy but have not shown it to be superior with regard to hard clinical endpoints.[14a,14b]

Prostheses

Currently available valve prostheses are the product of nearly half a century of engineering, biochemical, and clinical research and are designed to provide maximum hemodynamic performance, durability, and freedom from complications. Nonetheless, the "holy grail" of the perfect valve prosthesis—with no obstruction to flow, no regurgitation, lifelong durability, and no significant complications—may never be reached. In fact, patients and physicians will likely always be faced with the need to balance the pros and cons of each prosthesis. The currently available FDA-approved prostheses and the relative advantages and disadvantages of each class of prostheses are noted in Tables 47–2 and 47–3. The most commonly used valves are shown in Figure 47–3. The annuloplasty devices are described later with mitral valve repair.

The primary differentiating characteristics of valve prostheses are their hemodynamic profile and the incidence of valve-related complications. A consensus panel of the Society of Thoracic Surgery (STS) and the American Association of Thoracic Surgery (AATS) published standard definitions and guidelines for reporting valve-related complications in 1996.[2] The panel defined six specific, nonfatal valve-related events—structural valve degeneration, nonstructural valve degeneration, valve thrombosis, embolism, bleeding, and operated valvular endocarditis (Table 47–4). Time-related complications are typically reported as linearized rates (thrombosis, embolism, bleeding) or using actuarial methods (structural valve degeneration, endocarditis). As more elderly patients underwent valve surgery, it became apparent that actuarial methods can overestimate these rates because they do not censor patients who die from other causes. Reporting actual survival on the basis of Grunkemeier's cumulative incidence method[15,16] has become more popular because it is more relevant to clinical decision-making.

Mechanical Valves

Mechanical valves are generally characterized by good hemodynamics, excellent durability, and ease of implantation. These benefits must be balanced against a lifelong need for moderate anti-coagulation and sometimes troubling valve noise. Their dominant position has been steadily eroded over the past decade by improved bioprostheses and increasing mitral valve repair.

Mechanical valves are of three types—caged ball, tilting disc, and bileaflet. The Starr-Edwards valve, which consists of a Silastic ball within a titanium cage, has remained on the market, essentially unchanged, for nearly 4 decades. Despite a remarkable history and excellent durability, it is rarely used because it has been surpassed by valves with superior thromboembolic and hemodynamic profiles. In a tilting disc valve, such as the Medtronic-Hall valve (1977), the ball is replaced by a flat disc that tilts open along retaining guides during systole, increasing central flow and improving hemodynamics and thromboresistance. The St. Jude mechanical valve, also introduced in 1977, was the first bileaflet valve and, with more

than 1 million implants, remains the world's most popular valve prosthesis. It is manufactured from pyrolytic carbon with each leaflet rotating over a fixed range within pivots in the inner surface of the ring. Several other companies market similar pyrolytic carbon bileaflet valves that purport advantages on the basis of the purity of the carbon (On-X), pivot designs (ATS Medical) and supra-annular location of the leaflets and pivots (Carbomedics).

Numerous long-term studies have evaluated the absolute and relative performance of currently available mechanical valves. Several primary findings have been made. The incidence of structural valve degeneration of the currently marketed

mechanical valves is vanishingly low. The annual linearized rates (events/patient-year) of thromboembolism (0.5% to 4%), thrombosis (0% to 0.5%), and major bleeding complications (0.5% to 4%) vary widely from study to study and are greater for valves in the mitral than in the aortic position. A low but finite incidence of reoperation (5% to 10% at 15 to 20 years) exists for endocarditis, thrombosis, or nonstructural dysfunction (e.g., pannus overgrowth, endocarditis, perivalvular leak).

Grunkemeier et al[17] performed a meta-analysis of complication rates from the two most popular mechanical valves, St. Jude and Carbomedics, and found similar rates of thromboembolism (1.6% aortic, 2% to 2.5% mitral) and bleeding (1.5% aortic, 1.3% to 1.4% mitral). The Carbomedics valve had a lower thrombosis rate in the aortic position (0.02% versus 0.15%) but higher in the mitral position (0.17% versus 0.33%) (Table 47–5, Fig. 47–4). Several retrospective studies have suggested slightly higher long-term complication rates with the Medtronic-Hall valve compared with the bileaflet valves,[18,19] although a small randomized trial could not detect a difference.[20] The data on the newer valves (ON-X, ATS) are also comparable, but so far no irrefutable data support that they are superior.

The recommended target INR for the bileaflet and Medtronic-Hall valves is 2.0 to 3.0 in the aortic position and 2.5 to 3.5 in the mitral. Higher levels and the addition of aspirin should be considered in patients who are at higher risk for thromboembolism (atrial fibrillation, prior thromboembolism, hypercoagulable state). Significant interest has been expressed in alternatives to warfarin anticoagulation including the new oral direct thrombin inhibitor ximelagatran and even dual antiplatelet therapy with aspirin/clopidogrel in aortic valves. Data to determine whether these will be safe and effective alternatives are inadequate to date.

Table 47–4 Definition of Valve-related Complications

Structural valvular deterioration	Any change in function of an operated valve resulting from an intrinsic abnormality of the valve that causes stenosis or regurgitation exclusive of infection or thrombosis, such as wear, calcification, or leaflet tear.
Nonstructural dysfunction	Any abnormality resulting in stenosis or regurgitation at the operated valve that is not intrinsic to the valve itself, exclusive of thrombosis and infection, such as pannus overgrowth, paravalvular leak, inappropriate sizing or positioning; residual leak or obstruction; and clinically important hemolytic anemia.
Valve thrombosis	Any thrombus, in the absence of infection, attached to or near an operated valve that occludes part of the blood flow path or that interferes with valvular function.
Embolism	Any embolic event that occurs in the absence of infection after the immediate perioperative period. A neurologic event includes any new, temporary, or permanent focal or global neurologic deficit. A peripheral embolic event produces symptoms from complete or partial obstruction of a peripheral artery. Immediate postoperative neurologic deficits and myocardial infarction are generally excluded.
Bleeding event	Any episode of major internal or external bleeding that causes death, hospitalization, or permanent injury or requires transfusion, whether or not anticoagulants or antiplatelet drugs are being taken.
Operated valvular endocarditis	Any infection involving an operated valve, based on customary clinical criteria. Morbidity associated with active infection, such as valve thrombosis, thrombotic embolus, bleeding event, or paravalvular leak, is included under this category and is not included in other categories of morbidity.

Table 47–5 Pooled Event Rates and Hazard Ratios (HR) for Comparison of Event Rates

Stented Xenografts

The first xenograft bioprostheses were developed by Carpentier and Hancock in 1969. They consisted of a rigid or semirigid cloth-covered stent to which porcine aortic valve cusps were attached. Cusps created from bovine pericardium were later applied to similar stent structures. The key development was the introduction of glutaraldehyde fixation. By cross-linking collagen fibers and eliminating viable cells, this treatment increases the durability of the xenograft tissue and decreases its antigenicity. It soon became clear, however, that the Achilles heel of glutaraldehyde fixation was subsequent calcification, which is the final common pathway for structural valve degeneration of most bioprostheses. In addition to the loss of cusp mobility, areas of calcification become stress points that can lead to cusp tears. Extensive research over the past 3 decades has led to improved techniques of tissue preservation. Low- or zero-pressure fixation techniques combined with anti-mineralization treatment have led to significant gains in bioprosthesis durability. This has resulted in a dramatic shift over the past decade away from mechanical prostheses and lowering of the age threshold for bioprostheses.

The most commonly used stented xenograft in the United States is the Carpentier-Edwards PERIMOUNT Pericardial Valve (Edwards Lifesciences). The most recent design iteration of this valve, the Magna valve, purports to maximize hemodynamics

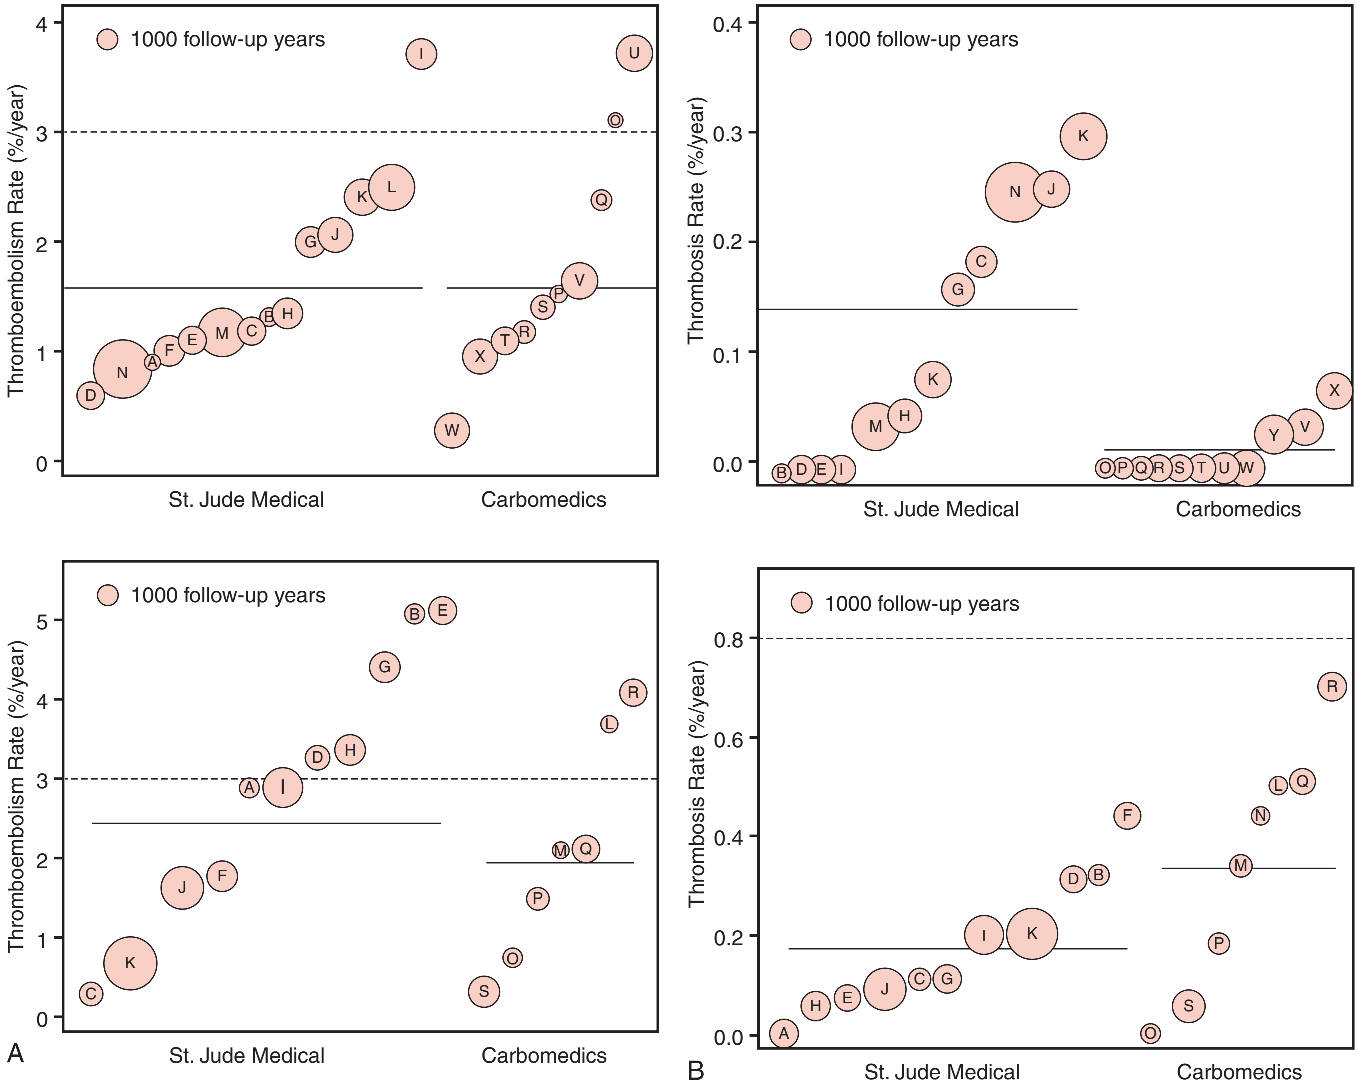

Figure 47–4 Valve-related complication rates of two types of mechanical valves—St. Jude Medical versus Carbomedics. Each circle represents a different study. **A,** Aortic. **B,** Mitral. (From Grunkemeier GL, Wu Y: "Our complication rates are lower than theirs": Statistical critique of heart valve comparisons. J Thorac Cardiovasc Surg 2003;125:290-300.)

through a true supra-annular design. Stented porcine valves currently marketed in the United States include versions of the Carpentier-Edwards Porcine valve (Edwards Lifesciences); the Hancock (I, II, and MO) and Mosaic valves (Medtronic); and the recently approved Biocor valve (St. Jude Medical). Durability data are discussed separately for aortic and mitral valve prostheses.

Stentless Xenografts

Stentless xenograft bioprostheses were developed to mimic the near-native hemodynamics of homografts and autografts while maintaining the ease of use and off-the-shelf convenience of stented bioprostheses. Eliminating the stent permits a larger valve to be inserted but increases the surgical complexity to some degree. Stentless valves can be inserted by one of several techniques. In a *subcoronary* implantation the valve is seated within the native aortic root. This typically requires two suture lines—a proximal suture line at the annulus and a distal one to secure the valve and commissures to the sinuses of Valsalva. The *hemi-root* or *full-root* techniques involve replacing part of the patient's aortic root with the bioprosthesis. The full root technique usually requires coronary reimplantation. Whichever technique is used, the implantation of a stentless valve is technically more challenging than that of a stented valve. Once implanted, stentless valves have an excellent hemodynamic profile and there is some evidence that they promote greater regression of LV hypertrophy.[21,22] The technical challenge and the lack of data showing an advantage with regard to hard endpoints have limited the adoption of stentless valves since their introduction in the early 1990s. Although some centers have adopted stentless valves as their valve of choice in the aortic position, most limit their use to specific indications, such as a small aortic annulus or diseased root.

Three stentless aortic valves are currently marketed in the United States. The Medtronic Freestyle and the Edwards Prima Plus are both delivered as full porcine aortic roots with the coronaries ligated and a cloth covering of the annulus. They can be used for a full root replacement or can be

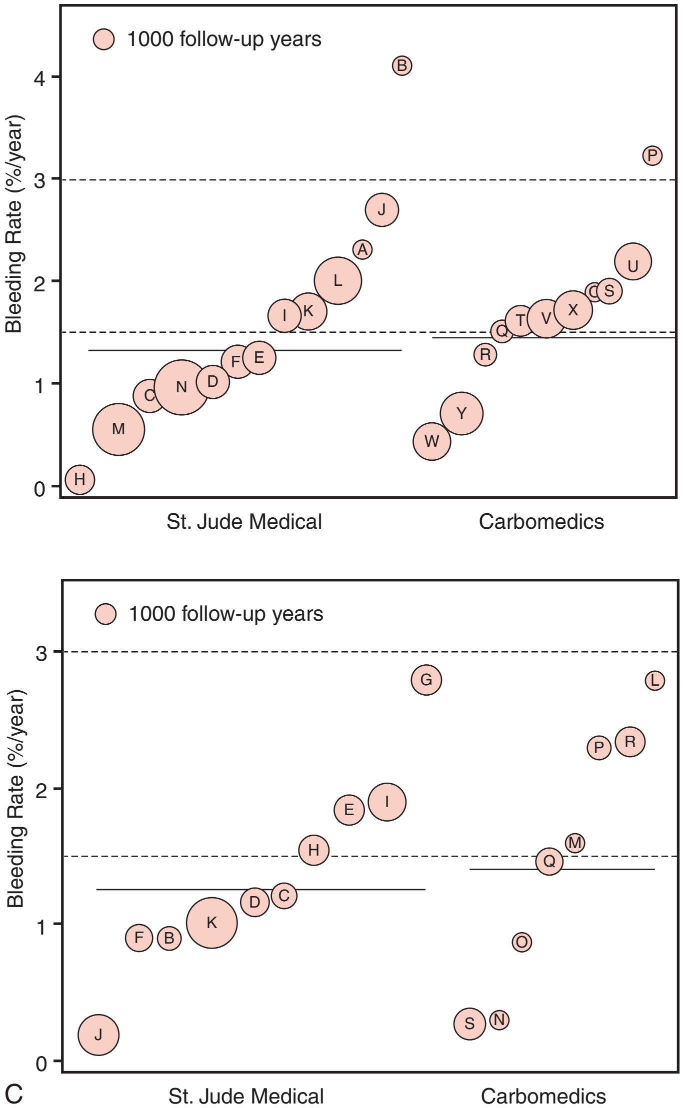

Figure 47–4, cont'd

trimmed for subcoronary implantation. The Toronto Stentless SPV valve (St. Jude Medical) is designed only for subcoronary implantation.

Homografts

Homograft valves have been used in the aortic position since the early 1960s following pioneering work by Ross and Barrett-Boyes. A variety of earlier preservation techniques have been replaced by cryopreservation. Homografts share many of the advantages of stentless valves including excellent hemodynamics and can also be used as full root or subcoronary implants. They appear to have a greater resistance to infection and are therefore commonly used in the setting of endocarditis. The primary limitation of homografts has been availability and storage requirements. Utilization of homografts appears to be declining; the most recent data indicate that their durability is not significantly better than modern-day bioprostheses.[23] Homografts tend to calcify as they fail, making reoperation in patients who have received full root replacements difficult.

Efforts to use mitral valve homografts have not been successful.[24] These efforts have been limited by the complex geometry of the mitral valve and accelerated degeneration. The increased utilization of valve repair and improvement in bioprostheses have also led to a decline in interest in this approach.

Postoperative Care

The postoperative care of patients undergoing valvular surgery must be tailored to the individual patient's specific condition. The immediate postoperative period is focused on maintaining an adequate cardiac output and monitoring for bleeding. Many, if not most, valve patients are candidates for a so-called "fast-track" protocol in which the anesthetic management is designed to permit extubation within 1 to 6 hours of arrival in the ICU, once hemodynamic stability and hemostasis have been achieved.

An increasing proportion of patients have decreased ventricular function, so it is not uncommon that patients will arrive in the ICU on inotropic support. In most patients the support can be weaned over the first 24 hours or so, but occasionally, in those with poor function, this process can take longer.

Pulmonary hypertension, if present, must be addressed carefully to protect the right ventricle, which is more difficult to protect and is therefore particularly vulnerable to myocardial stunning. Maneuvers may include avoiding hypoxia or hypercarbia; avoiding α-agonists; and use of pulmonary vasodilators, such as milrinone or, in severe cases, inhaled nitric oxide.

Patients with severe LV hypertrophy and diastolic dysfunction warrant careful postoperative hemodynamic management. These patients will often need aggressive volume resuscitation and require higher than expected intracardiac filling pressures to maintain an adequate stroke volume. An occasional patient with severe hypertrophy may develop dynamic outflow tract obstruction ("suicide ventricle"). In addition to maintaining adequate preload, inotropic agents should be avoided and peripheral vasoconstrictors should be used if necessary to maintain systemic blood pressure. If pacing is necessary, atrioventricular pacing is preferred because the hypertrophied ventricle will usually benefit from atrial contraction.

The next few days in the hospital course are typically focused on diuresis, rhythm management, reinstitution of cardiac and noncardiac medications, pulmonary toilet, mobilization, and anticoagulation. The incidence of postoperative atrial fibrillation is higher in valve patients than in coronary patients.[25,26] Preoperative prophylactic regimens have been proposed but are not widely used. Postoperative AF protocols vary from one institution to another but include β-blockers; amiodarone; calcium channel blockers; and, less commonly, digoxin.[27,28] Transient heart block is not uncommon, so most surgeons will place temporary pacing wires at the time of surgery. Most of the time this will resolve as edema subsides and electrolyte imbalances are corrected. Occasionally, however, a permanent pacemaker is required before discharge. It can be difficult to determine when to proceed with pacemaker implantation, but it is reasonable to wait 5 to 7 days for signs of recovery of the rhythm.

All patients with mechanical valves, most mitral valve patients, and those in atrial fibrillation will be anticoagulated

in the immediate postoperative period. Warfarin is usually initiated soon after surgery. Some surgeons are reluctant to bridge with IV heparin for fear of bleeding and tamponade. At a minimum, patients with mechanical mitral valves should be considered at high risk for early thromboembolism and should receive IV heparin if they are not therapeutic within a few days of surgery. Most centers still anticoagulate patients undergoing mitral valve repair, although some high-volume centers have chosen to be selective, using aspirin alone in younger, healthier patients with normal sinus rhythm and good ventricular function. Another area of controversy is whether to anticoagulate patients with aortic bioprostheses.[29-32] A survey indicated that most patients are not being anticoagulated in the absence of other indications.[33]

A baseline postoperative echocardiogram is usually performed before discharge in patients undergoing valve repair or stentless valve replacement. Predischarge education regarding antibiotic prophylaxis and anticoagulant therapy is important.

AORTIC VALVE SURGERY

Overview

Aortic valve replacement is the most commonly performed valve operation. It has been shown to be an effective therapy in all age groups including the very elderly (older than 90 years).[34] The most common etiologies for AS are calcific degeneration, rheumatic disease, and congenital bicuspid valves. The most common causes of pure aortic regurgitation (AR) include annulo-aortic ectasia and associated dilatation of the aortic root, endocarditis, aortic dissection, and rheumatic disease. The indications for surgery depend on the pathophysiology and symptoms. The choice of prosthesis can be difficult and depends on multiple clinical and lifestyle considerations. Early and late outcomes are generally quite good, even in high-risk patients.

Indications

Aortic Stenosis/Mixed Aortic Valve Disease

The indications for aortic valve surgery in pure AS and mixed disease are fairly well established[7] and are described in greater detail elsewhere. Current class I indications include severe AS with symptoms or signs of LV dysfunction, as well as other concomitant cardiac surgery. AVR is also recommended (class IIa) in patients with moderate AS undergoing CABG or other valve surgery to decrease the risk of early reoperation for progression of the AS. Intervening in mild AS at the time of CABG is more controversial but has been suggested, especially in patients who appear to be at high risk for progression, such as those with significant calcification.[35-39] Other possible but controversial indications for AVR include asymptomatic patients with normal ventricular function and severe AS (valve area < 0.6 cm^2), those with severe AS but abnormal response to stress testing (e.g., hypotension), and those with risk factors for more rapid progression.

Patients with poor LV function (ejection fraction < 30%) with AS will often present with relatively low gradients. Recent data suggests that carefully selected patients in this subgroup will benefit from surgery.

Aortic Regurgitation

The natural history of AR makes the timing of aortic valve surgery more difficult. Patients can remain relatively asymptomatic until significant ventricular damage has occurred. Class I indications include symptomatic severe AR and asymptomatic severe AR with LV dysfunction. Surgery is also recommended (class IIa) in asymptomatic patients with normal LV function but severe dilatation (end-diastolic or systolic dimensions of > 75 mm or > 55 mm, respectively). Severe, and probably moderate, AR should be corrected at the time of CABG or other valve surgery.

Aortic Valve Replacement

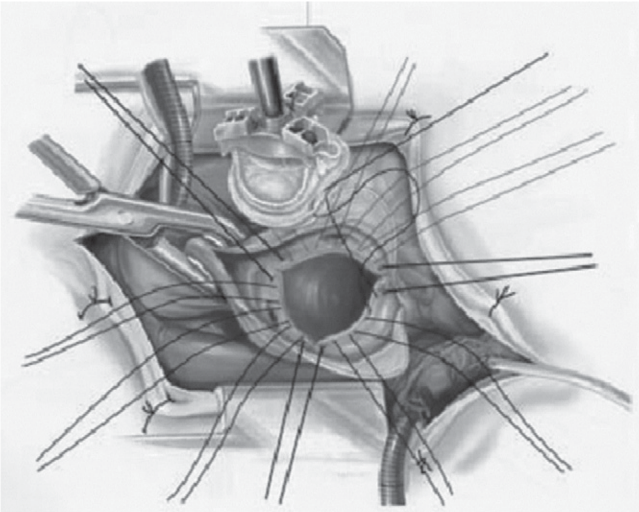
Surgical Technique

The steps involved in replacing the aortic valve are fairly well established (Fig. 47–5A). Routine scanning of the aorta is increasingly used before cannulation for cardiopulmonary bypass, usually via the distal aorta and right atrium. The aorta is clamped, and the heart is protected with hyperkalemic cardioplegia solution delivered anterograde in the aortic root or coronary ostia or retrograde via the coronary sinus, or both. This is usually supplemented with mild systemic or topical hypothermia, or both. An incision is made in the proximal aorta, and the valve is inspected. Débriding a highly calcified valve and annulus can be a significant challenge, and careful attention must be paid to removing all the calcium while maintaining adequate annular tissue and removing all loose debris that can later embolize. The calcium will sometimes continue up the aortic wall, and localized endarterectomies may be required.

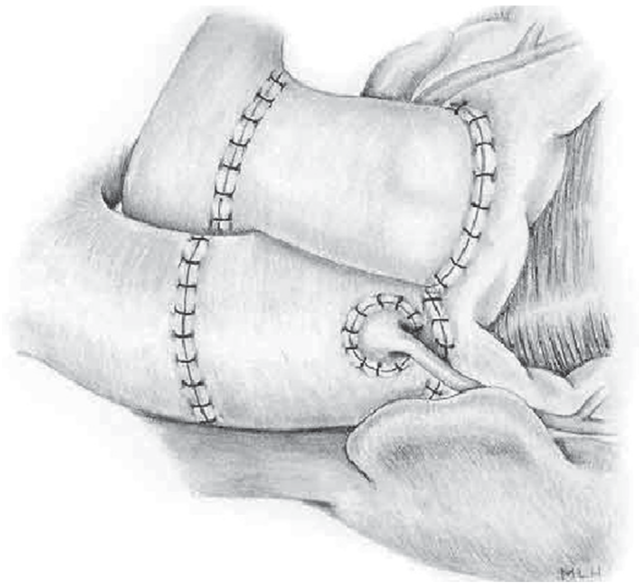
Once the annulus is fully débrided, the valve is secured with sutures. The specific suture technique (pledgets versus no pledgets, interrupted versus running, everting versus noneverting, supra-annular versus intra-annular) can vary from surgeon to surgeon. The suturing technique does not vary significantly between stented xenografts and mechanical valves. Subcoronary implantation of stentless valves, homografts, or even autografts require a second outflow suture line to secure the valve to the aortic wall. The largest-size valve that can be comfortably implanted is usually selected. If the annulus is small, the surgeon can enlarge it using a patch to permit a larger prosthesis to be implanted or use a stentless valve.

The aortotomy is sutured closed, air is evacuated from the heart, and the cross-clamp is removed. The patient is weaned off of cardiopulmonary bypass, heparin is reversed with protamine, and the cannulae are removed. Temporary epicardial pacing wires and chest drains are placed before sternal closure.

An aortic root replacement with coronary reimplantation (Bentall procedure) may be performed if there is concomitant aortic root disease (dilatation, calcification) or if the surgeon chooses to implant a stentless prosthesis or homograft as a full root. The aorta is resected from the annulus to ascending aorta (or further distally if indicated). The coronary ostia are preserved as buttons. A valved conduit (mechanical or stented valve attached to a Dacron tube graft), stentless valve (porcine root), or homograft is selected and secured proximally and distally to the annulus and aorta, respectively. The coronary buttons are sutured to holes created in the conduit.



A



B

Figure 47–5 (*See also Color Plate 47–5*.) Surgical technique of aortic valve replacement. **A,** Stented xenograft. **B,** The Ross ("Pulmonary Autograft AVR") Procedure – The patient's pulmonary valve and root are translocated into the aortic position and replaced with a homograft. The figure shows a completed procedure as seen by the surgeon standing to the patient's right. The patient's head is to the left and feet are to the right. The confluence of the superior vena cava and right atrial appendage is at the bottom of the figure. Moving up (from the patient's right to left) are (1) the pulmonary autograft with its distal suture line to the ascending aorta and proximal suture line to the aortic annulus; the right coronary artery has been reimplanted as a button, the left coronary button is posterior and not visualized; (2) the pulmonary homograft with its distal suture line to the confluence of the pulmonary arteries and the proximal arteries and the proximal suture line to the right ventricular outflow tract.

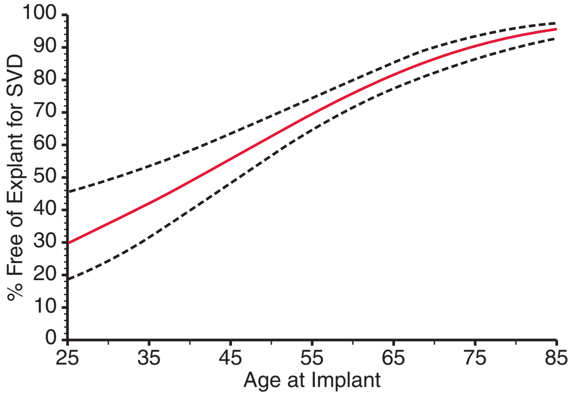


Figure 47–6 Age dependence of structural valve degeneration of Carpentier-Edwards pericardial valve in the aortic position.[70]

The pulmonary autograft or Ross procedure is usually performed as an aortic root replacement using the patient's own pulmonary valve/artery as the prosthesis (see Fig. 47–5B). The implant is similar to other root replacements except that the annulus and sinotubular junction are often reinforced with prosthetic material to prevent late dilatation. A pulmonary homograft is usually used to reconstruct the right ventricular outflow tract.

Choice of Prosthesis

Selecting the most appropriate prosthesis in a patient undergoing AVR is a complex decision with significant long-term consequences for the patient. As noted in Table 47–3, the available prostheses differ significantly with regard to key parameters, such as the need for anticoagulation, freedom from thromboembolism, durability, ease of operation, hemodynamic performance, and resistance to infection. Although broad, age-based guidelines do exist, the final choice should be tailored to the individual patient and should take into consideration multiple factors in addition to age, such as concomitant diseases (especially those affecting life expectancy), general lifestyle, physical activity, surgeon expertise, and ultimately overall patient preference.

The primary factor in prosthesis selection does, however, remain patient age. Elderly patients have lower life expectancies and tend to be less physically active. Younger patients, on the other hand, place a greater demand on the prosthesis with regard to durability and hemodynamic performance. Age has long been recognized as the primary determinant of bioprosthesis calcification and thus durability. Long-term follow-up of the Carpentier-Edwards pericardial valve confirms a strong correlation between age at implant and the likelihood of explant at 15 years (Fig. 47–6). The traditional age threshold for a bioprosthesis has been between 65 and 70 years. The actual lifetime likelihood of reoperation for structural valve dysfunction in a 65-year-old is less than 10%. Given the excellent durability of modern bioprostheses, it is difficult to justify implantation of a mechanical valve in any elderly patient. The fact that the patient is already on warfarin for another indication, such as atrial fibrillation, does not justify the use of a mechanical valve because it converts a relative indication for low-level anticoagulation to an absolute indication for higher levels of anticoagulation. It also eliminates

the option of discontinuing anticoagulation in the event of a major bleeding episode. Even the presence of another mechanical valve does not mandate a second mechanical valve because risk of thromboembolic and bleeding complications is higher with two mechanical valves than one.

The choice of prosthesis in patients younger than 65 is more complex and controversial. Traditionally these patients would receive a mechanical valve. The improvement in bioprosthesis durability and the decrease in the operative risk of replacing a failed prosthesis have led to an increase in the number of patients younger than 65 receiving bioprostheses including many patients in their 50s and some even younger. Women of child-bearing age pose a particular dilemma and often choose a bioprosthesis to avoid warfarin with the understanding that they will face at least one reoperation in their lifetime.

By eliminating the stent and most of the prosthetic material, stentless valves such as the Toronto SPV, Freestyle, and Prima Plus valves allow implantation of a larger valve than would be possible with a stented xenograft. The most commonly implanted stentless valve sizes are 25 to 29 mm, while most stented valve patients receive a 21- to 25-mm valve. In addition, when matched for size, the hemodynamic profiles of stentless valves are superior to stented valves, especially at the smaller sizes.[40] These differences are even greater when measured during exercise or pharmacologic stress.[41] These hemodynamic benefits may justify the use of stentless valves in younger, more active patients in whom a bioprosthesis is being considered. Whether this hemodynamic benefit translates into real clinical benefit remains controversial. Although the 10-year follow-up with the Freestyle is excellent,[42] duration of follow-up is not adequate to show improved durability. Some data suggest improved LV mass regression,[43,44] but only limited data suggest that this translates into greater survival.[45] Some data suggest fewer thromboembolic complications.[46] Despite these data, the specific indications for the use of a stentless valve are not well defined. At this point their use is primarily driven by surgeon preference.

The use of homografts as a primary aortic valve substitute has declined in recent years. Like stentless valves, homografts have excellent hemodynamics and are resistant to thromboembolism and infection. Recent data, however, suggest that their durability is not significantly better than stented xenografts. Without a durability advantage, it is difficult to justify their routine use given their limited availability and the cumbersome storage requirements. Their resistance to infection, however, makes them an excellent choice for patients with endocarditis.

The pulmonary autograft or Ross procedure involves replacing the aortic valve with the patient's own pulmonic valve, which in turn is replaced with a homograft or a stentless xenograft. The advantages are near-native hemodynamics and excellent autograft durability. The disadvantages are the high degree of technical complexity and need for reoperation for the homograft. On the basis of the data from the Ross Procedure International Registry, the Ross procedure peaked in popularity in the mid to late 1990s and procedure volume has declined since then. Several centers continue to report excellent results,[47,48] but it is now primarily a procedure for pediatric patients (where the potential for growth is important) and young adults in their 20s and 30s when no other good alternatives exist.

Patient-Prosthesis Mismatch

The concept of patient-prosthesis mismatch (PPM) remains hotly debated. Strictly speaking, it is defined as a prosthesis that is too small relative to the patient's size and provides residual obstruction to flow despite normal prosthesis function. The most common measure is the indexed effective orifice area (EOAI = EOA/BSA). The incidence of PPM depends on the cut-off used. Severe PPM defined as an EOAI < 0.65 cm^2/m^2 occurs in up to 10% of patients and moderate PPM in up to 70%.[49] Some authors argue that PPM is not clinically relevant—that LV ventricular mass regression and early and late cardiac events are not affected.[50-52] Others, led by Pibarot and colleagues, argue vigorously that PPM dramatically affects LV mass regression, operative mortality, late functional status, heart failure, and mortality.[49,53] Because surgeons will routinely attempt to implant the largest possible prosthesis, the debate can ultimately be distilled down to the question of whether the surgical technique should be modified to avoid PPM. Specific maneuvers include aortic annular enlargement and use of a stentless prosthesis. Opponents argue that these maneuvers carry additional operative complexity and risk and are therefore not justified.

Aortic Valve Repair

Selected patients with aortic insufficiency may be candidates for aortic valve repair, although they are rarely performed. Patients will occasionally present with isolated cusp perforation (iatrogenic, healed endocarditis) or cusp prolapse. These valves can be repaired using a pericardial patch over the perforation or plicating the prolapsing segment. Patients with retracted but mobile and noncalcified cusps from rheumatic disease can undergo leaflet extension with pieces of pericardium. Patients with noncalcified congenital bicuspid valve disease and AR are offered repair at some centers.[54-56] This typically involves resection of the redundant cusp and commissural plication.

Patients with normal cusps and aortic insufficiency secondary to concomitant aortic root dilatation can avoid valve replacement by undergoing one of several "valve-sparing" aortic root operations. These operations, pioneered by Yacoub[57,58] and David,[59,60] seek to reestablish the 3-D support of the native valve to permit adequate coaptation. Although technically difficult, these operations have good results in selected patients when performed at experienced centers.

Results

Early

The operative mortality for patients undergoing aortic valve replacement has declined steadily and is now 3.3% for isolated AVR and 5.5% for AVR CABG (STS 2005). A young, otherwise healthy patient with good ventricular function can be offered the procedure with a predicted operative mortality of 1% (STS Risk Calculator). Elderly patients[29,34,61,62] and those with decreased ventricular function[63-65] do surprising well following AVR for AS, presumably because of the immediate benefits of unloading the left ventricle. The operative risk does, however, increase in the presence of multiple-risk factors including age,

female gender, poor LV function, class IV heart failure, coronary artery disease, renal failure, endocarditis, urgent/emergent surgery, and reoperation. The most common causes of operative mortality are myocardial failure and stroke.

The most common complications following aortic valve surgery are similar to those of other cardiac surgery and include stroke (2% to 4%), deep sternal wound infection (1% to 2%), reoperation for bleeding (1% to 3%), and myocardial infarction (1% to 5%). Transient heart block, presumably as a result of traction or edema of the bundle of His in the vicinity of the right-noncoronary commissure, is not uncommon. It usually resolves within 5 to 6 days of surgery. The risk of complete heart block requiring pacemaker insertion is 3% to 5%.[66,67]

Late

Long-term survival following AVR depends on the patient's characteristics and comorbidity. Estimated 10-year survival can range from 85% in younger, healthier patients to 40% in elderly patients with CAD, class IV CHF, and decreased LV function.[68] Very elderly patients undergoing AVR have survival rates similar to their peers without aortic valve disease.[69] Approximately 40% of deaths following AVR are valve related, and another 20% are related to nonvalvular cardiac causes. There does not appear to be a clinically significant difference in survival between mechanical and biologic valves when age and other risk factors are controlled.

Freedom from reoperation depends on the prosthesis and age. Although they do not degenerate, modern mechanical valves do have a finite reoperation rate of 0.5% to 1% per year from endocarditis, pannus overgrowth, and thrombosis. Actual freedom from reoperation of modern bioprostheses at 15 years approaches 100% in elderly patients older than 70 years. It can be as low as 50% in patients younger than 50 years.[70,71]

MITRAL VALVE SURGERY

Overview

Although aortic valve surgery remains the most common valve operation (see Fig. 47–1C), the field of mitral valve surgery has been very dynamic with several important trends and advances in the past decade.[72] The incidence of rheumatic heart disease has declined, and techniques of percutaneous balloon mitral valvuloplasty have improved. These have led to a decline in the number of patients undergoing surgery for mitral stenosis. In contrast, the number of patients undergoing mitral valve repair, nearly all for mitral regurgitation, has doubled in the past decade (see Fig. 47–1C). A greater understanding of the benefits and techniques of mitral valve repair for degenerative disease has contributed to this trend, although mitral valve repair remains underused.[6] Other contributing factors include (1) broadening indications for surgical intervention including asymptomatic patients with normal ventricles; (2) a greater understanding of the pathophysiology, clinical course, and role of mitral valve surgery in ischemic MR; and (3) a greater acceptance of isolated or concomitant mitral valve repair in patients with poor ventricular function.

Anatomy

The surgical anatomy of the mitral valve is shown in Figure 47–7. The leaflets are divided into eight segments. The posterior leaflet is divided into three segments (P1, P2, P3) on the basis of anatomically distinct scallops. Each anterior leaflet segment (A1, A2, and A3) is defined by its corresponding posterior segment. The anterolateral commissure (Ac) and posteromedial commissure (Pc) have small but distinct leaflet scallops. The subvalvular apparatus consists of the papillary muscles and chordae tendinea, which are further subdivided into primary/marginal (attached to free margin), secondary (attached to underbelly of leaflet), and tertiary/basal (attached to annulus).

Carpentier's Functional Classification

Although several systems for classifying mitral valve dysfunction have been proposed, Carpentier's functional classification of mitral regurgitation based on the "pathophysiologic triad" (etiology → lesions → dysfunction) is the most robust (Table 47–6). Each etiology (degenerative, rheumatic, ischemic, dilated cardiomyopathy, endocarditis, etc.) results in one or more lesions of the annulus, leaflets, or subvalvular apparatus. These lesions result in a specific type of dysfunction on the basis of leaflet motion (see Fig. 47–7A). In a normally functioning mitral valve, the leaflets come together within the valve orifice, resulting in a surface of coaptation. The free margins of the leaflets remain below the plane of the annulus.

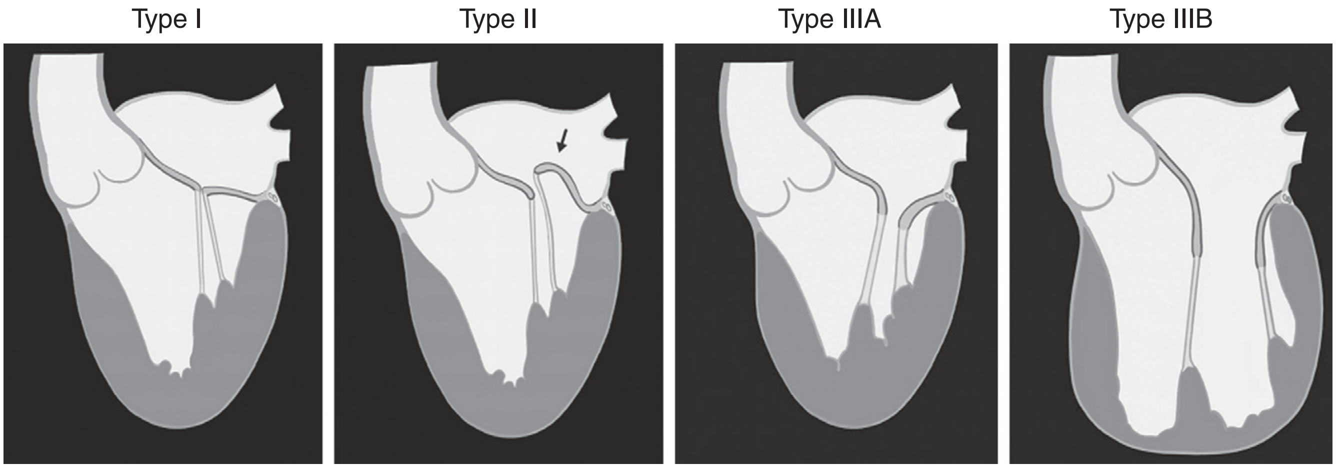
In *type I* dysfunction, the leaflets exhibit normal motion. The regurgitation results in annular dilatation, which prevents coaptation, or from leaflet perforation.

Type II dysfunction results from *leaflet prolapse,* in which the free margins of the involved portions of the leaflets rise above the plane of the annulus into the left atrium, preventing leaflet coaptation. The most common lesions resulting in leaflet prolapse and type II dysfunction include chordal elongation or rupture due to degenerative changes.

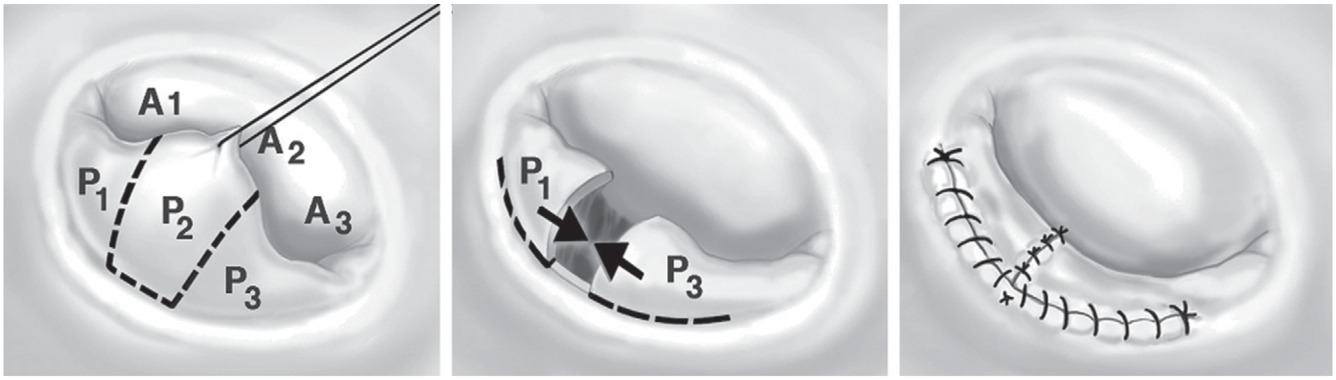
Finally, *type III* dysfunction results from *restricted leaflet motion*. Here, the free margins of portions of one or both leaflets are pulled below the plane of the annulus into the left ventricle, preventing them from rising up to the plane of the annulus and coapting during systole. The restricted leaflet motion can occur during both systole and diastole, related to valvular or subvalvular pathology (rheumatic fibrosis)—referred to as type IIIA dysfunction. Type III dysfunction more commonly occurs when abnormal ventricular geometry or function leads to papillary muscle displacement, which pulls the otherwise normal leaflets into the ventricle. This is known as type IIIB dysfunction and usually results from prior myocardial infarction (ischemic) or severe ventricular dilatation and dysfunction. Frequently, types I and IIIB dysfunction (except leaflet perforation) are referred to as "functional" MR because they occur in the absence of structural abnormalities of the valve.

Preoperative Evaluation

A high-quality echocardiogram is particularly important in the preoperative evaluation of patients with mitral valve disease. Transesophageal echocardiography may be necessary to obtain all of the important anatomic and physiologic data.



A



B

Figure 47–7 (*See also Color Plate 47–7.*) Principles of mitral valve repair. **A,** Carpentier's functional classification of mitral regurgitation. **B,** Quadrangular resection of the posterior leaflet with sliding valvuloplasty for P2 prolapse.

The severity of MS or MR may have already been established, but more quantitative assessment of MR (PISA, ERO, RV) may be particularly useful in patients with functional MR (type I, IIIB). The specific type of dysfunction (Type I, II, IIIA, or IIIB) should be determined preoperatively by carefully assessing the motion of each segment of each leaflet. The etiology can usually be determined with a combination of history, physical examination, and echocardiography. Distinguishing between specific lesions (e.g., ruptured versus elongated chord) is less important because the likelihood of repair and surgical techniques is determined by the etiology and type of dysfunction. Extensive mitral annular calcification is an important finding because it can significantly increase the complexity of the surgical procedure. Other echocardio-

Table 47–6 Carpentier's Functional Classification of Mitral Regurgitation

Dysfunction	Leaflet Motion	Lesions	Common Etiologies
Type I	Normal	Annular dilatation Leaflet perforation	Dilated cardiomyopathy Ischemic (basal infarction) Endocarditis
Type II	Increased (prolapse)	Chordal elongation Chordal rupture Papillary muscle Elongation Papillary muscle rupture	Degenerative Endocarditis Ischemic (PM infarction)
Type III	Restricted		
A	Systole and diastole	Leaflet thickening and retraction Subvalvular thickening and shortening	Rheumatic
B	Systole	Papillary muscle displacement Annular calcification	Dilated cardiomyopathy Ischemic

graphic characteristics, such as atrial and ventricular dimensions, ventricular function, estimated pulmonary artery pressures, and the status of the other valves remain critical.

Indications

Mitral Regurgitation

The indications for surgical intervention in mitral regurgitation have steadily expanded as the results of mitral valve repair have improved. Class I indications include severe MR in the presence of symptoms or LV dysfunction. On the basis of recent natural history data,[73] surgery is also recommended (class IIA) for asymptomatic patients with severe MR and normal LV function as long as valve repair is deemed likely with a reasonable operative risk. Because the likelihood of repair is lower, surgery is usually deferred in patients with rheumatic disease until the onset of symptoms or LV dysfunction.

Poor LV function and class III-IV heart failure were once considered an absolute contraindication to mitral valve surgery. This was based on data showing poorer early and late outcomes in these patients, especially when they undergo non–chordal-sparing valve replacement. It was theorized that the mitral regurgitation served as a "pop-off" valve, providing a low-afterload circuit (the left atrium) for the failing ventricle. This concept is now known to be false; it is clear that MR causes volume overload and *increases* wall stress on the ventricle. Severe ventricular function is no longer an absolute contraindication to mitral valve surgery. Recent data from Bolling[74] and others, however, have demonstrated that patients with severe LV function can undergo valve repair with a downsized annuloplasty with reasonable early outcomes. Whether valve repair in this setting improves long-term outcomes is unknown, so this remains a class IIB indication.[75]

Mitral Stenosis

The indications for surgery are more conservative than for mitral regurgitation for several reasons. First, the etiology is usually rheumatic heart disease which has a slower, more predictable natural history. A smaller proportion of patients are candidates for mitral valve repair so the additional risks associated with a mitral valve prosthesis must be taken into consideration in the remaining patients. Finally, patients who are good candidates for percutaneous balloon mitral valvuloplasty (PBMV) can avoid surgery, at least for the medium term. Currently accepted indications for surgery include symptomatic moderate-to-severe MS when PBMV is either unavailable or contraindicated (thrombus, significant MR, unfavorable morphology). Mildly symptomatic patients with severe pulmonary hypertension should also be considered for surgery before the onset of right heart failure.

Mitral Valve Repair

Principles

The techniques of mitral valve repair are based on certain fundamental principles developed by Carpentier and others over the past 35 years. They start with the notion that, in theory, any regurgitant valve with adequate, pliable, noncalcified leaflet tissue can be repaired as long as a systematic approach, based on pathophysiologic principles described earlier, is applied. The likelihood of a successful repair depends on surgeon experience and the complexity of the repair, which in turn depends on the etiology, type of dysfunction, and the distribution of lesions among the various anatomic components of the valve (leaflets, annulus and subvalvular apparatus). The complexity can range from a simple annuloplasty to a complicated Barlow's valve repair involving interventions to multiple leaflet segments. Although it can vary from patient to patient, generally anterior leaflet pathology is more difficult to repair than posterior leaflet pathology and rheumatic valves are more challenging than degenerative valves.

The first step in any repair is precise, systematic *valve analysis*, initially by TEE and then by direct assessment (see Fig. 47–7B). The central goal is to determine the type of dysfunction of each of the eight leaflet segments (A1-A3, P1-P3, Ac, and Pc). This is done by pulling the free margins of the leaflet segment up using a hook and determining whether the leaflet motion is normal (type I), excessive (type II), or restricted (type III). The annulus is assessed separately, noting it size and symmetry, as well as any calcification. Once the valve analysis is complete, the operative plan is established. The specific techniques used depend on the type of dysfunction and are described as follows.

Annuloplasty

Implantation of a prosthetic annuloplasty ring is an essential part of nearly all mitral valve repairs. The exceptions include the occasional patient with endocarditis involving only the body of a leaflet. Nonprosthetic annuloplasty techniques using suture or pericardium do not have a role in modern mitral valve repair because the results with these techniques are well below those of prosthetic rings.

The primary purpose of the annuloplasty is to restore the annular dimensions, bringing the leaflets together and permitting a broad surface of coaptation—a critical element to a durable repair. It also stabilizes the annulus, taking stress off of sutures lines. An annuloplasty ring typically is constructed from a core material (silicone, metal) that determines its rigidity (flexible, semirigid, rigid) sheathed in a cloth material (Dacron, polyester) through which the sutures are placed. Annuloplasty rings come in numerous sizes, shapes (partial band, complete ring), and rigidity but can be broadly categorized as *remodeling* or *nonremodeling*.

A remodeling annuloplasty seeks to restore the size *and* physiologic ("D," "kidney") shape of the annulus in contrast to a restrictive, nonremodeling annuloplasty, which merely decreases the overall circumference of the annulus. Many surgeons, especially those who subscribe to the Carpentierian principles of valve repair, feel that a complete remodeling annuloplasty (e.g., Carpentier-Edwards Physio) should be performed in all repairs to assure a long-term durable result. Others favor partial or complete flexible rings (e.g., Cosgrove-Edwards Band). Most surgeons, however, now acknowledge that a remodeling annuloplasty is superior in patients with type IIIB MR secondary to ischemic disease or dilated cardiomyopathy. The size of the annuloplasty ring is determined by the height of the anterior leaflet and the intercommissural (or intertrigonal) distance. Patients with degenerative disease and type II dysfunction will typically receive a ring in the 32- to 40-mm range, while those with type IIIB dysfunction

from ischemic disease or cardiomyopathy will receive much smaller rings, in the 24- to 30-mm range.

Mitral annular calcification (MAC) is not an infrequent finding in patients undergoing mitral valve surgery, especially elderly patients and those with coronary artery disease. MAC poses serious challenges to the surgeon in both mitral valve repair and replacement. It can interfere with seating of the annuloplasty ring, restrict and distort leaflet tissue, and in severe cases extend deep into the subannular ventricular muscle. Ideally, all annular calcification is removed, en bloc prior to reconstruction and ring implantation. This is usually straightforward for discrete superficial nodules in the posterior annulus but becomes progressively more challenging if it involves the commissures and is more diffuse and deep. Carpentier has shown that complete en bloc excision of even massive MAC, with subsequent reconstruction of the atrioventricular junction, can be performed safely. Many surgeons, however, remain wary of this approach for fear it will lead to atrioventricular rupture, a dreaded complication that is usually fatal.

Leaflet Prolapse Repair Techniques (Type II)

Leaflet prolapse can be corrected through one of several approaches involving the leaflets and subvalvular apparatus. The specific technique depends on the specific prolapsing segment more than the actual lesion (chordal rupture, or chordal elongation). The ultimate goal is to leave an adequate amount of mobile, well-supported leaflet to participate in coaptation.

Posterior leaflet prolapse is usually treated by resecting the prolapsing segment and reapproximating the nonprolapsing segments (see Fig. 47–7B). This most commonly involves a *quadrangular resection* of a prolapsed P2 segment. If the resection is relatively small, the annular gap can simply be plicated and the cut edges reapproximated. Usually, however, a *sliding valvuloplasty* is recommended. Here, the remaining P1 and P3 segments are partially detached from the annulus and then reattached, stretching them across the annular gap, which can be decreased with so-called compression sutures. The sliding valvuloplasty technique has two advantages. It avoids the need to plicate a large annular gap, which can lead to kinking of the circumflex artery. During the process of detaching and reattaching the remaining segments, the surgeon can decrease the height of the posterior leaflet. Left alone, the excessively tall posterior leaflets seen in Barlow's disease patients can lead to a systolic anterior motion (SAM) in which the anterior leaflet is pushed into the LV outflow tract, causing obstruction.

Anterior leaflet prolapse can be corrected by resecting the prolapsing segment or reestablishing its subvalvular support. *Triangular resections* with direct reapproximation of the cut edges can correct small areas of prolapse, especially when there is redundant tissue, such as in Barlow's disease. There is a limit to how much anterior leaflet tissue can be resected before the remaining tissue is inadequate for coaptation, however. If redundant tissue is not present or large areas of prolapse exist, subvalvular support to these areas must be reestablished. *Chordal transfer* involves detaching normal secondary chords attached to the body of the anterior leaflet and reattaching them to the margin of the prolapsing segments. With *chordal transposition* the chords are detached, along with some leaflet tissue, from a normal portion of the posterior leaflet, and then flipped anteriorly and reattached to the prolapsing segment, after which the gap in the posterior leaflet is closed primarily. Finally, if no good chords are available, an *artificial chordoplasty* can be performed. The new chords are creating using Gortex sutures secured to the papillary muscle and prolapsing leaflet segment. Chordal shortening techniques, in which the length of the elongated chord is decreased by burying the excess into the papillary muscle, were abandoned when retrospective studies showed that they were less durable.

Correcting *commissural prolapse* can be particularly technically challenging. Sliding valvuloplasty techniques similar to those used on the posterior leaflet can be applied, but care must be taken to avoid distortion of the valve. Chordal support to the prolapsing commissure can also be established using the same techniques as in the anterior leaflet.

Restricted Leaflets Techniques (Type III)

In patients with type IIIA dysfunction, usually from rheumatic disease, the restricted leaflet motion results when the fibrotic process leads to thickening and fusion of the subvalvular structures and thickening and retraction of the leaflets, particularly the posterior leaflets. As long as adequate, pliable leaflet tissue is available, valve repair can successfully be performed with good long-term results, but this type of repair is not widely practiced outside of major valve repair centers. *Leaflet mobilization* is accomplished by resection of secondary chordae and splitting or fenestrating fused marginal chordae. *Leaflet enlargement*, typically to the posterior leaflet, can be performed by detaching the leaflet annulus and suturing a patch of autologous glutaraldehyde-fixed pericardium. Patients with rheumatic MS, pure or in combination with MR, are treated with *open commissurotomy*. The fused commissures are split sharply within a few millimeters of the annulus, and the associated fused chords are split down the papillary muscles or fenestrated.

Patients with type IIIB dysfunction, resulting from ischemic heart disease or dilated cardiomyopathy, have structurally normal leaflets that are restricted as a result of papillary displacement from ventricular dilatation and regional wall motion abnormalities. In order to reestablish an adequate surface of coaptation, the restricted leaflets must be brought toward each other. The final anteroposterior dimension of valve must be less than its original dimension, in order to overcome the fact that the restricted leaflets cannot rise to their normal systolic position just below the plane of the annulus.

This can be accomplished with a *downsized remodeling annuloplasty* alone. The intercommissural or intertrigonal distance and the anterior leaflet height are measured, and a ring 2 to 4 mm smaller is selected to achieve proper downsizing. Recently introduced rings specifically designed for type IIIB dysfunction—the asymmetric Carpentier-McCarthy-Adams EtLogix ring for ischemic MR and the Geoform ring for cardiomyopathy (both Edwards Lifesciences)—are "predownsized." In other words, they are designed to be more squat with a significantly reduced anteroposterior dimension relative to the intercommissural dimension, allowing good leaflet coaptation while maximizing the overall orifice area.

Although insertion of an annuloplasty ring alone suffices in the vast majority of patients undergoing repair for type IIIB MR, occasionally adjunctive techniques may be useful.

Resection of secondary chordae, particularly to the anterior leaflet, can increase leaflet mobility and correct the "hockey-stick" deformity seen in patients with severe leaflet restriction. Occasionally, prominent clefts between the posterior leaflet scallops will be splayed out by the leaflet restriction and closing these clefts can prevent small areas of residual MR. Other techniques, such as papillary muscle relocation and patch extension of the posterior leaflet, have been reported but are not widely used in this condition.

Other Techniques

The *edge-to-edge* or *Alfieri* technique involves suturing the free edges of the anterior and posterior leaflets together (usually at A2-P2), creating a double orifice mitral valve. The percutaneous application of this technique is being explored. The technique can correct prolapse in one leaflet by using the other leaflet's chordae. In the process, however, it decreases the mitral valve orifice area. No long-term data are available on the durability of this type of repair.[76] Early data, however, clearly document poor outcomes in the absence of a concomitant annuloplasty[77] and in ischemic MR.[78]

Mitral Valve Replacement

Despite the broadening indications for mitral valve repair, the evidence base supporting valve repair when feasible, and the increased availability of surgeons proficient in these techniques, the majority of patients undergoing mitral valve surgery still undergo valve replacement. Some of these valve replacements are being performed in patients with valves that are not repairable, such as those with advanced rheumatic disease with calcification, endocarditis with extensive leaflet destruction, or ruptured papillary muscles following myocardial infarction. However, many of these replaced valves could have been repaired by experienced mitral valve repair surgeons. In particular, many surgeons are reasonably comfortable repairing valves with isolated posterior leaflet prolapse but proceed with valve replacement when they encounter prolapse of the anterior leaflet. Experienced surgeons, however, can repair > 90% of degenerative valves whether the anterior leaflet, posterior leaflet, or both are involved.

Chordal-Sparing Mitral Valve Replacement

In the early days of mitral valve replacement, the entire valve including leaflets and chordae were resected before implantation of the valve. In the late 1970s and 1980s, however, it became clear that the subvalvular apparatus was an integral component to global ventricular function and this practice frequently led to decreased LV function following valve replacement. *Chordal-sparing* techniques were developed and shown to be superior in terms of preservation of LV function, as well as early and late outcomes.

The posterior leaflet is now almost always left intact and plicated within the posterior suture line. The chordal apparatus to the anterior leaflet can also be preserved by resecting an elliptical portion of the body of the leaflet, splitting the remaining rim of leaflet with attached chordae in two and reattaching them to the anterior annulus. Occasionally, in patients with extensive rheumatic fibrosis, calcification, or endocarditic destruction, it may be impossible to preserve the chordal apparatus. In these cases artificial Gortex chords can be used to reestablish papillary muscle-annular continuity.

The actual implantation of the valve is similar to a prosthetic aortic valve replacement and can be performed using a variety of suturing techniques (interrupted versus running, pledgeted versus nonpledgeted, everting versus noninverting). As with aortic valve replacement, complete débridement of annular calcification is important to prevent perivalvular leaks, although this must be done with great care to avoid atrioventricular disruption, a highly fatal complication.

Choice of Prosthesis

The choice of valve prosthesis is somewhat less complicated in the mitral position than in the aortic posi-tion. For example, the options are limited to mechanical valves or stented xenografts (porcine or pericardial). In addition, although the durability of mitral bioprostheses has improved significantly, it is not yet good enough to justify routine use in middle-aged adults. Patients younger than 65 typically receive mechanical valves and those 65 and older receive biologic valves. The age threshold can certainly be lowered in selected situations. Patients with coronary artery disease, poor LV function, or comorbidities leading to decreased life expectancy may be candidates for biologic valves. Younger patients who cannot or choose not to take warfarin may also receive a biologic valve, but they need to understand that they almost certainly will face one, if not two, reoperations in their lifetime. Whenever possible, of course, a valve repair would be preferable in patients of all age groups.

Results

Early

The operative risk of mitral valve surgery varies significantly depending on the patient profile and operation. It can be as low as 1% for young, healthy patients undergoing elective mitral valve repair for degenerative disease or > 50% in an ill elderly patient undergoing emergent surgery for endocarditis. The overall operative mortality rates for isolated mitral valve repair and replacement are 1.4% and 6.0%, respectively (2005 STS database). It is significantly higher for patients undergoing concomitant CABG—7.2% for repair and 10.8% for replacement. In a recent study from the Northern New England Cardiovascular Disease Study Group, 10 variables were identified as independent predictors of in-hospital mortality: female sex, older age, diabetes, coronary artery disease, prior cerebrovascular accident, elevated creatinine, NYHA class IV, CHF, acuity, and valve replacement.[79,80] Ventricular function, prior cardiac surgery, and pulmonary hypertension have also been found to increase operative risk. Enriquez-Sarano and colleagues[81] have documented improved preservation of ventricular function with mitral valve repair relative to replacement.

The incidence of major morbidity in most mitral valve surgeries remains low. The overall risk of stroke has been reported to be 2% to 3%. Deep sternal wound infections and reoperation for bleeding occur at similar rates to other valve surgery at 2% to 5%. Mitral valve surgery is a significant risk factor for postoperative atrial fibrillation with overall rates of approximately 50%. The incidence of heart block requiring permanent pacemaker insertion is about 3%.[82]

Late

The late outcomes of mitral valve surgery depend to a large degree on the underlying etiology of the mitral valve disease and whether a valve repair or replacement is performed. Long-term survival in generally healthy patients undergoing mitral valve repair for degenerative valve disease approaches that of an age-matched population. Several studies have documented improved long-term survival with valve repair, at least for degenerative and rheumatic etiologies. Moss et al[83] recently used propensity score methods to show improved late survival (RR = 0.52) with mitral valve repair relative to replacement. Late survival is decreased with ischemic compared with nonischemic etiologies. Additional predictors of late survival include ventricular function, NYHA functional status, age, and concomitant coronary artery disease. The leading causes of late death include heart failure, thromboembolism, stroke, endocarditis, anticoagulation–related hemorrhage, and myocardial infarction. Late functional status following mitral valve surgery is good with most studies reporting 90% of patients in NYHA class I-II.

The durability of mitral valve repair is most directly related to the etiology of the disease. The long-term results for repair of degenerative valves is excellent (Fig. 47–8). Carpentier's group reported their 20-year results.[84] The overall linearized rate of reoperation was 0.4% per year. Freedom from reoperation was 97% for patients with isolated posterior leaflet prolapse, whereas it was 86% and 83% for those with anterior or bileaflet prolapse, respectively. The results for repair of rheumatic valves, even at experienced centers, are not as good. Carpentier's group reported linearized rates of reoperation of 1.9% to 2.7% and 20-year freedom of reoperation of 46% to 65% depending on whether the initial dysfunction was type II (leaflet prolapse) or type III (leaflet restriction).[85]

As with aortic valve replacement, the long-term freedom from reoperation following mitral valve replacement is a func-

tion of the prosthesis type and age. Although structural valve degeneration (SVD) of current generation mechanical valves is vanishingly rare, it is important to remember that the reoperation rate is not zero. Linearized rates of reoperation for prosthetic valve endocarditis, pannus overgrowth, and thrombosis are about 1% per year. Durability of bioprostheses in the mitral position, although improving, is not as good as in the aortic position, presumably because bioprostheses are exposed to greater forces during systole.[86,87] Durability remains excellent in elderly patients. Ten-year freedom from SVD for the Carpentier-Edwards pericardial valve was 100% in patients 70 and older. Performance in younger patients (60 and younger) is significantly worse with 60% to 80% freedom from SVD rates at 8 to 10 years,[86,88] highlighting the importance of achieving high rates of valve repair in these patients.

TRICUSPID VALVE SURGERY

Overview

Because most tricuspid valve dysfunction is a result of left heart lesions, isolated tricuspid valve surgery is relatively rare. Causes of isolated tricuspid disease requiring surgical correction included congenital anomalies (e.g., Ebstein's anomaly); RV dilatation from primary pulmonary hypertension; trauma (e.g., following endomyocardial biopsies); and endocarditis. Most tricuspid valve surgery is performed in conjunction with other valve surgery, usually mitral valve or replacement. Interest in tricuspid valve surgery has increased in recent years,[89,90] and the number of tricuspid valve operations in the STS database has increased significantly.

Indications

The indications for tricuspid valve surgery vary depending on whether the disease is primary or secondary. The data supporting these indications are not as well established as they are for aortic and mitral valve disease. Tricuspid stenosis is almost always rheumatic and rarely isolated, usually presenting with concomitant mitral valve disease. Severe symptomatic TR is considered a class IIA indication for isolated tricuspid valve surgery. The threshold for correcting TR at the time of other valve surgery has fallen in recent years. In the past even moderate degrees of TR were left alone with the assumption that correction of the left-sided lesions would decrease the pulmonary artery pressures and the degree of TR. Recent data, however, suggest that this does not reliably occur and most patients with moderate TR will undergo concomitant tricuspid annuloplasty. A recent report by Dreyfus et al[90] suggested that annular circumference alone, even in the absence of significant TR, should trigger concomitant annuloplasty.

Surgical Techniques

Approach

Most tricuspid valve surgery occurs in the context of multivalve surgery and thus is performed though a median sternotomy. Cannulation for cardiopulmonary bypass is usually performed in the ascending aorta and vena cavae, which are occluded below the cannulae to isolate the right atrium before atriotomy. The procedure can be performed under full cardioplegic arrest; under fibrillatory arrest; or on a beating heart under CPB, usually during rewarming.

Valve Repair

Most patients with TR will have type I or IIIB dysfunction without leaflet pathology (so-called "functional TR") and can be successfully treated with an annuloplasty alone. Commissuroplasty techniques, such as bicuspidization (obliterating the posterior leaflet), have largely been abandoned. Suture annuloplasty techniques, such as the DeVega annuloplasty, have been popular because they can be rapidly performed. Recent data, however, suggest that a formal prosthetic remodeling ring annuloplasty is superior to other techniques and should be the procedure of choice.[89]

Tricuspid valve repair of type II and IIIA dysfunction is rarely performed. Patients with Ebstein's anomaly can undergo successful repair using techniques developed by Carpentier and others. Those with degenerative changes or localized damage from trauma or endocarditis can undergo localized leaflet resection and reconstruction using techniques analogous to mitral valve repair.

Valve Replacement

Patients undergoing tricuspid valve replacement usually have extensive leaflet damage (rheumatic disease, endocarditis, biopsy trauma) or have failed prior valve repairs. The tradeoffs between tissue and mechanical valves are similar to valves in other positions, but there are fewer data. In the past, surgeons tended to avoid mechanical valves because of reports of high thrombosis rates secondary to low flow velocities. More recent data with bileaflet valves, however, are significantly better.[91,92] Although the rates of structural valve degeneration for bioprostheses in the tricuspid position appear to be lower than in the mitral position, the incidence of nonstructural degeneration, primarily pannus formation, appears to be higher, presumably as a result of organized thrombotic material. Most patients undergoing tricuspid valve replacement have limited life expectancy as a result of age or underlying disease and will therefore receive a bioprosthesis. Mechanical valves are generally reserved for younger, healthier patients and those who have or require another mechanical valve.

The techniques of implantation are similar to mitral valve replacement. Sutures along the septal leaflet must be taken superficially to avoid injury to the conduction system in the triangle of Koch. Patients undergoing mechanical valve implantation will usually have a permanent epicardial pacing lead placed in the operating room.

Results

Operative mortality rates following isolated tricuspid valve surgery are generally high (10% to 25%) because many of these patients have complex medical conditions and advanced right heart disease. Data on the additional risk of concomitant tricuspid valve repair in patients undergoing mitral valve surgery are limited. The operative mortality rate does appear to be higher but is probably due to the fact that the presence of TR is a marker for more advanced cardiopulmonary disease

than the impact of the tricuspid surgery itself. The main early morbidity is complete heart block requiring pacemaker insertion.

SPECIAL CONSIDERATIONS

Multiple Valve

Many patients presenting for heart valve surgery have multiple valve dysfunctions. Occasionally, two or more primary valve dysfunctions coexist and are both of sufficient severity to mandate surgery (such as in advanced rheumatic heart disease). More frequently, however, when valve dysfunctions coexist, it is usually possible to identify a primary dysfunction (which mandates surgery) and secondary dysfunctions (which arise from or coexist with the primary dysfunction). When the primary dysfunction is of the aortic valve, then secondary atrioventricular valve regurgitation may be a direct result of aortic valve disease and could resolve with isolated correction of the aortic lesion. In some patients, however, the secondary process is unrelated or may be so advanced that surgical correction of the aortic lesion alone will not suffice. Atrioventricular valve dysfunction as a primary lesion does not result in secondary aortic valve disease—the aortic valve disease in such cases is treated on its own merit.

Mitral and Tricuspid Disease

Tricuspid valve regurgitation often coexists in patients with mitral valve disease presenting for surgery. Traditionally such regurgitation was left uncorrected because it was assumed to be "functional" and that correction of mitral regurgitation results in resolution of tricuspid regurgitation. However, recent studies have challenged this thinking and evidence suggests that patients left with uncorrected tricuspid disease fare less well after surgery in terms of long-term symptoms and survival. Patients who initially have absent or mild/moderate tricuspid regurgitation at the time of mitral surgery also go on to develop worsening tricuspid regurgitation in the follow-up period.[90,93] Patients who do not have tricuspid repair at the time of surgery have a greater incidence of significant tricuspid regurgitation and higher incidence of congestive heart failure on long-term follow-up.[94,95] Mortality is high for reoperations performed to fix tricuspid regurgitation (up to 30%).[89]

Aortic and Mitral Disease

Patients with primary aortic valve disease will sometimes have secondary mitral valve disease. In patients with rheumatic disease, concomitant mitral valve repair or replacement is indicated if there is moderate mitral regurgitation or stenosis. In patients with degenerative AS, secondary mitral regurgitation is not uncommon, presumably as a result of left ventricular dilatation and pressure overload. Mitral valve repair is certainly indicated if the MR is severe. Most mild to moderate MR, however, is left alone because the data for intervening at this threshold is mixed.[96-99] In the past, some have argued that patients undergoing concomitant aortic and mitral valve surgery should receive a second prosthesis instead of a mitral valve repair. Given the current results of mitral valve repair, this does not appear justified and every effort should be made to repair the mitral valve in this setting. Gillinov et al[100] have documented improved survival with this approach.

Reoperation

The success and improved long-term outcomes of cardiac surgery in the 1980s and 1990s have resulted in millions of surviving patients worldwide who have had previous cardiac surgery. As these patients age, a proportion will require reoperative valve surgery for valve-related complications or for progression of native valve disease.

Valve surgery in the reoperative setting is more complex compared with first-time surgery because of pericardial adhesions, patent bypass grafts, often advanced cardiac dysfunction with pulmonary hypertension, and technical issues relating to re-replacing heart valves. The mortality risk is higher than for first-time surgery, although this risk has fallen in recent years, with some centers reporting mortality rates below 5%.

The indications for surgery differ slightly in the reoperative setting because the risk of operative mortality may outweigh the benefits if conventional indications (as for first time surgery) are applied. The major consideration in deciding to offer valve reoperation is the relief of symptoms rather than prolongation of life expectancy. In some instances reoperative surgery is undertaken for survival benefit, such as in young patients with structural valve degeneration and in patients in whom the valve disease would otherwise be fatal (such as endocarditis).

Patients requiring reoperations present unique surgical challenges. These patients are often managed medically until the disease is advanced, and surgery is only undertaken when there are no nonsurgical options. Subsequently, many patients are severely compromised, debilitated with poor functional state, have poor LV function, or are old with comorbidities. These patients must have a detailed preoperative work-up because even small lapses can precipitate major catastrophe. Cardiac catheterization is performed to delineate coronary anatomy and measure pulmonary pressures. CT is useful in defining the relationships of the cardiac chambers and great vessels to the sternum; sometimes sternal re-entry may be considered so hazardous that alternative surgical approaches are required. Thorough echocardiographic assessment of all heart valves is necessary because many patients will have multiple valve dysfunctions. Details of the prior cardiac operations are obtained because previous difficulties, observations, or complications may be relevant to the planned procedure. Screening for peripheral vascular disease is necessary in older patients because cannulation of peripheral vessels for cardiopulmonary bypass may be required and is occasionally life saving.

Principles of surgical repair or replacement are similar to that for primary valve surgery. When valves are repairable, this remains the treatment of choice. A failed prior valve repair does not mandate a valve replacement if the valve is easily repairable. If valve replacement is required, then choice of prosthesis should take into account the balance between the risks of anticoagulation and the probability and risks of another future reoperation (for biologic valve degeneration). Sometimes the surgeon may choose to re-replace a normal-functioning prosthetic valve so that the patient can stop anticoagulation (replace mechanical with bioprostheses) or to

avert inevitable future structural valve degeneration (such as a patient with a 10-year-old functioning porcine valve requiring another cardiac procedure).

Endocarditis

Although medical management remains the cornerstone of therapy for most bacterial endocarditis, surgery has a critical and life-saving role in the treatment of complicated cases. A detailed discussion of the surgical management of patients with endocarditis is beyond the scope of this chapter.

Diagnosis is usually based on characteristic lesions seen on echocardiography, with or without positive blood cultures (see Chapter 44). Transesophageal echocardiography is the most sensitive and specific investigation for defining endocarditis lesions and is performed on most cases of endocarditis to evaluate for indications for surgery. Once there is an indication for surgery, operation is generally undertaken within 24 hours because delay is associated with increased morbidity and mortality. One exception is if there has been an embolic stroke, in which case early surgery carries a higher risk of hemorrhagic extension of the stroke.

The principles of surgical treatment are débridement of all infected tissues, drainage of abscesses, and correction of hemodynamic dysfunction. Following débridement, the valve annulus (if affected) is reconstructed and the valve is repaired when feasible or replaced. Abscesses of the aortic root will usually necessitate root replacement. Choice of valve prosthesis usually depends on surgeon preference. Allografts and autografts are more resistant to infection, but with thorough débridement and continuation of antibiotic therapy, reinfection of the newly implanted valve is uncommon regardless of the type of prosthesis used.

Ischemic Heart Disease

Ischemic and valvular heart diseases frequently coexist, making surgical decision-making and management more complex. Although a patient with advanced disease can certainly present with both ischemia and congestive heart failure, in most patients one disease will dominate the presentation and the other is more incidental. The management depends on which disease dominates the clinical picture.

Incidental Coronary Disease in Valve Surgery Patients

Patients with risk factors for coronary artery disease (including age) requiring heart valve surgery generally undergo preoperative screening angiography. The presence of concurrent coronary artery disease reduces survival after heart valve surgery.[101] Furthermore, the presence of coronary artery disease can lead to patchy distribution of cardioplegic solution, complicating myocardial preservation. The subendocardial region is most vulnerable to poor protection and intraoperative ischemic injury in the presence of coronary disease, particularly in the setting of LV hypertrophy. In patients with poor ventricular function, incidental coronary artery disease may contribute to the poor ventricular function—MRI is useful in this setting to identify ischemic or infarcted myocardium and define potential utility of bypass grafting.

Most surgeons would perform concurrent coronary artery bypass at the time of heart valve surgery when there are critical coronary lesions (>70% stenosis in a proximal coronary artery or >50% in the left main coronary artery). Surgery classically consists of an internal mammary artery graft to the left anterior descending artery and venous conduits for other vessels. Although concurrent coronary artery bypass surgery is associated with higher perioperative mortality compared with isolated valve surgery, there is no evidence that this is related to the additional surgical procedure per se. Higher mortality is probably a reflection of the increased risk of valve surgery when there is concurrent ischemic heart disease. If critical coronary lesions are not bypassed, the patient is at greater risk of perioperative myocardial infarction.

Staged procedures with percutaneous coronary revascularization (PCI) followed by valve surgery is an alternative strategy for handling concurrent coronary artery disease. Revascularization before surgery allows for an expeditious valve operation with shorter ischemic and cardiopulmonary bypass times. The timing of PCI relative to valve surgery and management of antiplatelet therapy are important considerations with this approach.

Incidental Valve Disease in Coronary Surgery Patients

Widespread use of echocardiography in the work-up of cardiovascular disease has led to increased diagnosis of incidental valvular pathology in patients undergoing nonvalvular heart surgery, particularly coronary surgery. If the valve disease is truly incidental, then the patients are asymptomatic by definition. The indications for valve surgery in any asymptomatic valve patient (see earlier discussion) also apply in the patient having coronary artery bypass surgery. For example, severe AS and severe mitral regurgitation will require surgical correction.

Patients undergoing coronary bypass surgery who have valve lesions that do not warrant surgery on their own merit pose a diagnostic dilemma. These include patients with moderate degrees of valve regurgitation or stenosis. In these patients a balance must be made between the risks of concurrent valve surgery and the anticipated rate of disease progression if the valve were left untreated and the likelihood and implications of future reoperation. Untreated disease may progress such that the patient requires future reoperation at higher risk. Another important consideration is whether the valve is repairable or whether it requires replacement. The threshold for intervention may be lower in patients with repairable valves, but when a valve with moderate dysfunction is irreparable, decisions to do valve replacement should be taken seriously because a moderately diseased native valve is replaced by a prosthetic valve, which is at risk of prosthesis-related disease. Age also plays a role—younger patients are generally treated more aggressively with moderate lesions often ignored in elderly patients.

Aortic Stenosis in Coronary Artery Bypass Grafting Patients

AS is the most frequently diagnosed incidental valve disease. Elderly patients undergoing coronary artery bypass not infrequently have coexisting mild to moderate AS. Review of

the literature shows that AS gradient progresses at a rate of 5 to 10 mm Hg per year, and the valve area decreases by about 0.1 cm^2 per year.[39] Therefore young patients and older patients who have a life expectancy more than 5 years should be offered concurrent aortic valve replacement for moderate stenosis because future symptomatic AS is likely.[36]

Whereas concurrent aortic valve replacement in this setting does not substantially increase mortality, reoperative surgery for aortic valve replacement in the presence of patent coronary grafts has traditionally carried significant risk. Observation of significant valve calcification or severely restricted leaflet motion on TEE is also an indicator of aggressive disease and requires concurrent valve replacement. Mild AS (gradient < 25 mm Hg) does not require treatment.

Mitral Regurgitation in Coronary Artery Bypass Grafting Patients

Although unsuspected degenerative or rheumatic MR can occasionally be seen in patients undergoing CABG, in the vast majority of patients with MR at the time of CABG the underlying etiology will be ischemic. Our understanding of ischemic MR has improved dramatically over the past decade. The mechanism is complex but fundamentally results from displacement of the papillary muscles resulting in leaflet tethering and restricted leaflet motion (type IIIB dysfunction).

Severe ischemic MR has always been considered an indication for concomitant mitral valve surgery. The management of moderate ischemic MR, however, has been more controversial. Data from the early 1990s suggested that moderate ischemic MR could be ignored at the time of CABG.[102] More recent data, however, overwhelmingly support concomitant valve repair for moderate (3+) ischemic MR in most patients. Our group has shown that CABG alone does not reliably correct moderate MR with 90% of patients left with 2+ MR or greater (Fig. 47–9A).[103] This and other studies have also documented marked intraoperative downgrading of ischemic MR. The decision to intervene should therefore be based on a preoperative transthoracic echo. We have also shown that concomitant mitral annuloplasty can be performed with an operative risk of < 4%.[104] Patients with 2-3+ MR are particularly challenging, especially if they are elderly and have comorbidities that increase the risk of concomitant mitral valve surgery. Considering factors that indicate the ischemic MR is chronic and physiologically significant, such as ventricular function, atrial fibrillation, left atrial dilatation, and intraoperative provocative testing is important and may be useful in equivocal cases (see Fig. 47–9B).[105]

All patients had 3+ preoperative MR and underwent CABG alone.[103] **B,** Decision-making in ischemic MR at the time of CABG.[105]

Atrial Fibrillation

Surgical treatment of atrial fibrillation is based on the Maze operation, which was developed by Cox in the 1980s.[106] The operation is reported to be effective in curing atrial fibrillation in 80% to 90% of patients and involves making encircling incisions around the venous atrial inflows to stop the propagation of abnormal atrial impulses (which usually originate around these veins) (see Chapter 22). The classic Maze procedure, however, involved making a complex network of atrial incisions, which prolonged the operation and were associated with increased morbidity; for this reason, the Maze operation, despite its effectiveness, was not widely adopted by surgeons.

A recent resurgence of interest in atrial fibrillation surgery has occurred, however, because of the availability of technology that allows surgeons to easily perform ablation around the pulmonary veins without the added complexity and morbidity associated with the original “cut and sew” operation. With several commercially available energy sources (e.g., radiofrequency, cryotherapy, laser, microwave, ultrasound) and devices, the surgeon can create transmural lesions in the atria without making surgical incisions. These transmural lesions have been shown to be as effective as the original “cut and sew” lesions. Although the focus is primarily on pulmonary vein isolation, the surgeon can also create additional left and right atrial lesions to mimic a complete Maze operation (which may improve the efficacy compared with pulmonary vein isolation alone). Using the commercially available probes and clamps, ablation for atrial fibrillation can be undertaken epicardially before the surgeon commences cardiopulmonary bypass or endocardially with the atrium

open for the mitral repair. Modern devices are relatively simple to apply, do not require much specialized surgical skill, and do not unduly prolong the operation. Concurrent atrial fibrillation surgery is now the standard of care for patients undergoing heart valve surgery who have a prior history of atrial fibrillation. The left atrial appendage is often excised or oversewn at the time of mitral valve surgery.

Treatment of Cardiovascular Manifestations of HIV

Priscilla Y. Hsue and David D. Waters

CHAPTER CONTENTS

In 2004 an estimated 40 million people were living with HIV, and 5 million people were newly infected.[1] Since the introduction of highly active antiretroviral therapy (HAART) in the mid- to late 1990s, the rates of HIV-associated morbidity and mortality have been dramatically reduced.[2] In the HIV Outpatient Study, the mortality rate in 1255 patients in the United States with at least one CD4+ count below 100 cells/mm^3 declined from 29.4 to 8.8 per 100 patient-years from 1995 to the second quarter of 1997,[2] a time period that coincided with the initiation of protease inhibitors. Similarly, in a European cohort study of 4270 patients who had had a CD4+ count below 500 cells/mm^3, the mortality rate fell from 23.3 to 4.1 per 100 patient-years during mid-1995 and late 1997 to early 1998.[3] The decrease in mortality rates in these studies was accompanied by a decline in the incidence of opportunistic infections[2] and correlated with the intensity of antiretroviral therapy.[3]

However, with new medications and patients living longer, a new set of cardiovascular issues including atherosclerosis and metabolic abnormalities, such as hyperlipidemia, hypertension, and hyperglycemia, have appeared. Herein we review the different cardiovascular complications associated with HIV and discuss their treatment.

ANTIRETROVIRAL THERAPY

Current guidelines recommend that all patients with symptomatic HIV disease and asymptomatic patients with ≤ 200 CD4 cells/μL should be placed on antiretroviral therapy.[4] In asymptomatic patients with > 200 but ≤ 350 CD4 cells/μL, antiretroviral treatment should be considered.[4] Currently, HAART consists of four classes of drugs: nucleoside analogue reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and a cell membrane fusion inhibitor. Initial regimens usually consist of three drugs: two NRTIs combined with either an NNRTI or a PI.[4] The superiority of different treatment regimens compared with others is still being studied.[4]

PROTEASE INHIBITORS

Protease inhibitors are the most widely used class of antiretroviral agents used to treat HIV and are listed in Table 48–1 along with important drug–drug interactions and side effects.[5] PIs are also associated with a plethora of side effects including disorders of glucose and lipid metabolism, hepatotoxicity, gastrointestinal complaints, sexual dysfunction, and an increased risk of bleeding.[6] These symptoms are frequently severe enough to cause discontinuation of therapy.[7]

In addition, because all PIs inhibit metabolism of the cytochrome P450 3A4 enzyme, they interact with many cardiac medications, as shown in Table 48–1. Case reports of rhabdomyolysis have been reported with the combination of a PI and a statin[6,8]; in one patient, nelfinavir and simvastatin caused death due to severe rhabdomyolysis.[9] Simvastatin should not be used in patients who take PIs, and the dose of atorvastatin should be reduced. Because it is not metabolized by the cytochrome P450 system, pravastatin appears to be safe.

NUCLEOSIDE ANALOGUE REVERSE TRANSCRIPTASE INHIBITORS

NRTIs are structurally defective analogues of viral nucleotides, and, after being incorporated into viral DNA, they prematurely terminate viral strand synthesis and inhibit viral replication. Unlike PIs, NRTIs are generally well tolerated and do not inhibit the cytochrome P450 system; however, they

Table 48–1 Protease Inhibitors

Generic Name	Typical Dose*	Pills/Day	Common Adverse Events	Important Drug Interactions†
Amprenavir	1200 mg bid	16	Lactic acidosis, periorbital and peripheral numbness, rash, nausea, diarrhea	Lovastatin, simvastatin, bepridil
Atazanavir	400 mg/day	2	Lactic acidosis, hyperbilirubinemia, ↑ PR interval	Proton pump inhibitors, bepridil
Fosamprenavir	1400 mg bid	4	Prodrug of amprenavir with higher bioavailability	Flecainide, propafenone, lovastatin, simvastatin
Indinavir	800 mg tid	6	Dry eyes, mouth and skin, nephrolithiasis, hyperbilirubinemia, neutropenia, paronychia, vasculitis	See † below
Lopinavir/Ritonavir	400/100 mg bid	6	Pancreatitis, GI side effects common but mild	See ritonavir and † below
Nelfinavir	1250 mg bid or 750 mg tid	9-10	Nephrolithiasis, more diarrhea than other PIs	Amiodarone quinidine, lovastatin, simvastatin, ?atorvastatin
Ritonavir	600 mg bid	12	Pancreatitis, altered taste sensation	As for nelfinavir; bepridil, clozapine, estradiol, flecainide, methadone, propafenone
Saquinavir	1200 mg tid	18	Altered sense of taste	See † below

*The typical dose may not be the dose used with combination therapy.
†All PIs interact with antiarrhythmic drugs, ergots, triazolobenzodiazepines (alprazolam [Xanax], midazolam [Versed], triazolam [Halcion]), and pan-inducers of the cytochrome P450 enzymes (barbiturates, carbamazepine, ethanol, phenytoin, and rifamycins). These drugs should not be used with PIs.
PI, protease inhibitor.

do cause mitochondrial toxicity, which is expressed clinically as peripheral neuropathy, myopathy, lactic acidosis, hepatic steatosis, pancreatitis, and lipodystrophy (Table 48–2).[10]

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

NNRTIs block DNA elongation by directly binding to the reverse transcriptase enzyme.[10,11] The antiviral potency and good tolerability of NNRTIs make them a favored component of HAART regimens, particularly because toxicity and viral cross-resistance do not overlap with NRTIs. Their most frequently reported side effects are rash, elevation of liver enzymes, and fat redistribution (see Table 48–2).[10,11]

Enfuvirtide is one of the newest classes of antiretroviral drugs, entitled *fusion inhibitors*.[12] This medication prevents conformational changes that are necessary for the fusion of virions to host cells. Because this drug is costly and requires administration by injection, enfuvirtide is generally reserved for patients who have failed other antiretroviral regimens.

METABOLIC EFFECTS OF HIV INFECTION AND ANTIRETROVIRAL THERAPY

HIV disease and antiretroviral therapy have been associated with many different metabolic effects including hyperlipidemia, insulin resistance, and hypertension. However, the relationships among HIV infection, antiretroviral therapy, and cardiac risk factors remain poorly understood and complex. In untreated HIV patients, lower CD4 counts are associated with lower total blood cholesterol, lower HDL-cholesterol, and higher triglyceride levels.[13] Independent of changes in body composition, PIs induce hyperlipidemia and insulin resistance in HIV patients.[14] Different PIs appear to have differing effects on lipid metabolism. For example, ritonavir raises triglycerides and lowers HDL-cholesterol slightly, with no effect on LDL-cholesterol.[15,16] Indinavir has no effect on lipoproteins but causes insulin resistance,[17] whereas amprenavir does not affect lipoproteins.[16] Lopinavir/ritonavir increases triglycerides but has no effect on LDL or HDL-cholesterol or on insulin resistance.[18] These studies involved HIV-negative subjects to isolate the effects of the drugs and were short in duration.

The Multicenter AIDS Cohort Study included HIV-infected patients treated for longer periods of time; the results of this study help to provide a clearer picture of lipid changes associated with HIV disease and treatment.[19] Fifty HIV patients in this study had blood samples available from before they became HIV positive, from before HAART was initiated at a mean of 7.8 years later, and at 4 follow-up visits during treatment. As shown in Figure 48–1, total and LDL-cholesterol decreased after the onset of HIV disease but returned to preinfection levels or higher with HAART. However, HDL-cholesterol levels decreased markedly after the onset of HIV

Table 48–2 Nucleoside/Nucleotide Reverse Transcriptase Inhibitors (NRTIs) and Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs)

Generic Name	Typical Dose	Common Adverse Events
NRTIs		
Abacavir (ABC)	300 mg bid	Hypersensitivity reaction in about 4%
Didanosine (ddI)	250 mg/day if <60 Kg 400 mg/day if ≥60 Kg	Peripheral neuropathy in 15%, optic neuritis, rare pancreatitis
Emtricitabine	200 mg/day	Stopping may exacerbate hepatitis B
Lamivudine (3TC)	150 mg bid	Generally well tolerated
Stavudine (d4T)	30 mg/bid if < 60 Kg 40 mg/bid if ≥ 60 Kg	Peripheral neuropathy—higher risk in patients with CD4 counts < 50
Tenofovir	300 mg/day	Nausea; generally well tolerated
Zalcitabine (ddC)	0.375-0.75 mg tid	High rate of peripheral neuropathy, oral ulcers; rarely used due to toxicity
Zidovudine (AZT)	300 mg bid	Nausea, headache, fatigue, anemia, neutropenia, neuropathy, myopathy
Combination NRTIs		
AZT + 3TC	1 tab bid	Same as AZT
AZT + 3TC +ABC	1 tab bid	Same as AZT and ABC
NNRTIs		
Delavirdine	400 mg tid	Rash, fat redistribution, ↑ ALT/AST
Efavirenz	600 mg/day	Rash, CNS symptoms including insomnia
Nevirapine	200 → 400 mg/day	Rash, hepatitis

CNS, central nervous system; NNRTI, non-nucleoside reverse transcriptase inhibitor; NRTI, nucleoside analogue reverse transcriptase inhibitor.

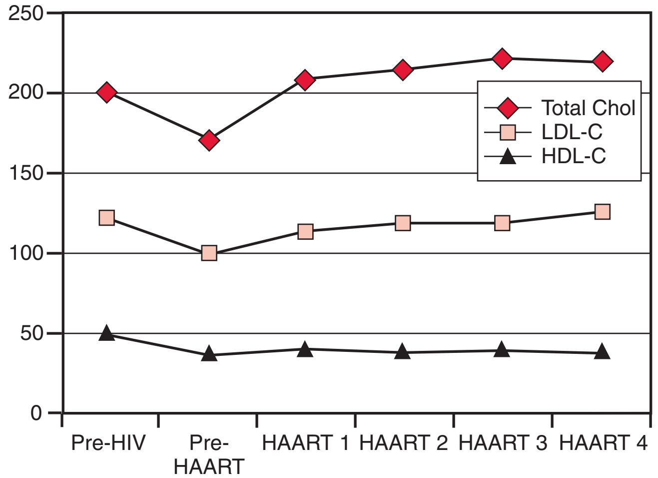

Figure 48–1 This figure shows lipid levels in HIV-infected men before HIV seroconversion (pre-HIV), before starting HAART (pre-HAART), first visit after starting HAART (HAART 1), second visit after HAART (HAART 2), third visit after HAART (HAART 3), and fourth visit after HAART (HAART 4). The mean interval between the pre-HIV measurement and the pre-HAART measurement was 7.8 years and between pre-HAART and the first post-HAART measurement 1.3 years; the subsequent mean intervals between measurements were 0.5, 2.1, and 0.6 years. Total and LDL-cholesterol levels increased during HAART but were depressed before treatment compared with the values before HIV infection. (From Riddler SA, Smit E, Cole SR, et al: Impact of HIV infection and HAART on serum lipids in men. JAMA 2003;289:2978-82.)

and did not recover. Triglycerides were measured once during treatment and were elevated at 225 mg/dL.

A summary of the effects of PIs on lipids in HIV patients showed that these drugs increase total and LDL-cholesterol by 20% to 60% and may more than double triglyceride levels.[20] Replacement of a PI with an alternative class of medication including NNRTI, such as nevirapine, efavirenz, or an NRTI like abacavir, has been shown to reduce LDL-cholesterol and triglyceride levels and to increase HDL-cholesterol.[21]

Hypertension has been reported in up to one third of HIV patients.[22,23] In some studies NNRTIs or PIs have been linked to hypertension,[24,25] although other studies show no association.[22] The hypertension associated with HIV appears to be linked to insulin resistance and the metabolic syndrome.[23]

LIPODYSTROPHY AND THE METABOLIC SYNDROME

HIV-associated fat redistribution, also called *lipodystrophy* or *lipoatrophy*, is characterized by a selective loss of fat from the face and extremities but can also be associated with an accumulation of fat in the neck, dorsocervical region, abdomen, and trunk.[21,26] Lipodystrophy in HIV patients is associated with metabolic abnormalities, such as insulin resistance, impaired glucose tolerance, elevated triglycerides, low HDL-cholesterol, and hypertension.[27,28]

Lipodystrophy becomes clinically evident in 20% to 35% of patients after 1 to 2 years of combination HAART.[29] The type and duration of antiretroviral therapy is strongly associated with the development and severity of lipodystrophy.

Combination therapy with a PI and two NRTIs, particularly stavudine with didanosine, is most likely to induce severe lipodystrophy.[21] Exercise training, either alone[30] or with metformin,[31] has been reported to improve body composition in patients with lipodystrophy. Injection of synthetic fillers has been reported to improve cosmetic appearances in HIV patients.[32]

SURROGATE MEASURES OF ATHEROSCLEROSIS IN HIV PATIENTS

The use of PIs in HIV-infected adults is associated with endothelial dysfunction as assessed by brachial artery flow-mediated vasodilation, which appears to be mediated by the atherogenic dyslipidemia induced by PIs.[33] Carotid B-mode ultrasound has been used to assess subclinical atherosclerosis in HIV patients.[34-39] In a study of 423 HIV-infected patients, conventional risk factors but not lipodystrophy or HAART were independent predictors of increased carotid IMT.[38]

At San Francisco General Hospital, mean carotid IMT in 148 HIV-infected adults was thicker than in age- and sex-matched controls ($P < 0.001$).[39] At 1-year follow-up, HIV patients had rapid progression of carotid IMT compared with controls ($P = 0.002$). Carotid IMT thickness correlated with classic risk factors, but progression of carotid IMT also correlated with a low nadir CD4 count.

HIV INFECTION AND MYOCARDIAL INFARCTION

The first cases of coronary disease in two young HIV-infected men who received PIs were reported in 1998. Presently, controversy still exists as to whether the rate of coronary events is increased in HIV patients and whether or not this increase is mediated by HAART.

A retrospective study of 36,766 HIV patients treated at Veterans Affairs facilities between 1993 and 2001 found no increase in cardiovascular or cerebrovascular events in patients who received HAART during a mean follow-up period of 40 months.[40] Similarly, in a meta-analysis of 30 randomized clinical trials, the incidence of myocardial infarction (MI) was not higher in patients receiving PIs compared with NRTIs; however, the duration of treatment was only one year and the number of events was small.[41]

However, in the HIV Outpatient Study (HOPS), the frequency of MI increased after the introduction of PIs ($P = 0.0125$) and MI occurred in 19 of 3247 patients taking PIs, but in only 2 of 2425 not taking PIs.[42] The Data Collection on Adverse Events of Anti-HIV Drugs (DAD) Study Group was a prospective study of 23,468 HIV patients followed for a mean duration of 1.6 years, with an average exposure to antiretroviral therapy of 1.9 years.[43] The risk of MI increased with longer exposure to combination antiretroviral therapy with the adjusted relative risk per year of exposure of 1.26 (95% CI 1.12 to 1.41, $P < 0.001$).

In the French Hospital Database on HIV, MI was diagnosed in 60 of 34,976 patients during a median follow-up of 33 months.[44] In this study, patients taking PIs had a significantly higher risk of MI compared with patients not taking PIs, with a relative risk of 2.56; the relative risk for those taking PIs for > 30 months compared with < 18 months was 3.6 (95% CI 1.8 to 6.2). In the Kaiser Permanente Medical Care Program of Northern California database, 72 coronary events including 47 MIs were documented in 4159 HIV patients during a median follow-up of 4.1 years.[45] Median exposure time to PIs was 2.8 years. The coronary event rate was similar in patients taking and not taking PIs; however, HIV-infected patients had a rate of 6.5 compared with 3.8 events per 1000 patient-years in non-HIV controls ($P = 0.003$).

Although additional studies are necessary with longer-term follow-up, together these studies suggest that the rate of MI is higher in HIV patients who take PIs and that the risk increases as the duration of treatment lengthens. Traditional coronary risk factors usually exert their influence for decades before a coronary event occurs. Because an increase in risk can be detected after only a short exposure, the use of PIs may be associated with a period of high risk or may serve as potent stimuli for atherogenesis. The coronary event rates in these studies are relatively low but might be expected to increase as the HIV population ages.

CLINICAL FEATURES OF CORONARY DISEASE IN HIV PATIENTS

The clinical features of 334 patients, 225 (67%) of whom presented with acute MI, are tabulated from 7 reports and are shown in Table 48–3.[7,46-52] Only 31 (9%) of these patients were women. The average age of the patients with HIV and MI is

Table 48–3 Clinical Features of Coronary Disease in HIV Patients

Study	Patients (*n*)	Age (yr)	Current Smoking	CD4 Count (cells/mm^3)	PI Use	MI on Presentation	1 Vessel Disease
David et al[46]	16	43*	81%	234 (74-731)*	69%	8/16 (50%)	NA
Matetzky et al[47]	24	47 ± 9	58%	318 ± 210	71%	All MI	5/21 (24%)
Escaut et al[48]	17	46 ± 6	71%	272 ± 185	65%	11/17 (65%)	9/17 (53%)
Mehta et al[49]	129†	42 ± 10	NA	313 ± 209	NA	82/106 (77%)	26/76 (35%)
Ambrose et al[50]	51	48 ± 9	55%	426 ± 290	59%	34/51 (67%)	21/45 (47%)
Varriale et al[51]	29	46 ± 10	55%	>500 in 18/29	66%	All MI	NA
Hsue et al[52]	68	50 ± 8	68%	341 (3-4360)*	49%	37/68 (54%)	20/56 (36%)

*Median value; all other values are means.
†Patients drawn from 25 previous reports.
MI, myocardial infarction; NA, not reported; PI, protease inhibitor.

approximately 8 to 11 years younger than in HIV-negative patients with MI. The proportion of patients receiving PIs ranged from 49% to 71%. In each of these studies, more than half of the patients smoked cigarettes at the time of their coronary event.

Mean HDL-cholesterol levels were low in each of the 3 studies in which they were reported, ranging from 28 to 35 mg/dL.[47,48,52] These levels were significantly lower than those of HIV patients without coronary disease in the French cohort[48] and lower than non-HIV controls with coronary disease in the other two studies.[47,52] Mean LDL-cholesterol levels were lower in HIV coronary patients than in non-HIV coronary controls in one study[47] but not in another.[52] In the French cohort, LDL-cholesterol levels were much higher in the HIV patients with coronary disease than in those without.[48]

As expected in a younger population, single vessel disease is common,[47-50,52] and the TIMI risk score[53] is low if an acute coronary syndrome is present.[52] Thus, HIV-infected patients tend to have good outcomes after coronary events. Only 9 deaths (4.8%) occurred in hospital among 189 patients with follow-up reported among the studies included in Table 48–3.[47,48,50-52]

Coronary angioplasty or stenting has often been performed in these patients, and the immediate results have been excellent; however, the restenosis rate appears to be higher than that of patients without HIV infection.[47,52] In one study, restenosis developed in 15 of 29 HIV patients compared with 3 of 21 non-HIV controls (52% versus 14%, $P = 0.006$).[52] Similarly, in another study, 6 of 14 HIV patients had restenosis that required target vessel revascularization compared with 4 of 38 uninfected controls (43% versus 11%, $P = 0.02$).[47] Restenosis rates are higher after both balloon angioplasty and stenting. Thus because of higher restenosis rates, HIV patients should be considered for drug-eluting stents. To date, no studies have examined the utility of drug-eluting stents in this patient population.

In a small series of 37 HIV patients who were followed after coronary bypass surgery, event-free survival was 81% at 3 years.[54] Of note, the median age of the bypass patients in this study was only 44 years. There have been no large-scale studies of HIV patients who were referred for bypass grafting studying with long-term follow-up, and no studies have reported graft patency rates after coronary bypass in HIV patients.

TREATMENT OF CORONARY RISK FACTORS IN HIV PATIENTS

Currently, there is no direct evidence that treating risk factors for CAD in HIV patients improves outcomes; however, it appears reasonable to extrapolate from observations on the treatment of traditional risk factors in non-HIV patients.

Cigarette smoking is one of the most common and modifiable risk factors in patients with HIV infection; the prevalence of cigarette smoking in HIV patients has been reported to be as high as 70% to 80% in some areas,[55] and compared with other smokers, HIV patients are less likely to have contemplated quitting.[55] Different treatments that have been tested in pilot studies of HIV-infected smokers include interventions led by nurses[56] and the provision of cellular telephones to low-income, HIV-infected smokers in order to assist counseling.[57] Cigarette smoking is implicated in many of the other complications of HIV,[55] along with atherosclerosis and pulmonary disease, and it should be a major focus of attention by the physician in HIV patients.

The Adult AIDS Clinical Trials group recommends that dyslipidemia be managed according to the guidelines of the National Cholesterol Education Program Adult Treatment Panel III.[58] However, HIV patients have several particular issues in dyslipidemia. All current PIs and all statins, except pravastatin, are metabolized by the cytochrome P450 system. In healthy volunteers the PI combination of ritonavir/saquinavir has been shown to increase the area under the curve (AUC) for 24-hour blood statin level by 30-fold for simvastatin and by 79% for atorvastatin, while the AUC decreased by 50% for pravastatin.[59] Simvastatin and lovastatin are contraindicated in patients taking PIs, and atorvastatin should be used cautiously.[58] Although pravastatin is safe, it has weaker LDL-cholesterol lowering effects. Ezetimibe, which works by inhibiting cholesterol absorption, has not been studied in HIV patients but may represent an attractive approach to LDL-cholesterol lowering because of its lack of drug–drug interactions. Atazanavir, one of the newer protease inhibitors, does not appear to be associated with lipid abnormalities,[60] and thus switching HIV patients to this drug represents an option for patients who have lipid levels that are difficult to manage. An algorithm for management of elevated LDL in HIV patients is shown in Figure 48–2.

NNRTIs also affect the P450 cytochrome 3A4 enzyme, but in different ways: delavirdine inhibits it and thus has the same implications with respect to statin use as PIs do.[58] Efavirenz is a mixed inducer and inhibitor of this enzyme, and little data are available to define how this NNRTI affects statin concentrations.[58]

Elevated triglycerides are common in HIV-infected patients. Fibrates (bezafibrate, fenofibrate, and gemfibrozil) appear to reduce triglycerides effectively in HIV patients who receive HAART[21,61]; however, fibrates are conjugated by glucuronidation with renal elimination. Ritonavir and nelfinavir

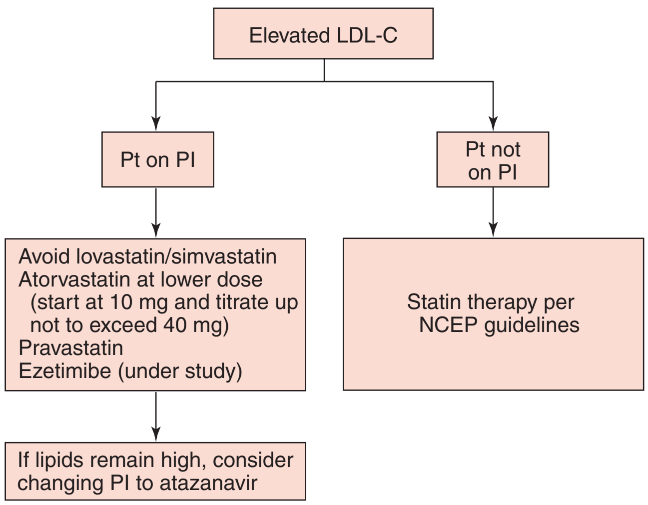

Figure 48–2 A suggested algorithm for management of elevated LDL cholesterol in HIV-infected patients. PI, protease inhibitor.

are known inducers of glucuronidation and thus could diminish the efficacy of fibrates.[58] If fibrates are prescribed in combination with statins, regular monitoring of CK levels is recommended because of the increased risk of myopathy. Niacin is an alternative choice to raise HDL levels and lower triglycerides but may be a poor choice for many HIV patients because of its propensity to worsen blood glucose levels. An algorithm for management of elevated triglycerides and low HDL cholesterol is shown in Figure 48–3.

Hypertriglyceridemia is often accompanied by other components of the metabolic syndrome: low HDL-cholesterol, increased remnant lipoproteins, small LDL particle size, abdominal obesity, hypertension, insulin resistance, and glucose intolerance (a proinflammatory state and a prothrombotic state).[62] The primary treatment target for the metabolic syndrome is obesity, and the recommended measures include diet and exercise.[63] Even modest reductions in body weight improve dyslipidemia, hypertension, and glucose intolerance, as well as levels of inflammatory and thrombotic markers.[63]

Similar to other patients with chronic infection, HIV patients have higher levels of hs-CRP compared with age- and sex-matched controls.[39] CRP was an independent predictor of 5-year mortality in one small study of HIV-infected women.[64] The anti-inflammatory effects of statins might thus contribute to any benefit these drugs might have in HIV patients, as they also might be beneficial in patients without HIV disease. Finally, as with HIV-uninfected patients, primary prevention of coronary disease in appropriate patients using aspirin therapy should be implemented.

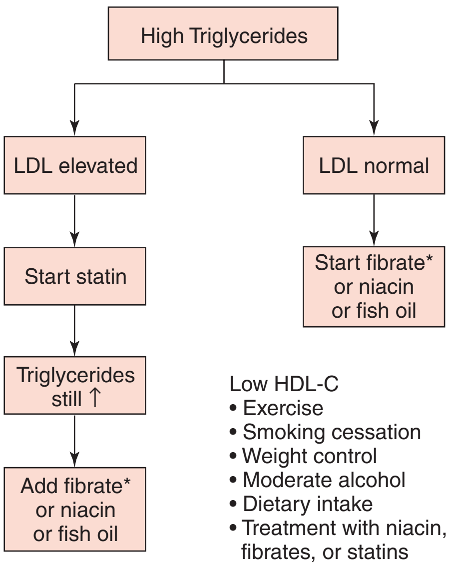

Figure 48–3 Algorithm for managing elevated triglycerides and low HDL-cholesterol in HIV-infected patients. *Caution is advised when considering the combination of fibrates and statins due to increased risk for myopathy. When used in combination with a statin, fenofibrate is preferred. The efficacy of fibrates is reduced in patients receiving Ritonavir or Nelfinovir.

MYOCARDIAL INVOLVEMENT IN HIV

The HIV virus has been recognized as an important cause of dilated cardiomyopathy (DCM). The diagnosis of HIV-related DCM carries a poor prognosis, with a mortality hazard ratio of 4.0 when compared with uninfected controls with idiopathic DCM.[65] Myocarditis and HIV-1 infection are the most studied causes of DCM in HIV disease.[66]

Before the advent of antiretroviral therapy, global left ventricular dysfunction was detected by echocardiography in 15% of HIV patients who were selected randomly in one study.[67] In almost all cases, myocardial biopsy revealed myocarditis with cardiotropic viral infection.[68] In autopsy studies of patients with HIV, myocarditis was identified in more than 50% of the 71 patients evaluated, and biventricular dilatation was present in 10% of cases.[69]

Zidovudine may cause mitochondrial myopathy in skeletal muscles, providing a possible link to involvement of myocardial muscle.[70] Studies performed on transgenic mice suggest that zidovudine is associated with diffuse destruction of cardiac mitochondrial ultrastructures and with inhibition of cardiac mitochondrial DNA replication.[71] Clinical studies on AZT have been mixed, showing both association[72] and no association with LV dysfunction.[73,74]

Many organisms, such as herpes simplex virus,[75] cytomegalovirus, *Mycobacterium tuberculosis, Mycobacterium avium,*[76] *Cryptococcus neoformans,*[77] *Toxoplasma gondii,*[78] and *Histoplasma capsulatum,* may cause pericarditis and myocarditis in HIV-infected individuals. In one autopsy series, cardiac toxoplasmosis was diagnosed at autopsy in 21 of 182 (12%) of HIV-infected patients.[80] In another autopsy series performed before the introduction of potent combination ART, myocarditis was documented in 40% to 52% of patients who died of AIDS.[79] In more than 80% of these patients, no specific etiologic factor was found, whereas the remaining cases were attributable to the previously mentioned infectious agents.[79]

The introduction of potent ART regimens seems to influence the course of HIV-associated DCM, with a decreasing rate of mortality from heart failure. In a study performed in 1999 involving 105 ambulatory HIV patients, the prevalence of myocardial systolic dysfunction was low (3%) and none of the patients developed end-stage DCM.[80] The authors suggest a myocardial protective effect of antiretroviral therapy to explain this low prevalence of cardiac dysfunction compared with previous studies.[80] A decrease in the prevalence of global cardiac involvement has been shown in a retrospective study comparing HIV-positive patients treated with ART with those treated with NRTIs.[81]

The exact pathogenesis of DCM in the setting of HIV infection remains unknown and may involve direct effects of HIV on the heart, toxic effects from antiretroviral therapy, opportunistic infections, illicit drug use, nutritional disorders, and increased cytokine activity.[82]

Treatment of DCM in HIV patients has not been specifically studied; however, again by extrapolation of studies from HIV-negative patients, diuresis, afterload reduction with ACE-inhibitors, β-blocker therapy, and digoxin would appear

to be beneficial. Discontinuation of possible contributing substances, such as alcohol, cocaine, methamphetamine, and NRTI medication, as mentioned earlier, should be considered. IV immunoglobulin therapy may serve to improve left ventricular structure and function in HIV-infected patients.[83] Only a few cases have been reported in the literature regarding the use of left ventricular assist devices[84] or heart transplant in HIV-infected individuals.[85]

PERICARDIAL DISEASE IN PATIENTS WITH HIV INFECTION

Pericarditis in HIV-infected patients may present with large effusions and often with cardiac tamponade.[86-88] The incidence of pericardial effusion in patients with asymptomatic AIDS (defined as patients with CD4 < 200 cells/mm^3) was 11% per year before the introduction of effective ART.[88] The survival of AIDS subjects with effusion was significantly shorter (36% at 6 months) than the survival of AIDS subjects without effusions (93% at 6 months). In HIV patients, culture of pericardial fluid is often unrevealing. There are isolated case reports of pathogens, such as *Mycobacterium tuberculosis,*[89-91] staphylococcus,[92,93] *Cryptococcus neoformans,*[94] and herpes simplex,[95] as causes of pericarditis. The incidence of pericardial effusions after the introduction of HAART has not been evaluated, and treatment and evaluation of effusions in the HIV+ subject is similar to that in uninfected subjects involving echocardiography and pericardiocentesis, if indicated.

HIV-RELATED PULMONARY HYPERTENSION

The incidence of HIV-associated pulmonary hypertension before the advent of HAART was 1% to 2%.[96] The pathogenesis of HIV-associated pulmonary hypertension remains unclear. In patients without HIV infection, a report linked infection with human herpesvirus 8 (HHV-8) to primary pulmonary hypertension.[97] HHV-8 is one of the causal agents for Kaposi's sarcoma[98]; although only a small fraction of patients infected with HHV-8 develop Kaposi's sarcoma, the magnitude of immunosuppression predicts risk.[99] The seroprevalence of HHV-8 remains high in populations at risk for HIV.[100] For patients with HIV, HHV-8 may thus be a causative agent for pulmonary hypertension, but this has not yet been demonstrated.

The effect of antiretroviral infection on pulmonary hypertension is not known; however, in a recent report from the Swiss Cohort Study, pulmonary artery pressure increased in untreated patients but decreased in patients treated with HAART.[101] The oral endothelin receptor antagonist, bosentan, improved exercise tolerance and hemodynamic measurements in a small study of HIV patients.[102]

SUMMARY

With the number of HIV-infected adults increasing and HIV patients continuing to live longer, cardiovascular complications specific to HIV-infected individuals will represent an increasingly important health issue for physicians. Many of the long-term side effects of HIV infection and HIV medication remain unknown. Although studies on these issues are ongoing, physicians should remain aware of the possibility of HIV-associated cardiovascular complications in their patients with HIV infection, especially atherosclerosis, and treat all risk factors aggressively.

Rehabilitation of the Patient with Cardiovascular Disease

Jonathan N. Myers and Victor F. Froelicher

CHAPTER CONTENTS

Before the 1970s, patients were completely immobilized after a myocardial infarction (MI) for 6 weeks or longer; the prevailing view was that this time period was necessary for complete healing of the myocardium. The post-MI patient was generally not expected to return to normal occupational or recreational activities. The process known as cardiac rehabilitation evolved in order to restore the patient to optimal physical, psychological, and social function. A significant body of data over the past 3 decades has documented both the benefits of early ambulation, as well as the numerous detrimental effects of strict bed rest. The act of merely sitting in the upright position has been shown to reduce the detrimental effects of remaining supine.[1] Both the indications for and scope of cardiac rehabilitation services have broadened. Advances in the treatment of cardiovascular diseases and data supporting the value of secondary prevention have greatly increased the spectrum of patients who may benefit from cardiac rehabilitation. This spectrum of patients now includes not only post-MI patients (both ST-elevation and non-ST-elevation) but also post–cardiac transplantation patients; post–percutaneous coronary intervention (PCI, stent implantation, angioplasty) patients; patients with chronic heart failure (CHF), implantable cardioversion devices (ICDs), and pacemakers. In addition, it is now widely recognized that exercise is only one component of cardiac rehabilitation.

The objectives for patients include not only preventing the effects of deconditioning but also improving functional capacity; relieving symptoms; and providing education, risk factor reduction, assistance in returning to normal activities, and psychosocial support. Societal objectives include decreasing health care costs by reduction in treatment time; reduction of medications; and prevention of premature disability, thus maintaining individual productivity and lessening the need for societal support. It is noteworthy in this context that randomized exercise trials, when combined, have shown that the rate of mortality from cardiovascular causes (defined as fatal reinfarction or sudden cardiac death) is reduced 20% to 25% among patients participating in rehabilitation. Even with major advances in the treatment of acute MI (e.g., thrombolytic therapy), updates of the meta-analyses of the trials performed from the 1970s through the 1990s have shown 25% to 30% reductions in mortality with rehabilitation.[2-4]

PHYSIOLOGIC EFFECTS OF IMMOBILITY

Data published since the late 1960s on the deleterious physiologic effects of bed rest have been an important stimulus for the growth of cardiac rehabilitation and contributed to an appreciation of its benefits. It is now widely recognized that the negative effects of bed rest include not only reductions in functional capacity but also adverse hemodynamic changes, alterations in cardiac size and function, orthostatic intolerance, and increased risk of thrombus formation. Patients hospitalized for cardiac events today are encouraged to begin physical activities as soon as possible. Simply exposing the patient to orthostatic stress and early ambulation counteracts the negative physiologic effects of prolonged bed rest and also provides the patient with tangible affirmation of improvement and increased self-confidence.

PHYSICAL TRAINING

Regular exercise increases work capacity; hundreds of studies have documented greater exercise capacity among active persons than among sedentary individuals. In general, patients with cardiovascular disease are equally able to benefit from exercise training. Although there are some notable differences, the mechanisms underlying the response to training are similar between those with and those without cardiovascular disease. The magnitude of the improvement in exercise capacity with training varies widely, generally ranging from 5% to 25%, but increases as large as 50% have been reported. The degree of change in peak oxygen uptake ($\dot{V}O_2$) depends primarily on the patient's initial state of fitness, but it is also affected by age and the type, frequency, and intensity of training. Peak $\dot{V}O_2$ may be as low as 10 to 15 mL/kg/min in patients with severe cardiovascular disease, and values as high as 80 to 90 ml/kg/min have been observed among elite endurance athletes.

The physiologic benefits of a training program can be classified as morphologic, hemodynamic, and metabolic (Table 49–1). Many animal studies have demonstrated significant morphologic changes with training including

Table 49–1 Physiologic Adaptations to Physical Training in Humans

Morphologic Adaptations
Myocardial hypertrophy (generally only in younger, healthy subjects)
Hemodynamic Adaptations
Increased blood volume
Increased end-diastolic volume
Increased stroke volume
Increased cardiac output
Decreased heart rate for any submaximal workload
Metabolic Adaptations
Increased mitochondrial volume and number
Greater muscle glycogen stores
Enhanced fat utilization
Enhanced lactate removal
Increased enzymes for aerobic metabolism
Increased maximal oxygen uptake

myocardial hypertrophy with improved myocardial function, increases in coronary artery size, and increases in the myocardial capillary-to-fiber ratio. However, such changes have been difficult to demonstrate in humans.[5,6] The major morphologic outcome of a training program in humans is probably an increase in cardiac size. However, although this adaptation has been demonstrated by many investigators among young, healthy individuals, it is unlikely to occur among older subjects (e.g., older than 40 years) or in patients with cardiovascular disease. Hemodynamic changes after training include reductions in heart rate at rest and any matched submaximal workload. For the patient with coronary artery disease, this is beneficial in that it results in a reduction in myocardial demand during activities of daily living. Other hemodynamic changes that have been demonstrated after training include reductions in blood pressure, increases in blood volume, and increases in maximal cardiac output; the latter underlies an increase in maximal oxygen uptake. In patients with heart disease, the major physiologic effects of training occur in the skeletal muscle. The metabolic capacity of the skeletal muscle is enhanced through increases in mitochondrial volume and number, capillary density, and oxidative enzyme content. These adaptations enhance perfusion and the efficiency of oxygen extraction.[6]

Newer Concepts Regarding Physiologic Benefits of Exercise Training

The effects of exercise training on the coronary vasculature have long been of interest. Although the hypothesis that training might reverse or retard the progression of atherosclerosis in humans had generally been abandoned, contemporary studies performed in patients with coronary artery disease (CAD) indicate that exercise training, when combined with multidisciplinary risk management, can improve myocardial perfusion.[7-9] This has been demonstrated indirectly using nuclear imaging[7] and directly by angiography.[8,9] Because most of these studies involved multifactorial risk reduction (e.g., diet, smoking cessation, stress management, pharmacologic management of risk factors) in addition to exercise, it is not possible to determine the independent effects of exercise training.

The mechanism by which the apparent improvement in myocardial perfusion might occur following training has stirred debate. Generally, it is considered unlikely that changes in coronary blood flow during exercise observed in animals would apply to humans. Three mechanisms could potentially explain an improvement in perfusion after training: (1) direct regression of atherosclerotic lesions; (2) formation of collateral vessels; or (3) a change in the dynamics of epicardial flow via flow-mediated or endogenous stimuli of the vessel. Evidence of small but significant improvements in lumen diameter after intensive exercise and risk-reduction programs in patients with CAD exist, but there is no evidence that collateral vessel formation occurs after training in humans. Interestingly, although changes in lumen diameter after these intervention programs are quite small, they are associated with considerable reductions in hospital admissions for cardiac reasons.[9] This suggests that patients in the intervention groups may achieve greater plaque stability without large changes in the coronary artery lumen.

A significant amount of research has demonstrated that training improves endothelial function, thus permitting enhanced peripheral and coronary blood flow in response to exercise. This represents a paradigm shift in the pathophysiology of CAD. We are now aware that the luminal diameter of epicardial vessels changes rapidly in response to mechanical (flow-related) and endogenous or pharmacologic stimuli. Hambrecht et al[10] studied the effects of exercise training in patients with reduced ventricular function and reported that leg blood flow during acetylcholine infusion was enhanced compared with controls. The improvement after training was attributed to an increase in endothelium-dependent vasodilation with an increase in basal nitric oxide formation. In a subsequent study, these investigators demonstrated an improvement in endothelium-dependent vasodilation in epicardial vessels, as well as resistance vessels in patients with CAD. After 4 weeks of exercise training, there was a 29% increase in coronary artery flow reserve in comparison with the non–exercise control group.[11]

These findings have been confirmed by other groups[12-14] and suggest that exercise training may have a profound effect on the vasodilatory properties of the vascular endothelium. Further exploration into the effects of exercise training on the dynamic behavior of the endothelium is an important target area for future research in patients both with and without existing cardiovascular disease.

CARDIAC REHABILITATION AFTER A MYOCARDIAL INFARCTION

Changes in health care economics have drastically altered the way in which cardiac rehabilitation is implemented. Hospital stays are shorter, progression through the program is quicker, and much of "cardiac rehabilitation" as it was traditionally known has changed. Reimbursement patterns differ considerably from one state to another and from one program to another. With shorter periods of time for physicians to interact with and monitor patients, as well as to cover educational materials adequately, there is a greater need for structured

outpatient programs in the home or community. Traditionally, typical phases that were included in rehabilitation were phase I, which includes the coronary care unit and inpatient care during the first few days after the event; phase II, which involves convalescence, an outpatient program, or a home program; and phase III, which was usually a longer-term community-based or home program. The precise course of each program naturally depends on the individual's needs and clinical status.

Disability Due to Myocardial Infarction

Cardiovascular diseases are the leading cause of activity limitation and disabled worker benefits in the United States. In fact, CAD alone is responsible for almost one of five disability allowances paid by the Social Security Administration. However, the total economic impact results from the combination of Social Security benefits, welfare support, disability insurance income, unemployment compensation, loss of taxable revenue, and reduced worker productivity related to cardiovascular diseases. From a purely economic standpoint, it is essential that patients with CAD be rehabilitated as quickly and efficiently as possible in order to enable their return to remunerative employment. Just as important, however, is amelioration of the psychosocial impact of heart disease including lessened depression and expedient return to pre-illness social roles in the family and community.

Historically, the patient's return to work, ability to drive, and sexual activity have been based on clinical judgments rather than on physiologic assessments. These decisions should be based on the consequence of the coronary event (e.g., ischemia, symptoms of CHF, dysrhythmias), the nature of the patient's occupational or recreational activities, and the response to the predischarge exercise test. In general, if the patient does not exhibit any untoward responses to submaximal exercise testing and achieves five or more metabolic equivalents (METs), it is unlikely that he or she will encounter difficulties during activities of daily living. More strenuous jobs or recreational requirements should not be initiated until a symptom-limited exercise test can be performed and exercise capacity can be determined and related to the desired physical activities of the patient.

Factors that influence a patient's return to work include age; work history; severity of cardiac damage; financial compensation for illness; employer's ignorance about the patient's abilities; termination of employment; and, most important, the patient's perception of his or her clinical status. Efforts of the rehabilitation team to develop a positive attitude and a sense of well-being for the patient may assist appropriate vocational adjustments. The physician's attitude also greatly affects the patient's return to work; encouragement can be beneficial.

In-Hospital Exercise after a Coronary Event

The purpose of beginning cardiac rehabilitation immediately is to counteract the negative effects of deconditioning rather than to promote training adaptations. It also provides an ideal time to begin education and psychological support. These first 3 to 5 days after an MI or bypass surgery are critical for beginning these processes. The literature is replete with studies documenting the efficacy and safety of beginning activities and education soon after a coronary event in stable patients.[15] Appropriate activities initially include sitting at the bedside, active range of motion exercises, self-care, and progressing to ambulation around the hospital unit under supervision and later to climbing a flight of stairs.

Patient Education

Education should be initiated before physical activities are begun; the patient may lack self-confidence and need affirmation that the activities are safe. Patient education during the acute phase usually consists of explanation about the coronary care unit, the cardiac rehabilitation program, symptoms, and the delivery of routine diagnostic and therapeutic modalities. The patient should be educated as to the limitations imposed by the disease, potential for improvement, and precautions to be observed. The program must be individualized for the patient depending on his or her psychosocial status. Clinical status is determined largely by the severity of the MI, but the medical history must also be considered.

Exercise Testing before Hospital Discharge

Performing an exercise test before hospital discharge provides much useful information including clarification of the response to exercise, development of an exercise prescription, and recognition of the need for medications or interventions. It can also have a beneficial psychological impact on recovery and begins the rehabilitation process. The test is considered the first step in the outpatient cardiac rehabilitation exercise program.

Experts have debated whether the predischarge test should be performed to a maximal level and whether it should be performed in patients with ST-elevation MIs. Available data indicate that it is safe to perform maximal or near-maximal testing in most post-MI patients, although a distinction has not been made for the presence or absence of ST-elevation MIs. The predischarge test has generally been submaximal, but the appropriate "submaximal" endpoint has varied. Traditionally, the test is stopped at a level not exceeding 5 METs or a Borg perceived exertion level of 16. In many hospitals a submaximal target heart rate is used (e.g., 110 beats/min for patients taking β-blockers). The protocol should be modified to accommodate the reduced exercise tolerance of most patients recovering from a myocardial infarction; individualized ramp or Naughton protocols are preferable.[16] Later, when return to full activities is intended, the test can be symptom and sign limited.

The prognostic value of the predischarge test has been widely studied. A meta-analysis has shown that an abnormal exercise capacity or abnormal systolic blood pressure responses are better predictors of increased risk than is ST-segment depression.[17] However, ST-segment depression probably indicates increased risk in men who do not take digoxin and whose resting ECG does not show extensive damage. The criterion of 2 mm or more of ST-segment depression, along with symptoms or abnormal hemodynamic responses, appear to be useful for identifying higher-risk patients who should be considered for cardiac catheterization and possibly revascularization.

Outpatient Cardiac Rehabilitation

Multiple approaches to outpatient rehabilitation have been employed. Traditionally, this phase begins 1 to 2 weeks after discharge from the hospital and may last from 1 to 4 months. Most commonly, patients attend group exercise sessions three times per week; however, frequency of exercise is often modified by the individual patient's overall goals, functional capabilities, reimbursement, proximity to the hospital or clinic, and personal commitment. The first few exercise sessions usually emphasize warm-up and cool-down activities with only a modest aerobic component. A symptom-limited maximal exercise test is often recommended approximately 6 weeks after hospital discharge to determine appropriate activity limitations.

Changes in reimbursement patterns have changed outpatient programs more than other components of cardiac rehabilitation. In many instances only a few exercise or educational sessions are reimbursed. The transition from an outpatient to a home-based maintenance program now occurs more rapidly. Randomized trials have demonstrated that patients can return to work quickly and safely during rehabilitation and that participation in rehabilitation assists this process. DeBusk and colleagues[18] pioneered the application of home rehabilitation programs in the 1980s; these programs use either unmonitored or monitored surveillance via telephone or microprocessor. Home programs are now widely used, and their safety and efficacy have been shown to be similar to those of more conventional programs.

Safety of Cardiac Rehabilitation

The safety of outpatient cardiac rehabilitation has been well documented. Van Camp[19] gathered data from 167 randomly selected cardiac rehabilitation centers on more than 51,000 patients who exercised more than 2 million hours. Over a 4-year period there were only 21 cardiac resuscitations (3 of which failed) and 8 myocardial infarctions. This amounts to 8.9 cardiac arrests, 3.4 infarctions, and 1.3 fatalities per million hours of patient exercise. Surprisingly, ECG monitoring had little influence on complications, which suggests that the additional expense of telemetry may not be necessary. In a 16-year follow-up from William Beaumont Hospital in Michigan, 292,254 patient exercise hours were recorded in phase II and III programs.[20] During this period, only 5 major cardiovascular complications occurred, representing a rate of 1 per 58,451 patient exercise hours. Despite the low incidence of these events, appropriate medical personnel trained in the use of automated external defibrillators must be available to respond when events do occur.

Monitoring in Outpatient Rehabilitation

Experts now recognize that only a small percentage of patients require continuous ECG monitoring during exercise. Efforts to reduce the cost of rehabilitation, in addition to the recognition that most patients can exercise quite safely without continuous telemetry, have brought about this change. Table 49–2 lists the criteria for ECG monitoring outlined in the American College of Cardiology Position Statement on Cardiac Rehabilitation.[21]

Table 49–2 American College of Cardiology Criteria for Electrocardiographic Monitoring during Cardiac Rehabilitation

1. Severely depressed left ventricular function (ejection fraction < 30%)
2. Resting complex ventricular arrhythmia (Lown type 4 or 5)
3. Ventricular arrhythmias appearing or increasing with exercise
4. Decrease in systolic blood pressure with exercise
5. Survivors of sudden cardiac death
6. Patients following myocardial infarction complicated by congestive heart failure, cardiogenic shock, and/or serious ventricular arrhythmias
7. Patients with severe coronary artery disease and marked exercise-induced ischemia
8. Inability to self-monitor intensity due to physical or intellectual impairment

From American College of Cardiology: Position paper on cardiac rehabilitation. J Am Coll Cardiol 1986;7:451-3.

Maintenance Program

Progression to an out-of-hospital maintenance program is desirable to maintain training adaptations and to help prevent recurrence of events or symptoms. The period of time required before patients move from a supervised program to a maintenance program can vary considerably, depending on reimbursement, patient stability, exercise capacity, and individual patient needs, but it rarely exceeds 12 weeks. The patient must understand how to monitor his or her own exercise intensity, understand how to recognize symptoms, and have a basic knowledge of his or her particular disease and medications. When making occupational activity recommendations for patients, it can be helpful to know the estimated energy requirements of various activities (Table 49–3). This way, appropriate recommendations can balance the patient's functional limitations with the need to return work, desire to continue recreational activities, or both.

Performing an exercise test before the maintenance program is essential in order to provide an outgoing exercise prescription, confirm the safety of exercise for a given patient, and assess risk for future cardiac events. Funding for this phase must often be borne by the patient because most types of health insurance do not cover it.

Exercise Prescription for Outpatient Rehabilitation

The American College of Sports Medicine defines exercise prescription as " … the process whereby a person's recommended regimen of physical activity is designed in a systematic and individualized manner."[22] An "individualized manner" implies the establishment of specific strategies to optimize return to work or activities of daily living, reduction of risk factors for future cardiac events, and maximization of the patient's capacity to maintain an active lifestyle. The development of an appropriate exercise prescription to meet

Table 49–3 Energy Costs of Various Occupational and Recreational Activities

	Occupational	Recreational
1 to 2 METs	Desk work, auto driving, typing	Standing, walking (1 mph), playing cards, sewing, knitting
2 to 3 METs	Auto repair, radio, janitorial work, bartending	Level walking (2 mph), level bicycling (5 mph), riding lawnmower, billiards, bowling, shuffleboard, woodworking (light), powerboat driving, golf (power cart), canoeing (2.5 mph), horseback riding (at a walk), playing piano and other musical instruments
3 to 4 METs	Bricklaying, plastering, using a wheelbarrow (light load), machine assembly, welding (moderate load), cleaning windows	Walking (3-3.5 mph), cycling (8 mph), table tennis, golf (carrying clubs), dancing, badminton (singles), tennis (doubles), raking leaves, hoeing, many calisthenics
4 to 5 METs	Digging gardens, shoveling light earth	Walking briskly (4 mph), cycling (10 mph), canoeing (4 mph), horseback riding, stream fishing, ice or roller skating (9 mph)
6 to 7 METs	Shoveling (10 lb), carrying objects 50-75 lb, using heavy power tools	Walking quickly (5 mph), cycling (11 mph), playing badminton (competitive) and tennis (singles), splitting wood, shoveling snow, hand lawn mowing, folk dancing, light downhill skiing, ski touring (2.5 mph), water skiing
7 to 8 METs	Digging ditches, carrying 80 lb, sawing hardwood	Jogging (5 mph), cycling (12 mph), horseback riding (at a gallop), vigorous downhill skiing, basketball, mountain climbing, ice hockey canoeing (5 mph), touch football, paddleball
8 to 9 METs	Moving or pushing heavy objects > 75 lb	Running (5.5 mph), cycling (13 mph), ski touring shoveling (14 lb), baling hay (4 mph, loose snow), squash (social), handball (social), fencing, basketball (vigorous)
10^{+} METs	Shoveling > (16 lb), firefighting—climbing ladder in full gear	Running: 6 mph = 10 METs; 7 mph = 11.5 METs; 8 mph =13.5 METs; 9 mph = 15 METs; 10 mph = 16 METs; ski touring (5+ mph), handball (competitive), racquetball (competitive)

MET, maximal exercise test.

the individual patient's needs has a sound scientific foundation,[15,22,23] but there is also an art to effective exercise programming. No single program is best for all patients or even one patient over time; capabilities, vocational needs, and expectations differ among patients and can change with the passing of time. Thus, the art of exercise prescription relies on the physician's or exercise physiologist's abilities to synthesize pathophysiologic, psychosocial, and vocational factors and tailor the exercise prescription to the patient's needs and realistic goals. A final but important consideration is the selection of activities that the individual enjoys and will be more likely to continue to perform after the formal rehabilitation program ends.

Principles of Exercise Prescription

Training implies chronic adaptations of the body to the demands placed on it. A training effect is best measured as an increase in peak $\dot{V}O_2$, but not all institutions have gas exchange equipment, and there are many ways of quantifying functional outcomes of rehabilitation. For example, after rehabilitation some patients may be better suited to carry out submaximal levels of activity for longer periods, remain independent, continue working, or rejoin their friends on the golf course. All of these can be important goals for a given patient and may occur even with a minimal change in peak $\dot{V}O_2$.

The major components of the exercise prescription are the frequency, intensity, duration, mode, and the rate of progression. In general, these principles apply for both the patient with heart disease and the healthy adult; however, the ways in which they are applied differ. It is generally accepted that increases in $\dot{V}O_2$ max are achieved if a person exercises dynamically for a period ranging from 15 to 60 minutes, 3 to 5 times per week, at an intensity equivalent to 50% to 80% of their maximum capacity. Dynamic exercises are those that employ large muscle groups in a rhythmic manner, such as treadmill walking, cycle ergometry, rowing, stepping, and arm ergometry. Short warm-up and cool-down periods are strongly encouraged for participants in cardiac rehabilitation programs.

Much of the art of exercise prescription involves individualizing exercise intensity. Typically, exercise intensity is expressed as a percentage of maximal capacity, either in absolute terms (i.e., workload or watts) or in relation to the maximal heart rate, maximal oxygen uptake, or perceived effort. Training benefits have been shown to occur with the use of exercise intensities ranging from 40% to 85% of maximal oxygen uptake, which are generally equivalent to 50% to 90% of maximal heart rate. However, the intensity that a given individual can maintain for a specified period of time varies widely. In general, the most appropriate intensity for most patients in rehabilitation programs is 50% to 70% of

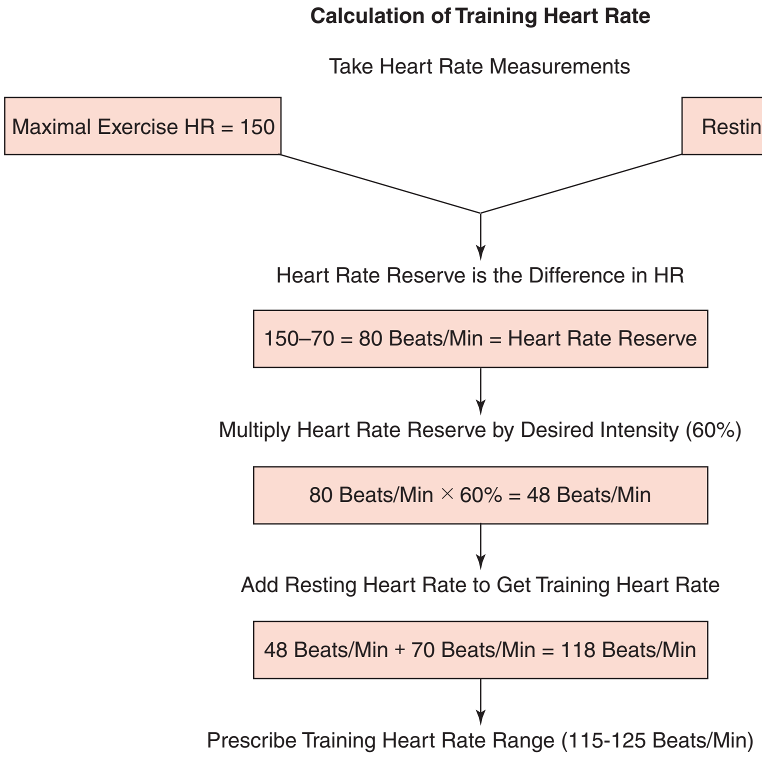

Figure 49–1 Flow diagram for development of an exercise prescription using heart rate in a typical patient initiating a rehabilitation program.

maximal capacity. The actual prescribed exercise intensity for the patient should naturally depend on goals, health status, length of time since infarction or surgery, symptoms, and initial state of fitness.

Training is a general phenomenon; there is no true threshold beyond which patients achieve benefits. Thus, as long as patients exercise safely, setting the exercise intensity is a less rigid practice than it was years ago. In addition, the patient's ability to tolerate activities can change daily. Other factors, such as time of day, environment, and time since medications were taken, can influence the patient's response to exercise, and the exercise prescription must be adjusted accordingly. It is also useful to employ a window of intensity that ranges approximately 10% above and 10% below the desired level.

The graded exercise test is the foundation on which a safe and effective exercise prescription is based. To achieve a desired training intensity, oxygen uptake or some estimation of it must be quantified during a maximal or symptom-limited exercise test. Because heart rate is easily measured and is linearly related to oxygen uptake, it has become a standard by which training intensity is estimated during exercise sessions. The most useful method is known as the *heart rate reserve*. This method uses a percentage of the difference between maximal heart rate and resting heart rate and adds this value to the resting heart rate. An example of a typical patient given an exercise prescription at 60% of the heart rate reserve is illustrated in Figure 49–1. This is also referred to as the *Karvonen formula* and is reliable in patients with normal sinus rhythm whose measurements of resting and maximal heart rates are accurate. An estimated target heart rate for exercise should be supplemented by considering the patient's MET level relative to his or her maximum, the perceived exertion, and symptoms.

Contraindications to Exercise Training

Absolute contraindications include unstable angina pectoris, aortic dissection, complete heart block, uncontrolled hypertension, decompensated heart failure, uncontrolled dysrhythmias, thrombophlebitis, and other complicating illnesses that prevent exercise. Relative contraindications include frequent premature ventricular contractions, controlled dysrhythmias, intermittent claudication, metabolic disorders, and moderate anemia or pulmonary disease. Studies show that if these contraindications are considered, the incidence of exertion-related complications in cardiac rehabilitation programs is extremely low and, because of the availability of rapid defibrillation, serious events rarely occur.

Rehabilitation in Patients with Chronic Heart Failure

Until the late 1980s, stable CHF was considered by many authorities to be a contraindication to participation in an exercise program. Today it is known that patients with CHF derive considerable benefits from cardiac rehabilitation. Randomized trials performed during the 1990s indicate that the major physiologic benefit from training in CHF occurs in the skeletal muscle rather than in the heart itself.[24]

The clinical approach to the patient with CHF who is considered for a rehabilitation program is similar to that for the post-MI patient described earlier, although several important differences are worth noting. Patients must be stable, and those exhibiting significant dyspnea with exertion, peripheral edema, or other signs indicative of right-sided failure should be deferred until the absence of these signs is assured. The potential for complications during exercise may be higher in patients with CHF relative to patients with normal left

ventricular function. A greater number of medications that can influence exercise responses including vasoactive, antiarrhythmic, inotropic, and β-blocking agents should be considered. Exercise capacity tends to be significantly lower than that in the typical patient with coronary disease. Numerous hemodynamic abnormalities underlie the reduced-exercise capacity in CHF including impaired heart rate responses, inability to distribute cardiac output normally, abnormal arterial vasodilatory capacity, abnormal cellular metabolism in skeletal muscle, elevated systemic and pulmonary vascular resistance, and ventilatory abnormalities that increase the work of breathing and cause exertional dyspnea.[24,25] Studies suggest that many of these abnormalities can be improved by exercise training.[24]

Most patients with reduced left ventricular function who are clinically stable (including the absence of signs of right-sided failure, absence of significant dyspnea on exertion, and absence of peripheral edema) and have reduced exercise tolerance are candidates for exercise programs. Excluding patients with signs and symptoms of right-sided failure or treating them judiciously before entry into a program is often necessary. An exercise test is particularly important before initiating the program to ensure safety of participation. Rhythm abnormalities, exertional hypotension, or other signs of instability should be ruled out. Expired gas exchange measurements are particularly informative in this group because they provide an improvement in accuracy and permit an assessment of ventilatory abnormalities that are common in this condition.[24,25] ECG monitoring during exercise is more often indicated in this group. Attention should be paid to daily changes in body weight, rhythm status, and symptoms.

Increasing numbers of patients have undergone cardiac transplantation for end-stage heart failure, and today approximately three quarters of these patients remain alive after 5 years. Several reports have addressed the effects of training after cardiac transplantation. These studies have demonstrated increases in peak oxygen uptake, reductions in resting and submaximal heart rates, and improved ventilatory responses to exercise.[26,27] The combination of improved cardiac function, changes in skeletal muscle metabolism, and improvements in strength contributes to improved exercise tolerance with training in these patients.

Meta-Analyses of Survival after Cardiac Rehabilitation

The overall benefits of cardiac rehabilitation are now widely accepted. Comprehensive reviews confirming these benefits are available.[5,15,24] Because none of the single-center studies alone have been sufficiently powered to adequately document changes in mortality, a series of meta-analyses has been performed to evaluate the impact of cardiac rehabilitation on fatal and nonfatal events. O'Connor and colleagues[28] performed a meta-analysis of 22 randomized trials of cardiac rehabilitation involving 4554 patients. They found a 20% reduction of risk for total mortality, a 22% reduction for cardiovascular mortality, and a 25% reduction in the risk for fatal reinfarction. Oldridge and associates[29] performed a similar meta-analysis with 10 randomized trials that included 4347 patients and found a similar reduction for all-cause and cardiovascular mortality in the patients undergoing cardiac rehabilitation. The pooled odds ratios for the combined studies suggest 24% and 25% reductions in all-cause and cardiovascular deaths, respectively, among the exercise groups. Criticisms of these analyses are that each of the pooled studies was not uniform in its treatment of patients and that a nonexercise intervention done in the different trials may have biased the results. Nevertheless, these two meta-analyses have been widely cited and have been highly influential in support of cardiac rehabilitation.

Taylor and colleagues[2] performed an updated meta-analysis of rehabilitation trials among patients with coronary heart disease. The aforementioned studies focused on studies performed during the 1970s and 1980s, but the latter study included trials up to 2003. A total of 48 trials involving 8940 patients met the inclusion criteria. Compared with usual care, cardiac rehabilitation was associated with reduced all-cause mortality (odds ratio [OR] = 0.80) and cardiac mortality (OR=0.74). In addition, participation in cardiac rehabilitation was associated with greater reductions in cholesterol, triglycerides, and systolic blood pressure. However, there were no differences between rehabilitation and usual care groups in nonfatal reinfarctions or revascularization rates. Importantly, the effect of rehabilitation on mortality was independent of CHF diagnosis, type of rehabilitation, dose of exercise intervention, length of follow-up, trial quality, or trial publication date.

Although the mortality effects of exercise-based rehabilitation on outcomes in post-MI patients have been known for some time (i.e., since the 1980s), meta-analyses among patients with CHF have only recently been performed. Until the late 1980s, activity was generally restricted in patients with CHF, due largely to concerns over safety and unknown effects on the myocardial remodeling process. During the 1990s numerous trials demonstrated that exercise training is safe for these patients, and several landmark trials were published that used highly technologic imaging techniques which allayed concerns over the effects of training on left ventricular remodeling.

A collaborative study (the ExTraMATCH study) of European centers that performed exercise training trials in patients with CHF during the 1990s has been completed.[3] This meta-analysis included controlled exercise trials in CHF and was designed to provide estimates of treatment benefits on mortality and hospital admission. Nine trials met the study inclusion criteria, comprising a total of 395 exercise intervention patients and 406 controls. After a mean follow-up period of 705 days, it was found that exercise training reduced mortality by 35% and reduced the composite outcome of death or hospital admission by 28%. Moreover, there was no evidence that any subgroup (elderly, severely reduced exercise capacity or ventricular function, type of CHF, duration of training, or gender) was less likely to benefit from training.

EVOLVING LANDSCAPE FOR CARDIAC REHABILITATION

Early and progressive ambulation of patients after a myocardial infarction is now considered routine care. Despite many new therapies in cardiovascular medicine, cardiac rehabilitation maintains an important place in reducing morbidity and mortality.[2,3,4,15,28,29] The controlled trials, when combined, demonstrate that the efficacy of rehabilitation in reducing

mortality is similar to the best medical interventions.[15] Moreover, cardiac rehabilitation has redirected interest to humanistic concerns, providing a balance to the emphasis on complex technology. It also provides an ideal environment for patient supervision and for ensuring stability after an interventional procedure. Guidelines now regard cardiac rehabilitation as an appropriate medium for comprehensive risk reduction and secondary prevention.[30] Available data suggest that cardiac rehabilitation is economically sound.[31,32]

Medicine is presently experiencing an evolution toward technologic efficacy and outcomes assessment. Health economists and legislators are reexamining the value placed on all forms of medical care. Although this movement has changed the way that cardiac rehabilitation is implemented, studies have confirmed its value. Some of the ways in which the current economic environment has changed cardiac rehabilitation include a lessening of direct ECG monitoring, shorter hospital stays, and a more rapid progression to home programs. The frequency of interventions has lessened the morbidity associated with myocardial infarction. Data on efficacy, safety, and technologic advances in the treatment of cardiovascular disease have shown that cardiac rehabilitation has changed in such a way that a wider range of patients can benefit from these services than in the past. For example, patients with stable CHF, once excluded from cardiac rehabilitation programs, are now thought to be among those who benefit the most. Pacemaker, post-transplantation, post-bypass, post-valvular surgery, and claudicant patients now make up a significant fraction of the patients in many programs. Despite this fact, most eligible patients (up to 90%) fail to receive these services. Not all patients need all the components of cardiac rehabilitation, but directing these services to patients who need them the most remains one of the important challenges for the field.[33]

Lastly, there has been a change in the public health care message toward physical "activity" as inherently beneficial regardless of objective measurements of "fitness." This has caused a shift in focus from morbidity, mortality, and exercise capacity to issues related to maintaining an active lifestyle and optimizing the patient's capacity to perform the physical challenges offered by occupational or recreational activities.

Cardiovascular Drugs: Comprehensive Drug Tables

Jeffrey B. Washam, PharmD

GUIDE TO INTERPRETATION OF COMPREHENSIVE DRUG TABLES

The comprehensive drug tables that follow are arranged generally in the sequence of the chapters in this textbook. They are meant to serve as a reference and guide to clinicians. However, it remains the responsibility of every clinician to evaluate the appropriateness of therapy and dosing in the context of the clinical situation of an individual patient. When dealing with new therapeutic agents, clinicians should familiarize themselves with the appropriate indications, dosing, and monitoring recommendations such as those found in the corresponding chapters in this textbook, as well as in the literature citations that are provided.

Table A1–1

	F	V_d	Protein Binding	Elim	$T_{1/2}$	Dose	PKIN Drug Interactions	Clinical Cautions	Notes	Reference
I. β-Blockers										
Acebutolol	40%	1.2 ± 0.3 L/kg	30-36%	Hepatic/renal	3-4 hr	200-1200 mg/day in 1-2 divided doses	NS		Drug has ISA	
Atenolol	50%	0.95 ± 0.15 L/kg	6-16%	Renal	6-9 hr	PO: 25-100 mg PO q.d. IV: MI (myocardial infarction) 5 mg IV over 5 min followed by another 5 mg injection 10 min later	NS		Avoid use in patients with CrCl <30 mL/min	
Bisoprolol	80%	3.2 ± 0.5 L/kg	30%	Hepatic/renal	9-12 hr	HTN: 2.5-20 mg PO q.d. CHF: 1.25 mg PO q.d. to start, increase dose q 2 wk as tolerated to target dose of 10 mg or max tolerated dose	NS	Bradycardia, conduction abnormalities, hypotension, bronchospasm, blunting of hypoglycemia response (nonselective β-blockers may delay recovery from hypo-glycemia), weight gain, decreases maximum exercise tolerance, vivid dreams, decreased libido. Avoid initiating therapy among patients with decompensated CHF.		CIBIS-II Investigators and Committees: The Cardiac Insufficiency Bisoprolol Study II (CIBIS-II). Lancet 1999;353:9-13.
Carvedilol	25-35%	1.5 ± 0.3 L/kg	95%	Hepatic (CYP 2D6 and 2C9)	7-10 hr	CHF: 3.125 mg PO b.i.d. to start, double dose q 2 wk as tolerated to target dose of 25 mg PO b.i.d. or max tolerated dose. Target dose 50 mg PO bid for patients >85 kg. HTN: 6.25 mg PO b.i.d. to start, up to 25 mg PO b.i.d. Post-MI LVD: 6.25 mg PO b.i.d. to start gradually titrated to target dose of 25 mg PO b.i.d.	Hypotensive (vasodilatory) effects may be increased by drugs that inhibit CYP 2D6: amiodarone, cimetidine, fluoxetine, haloperidol, paroxetine, propofenone, quinidine, and ritonavir. May increase serum digoxin and cyclosporine concentrations.		Take with food to minimize dizziness.	
Esmolol	N/A	1.9 ± 1.3 L/kg	55%	RBCs	9 min	Loading dose of 200-500 mcg/kg IV over 1 min, then 50-100 mcg/kg/min; titrate by 50 mcg/kg/min q 15-20 min. up to 200 mcg/kg/min	NS			

Labetalol	40%	9.4 ± 3.4 L/kg	50%	Hepatic	3-5 hr	PO: 100 mg PO b.i.d. to start; max dose of 2400 mg/day in 2-3 divided doses IV: 20 mg IV over 2 min, may give 20-80 mg at 5- to 10-min intervals up to 300 mg; CI of 0.5-2 mg/min	Cimetidine may increase oral bioavailability.	Bradycardia conduction abnormalities, hypotension, bronchospasm, blunting of hypoglycemia response (nonselective β-blockers may delay recovery from hypo-glycemia), weight gain, decreases maximum exercise tolerance, vivid dreams, decreased libido. Avoid initiating therapy among patients with decompensated CHF.		
Metoprolol	50%	4.2 ± 0.7 L/kg	12%	Hepatic (CYP 2D6)	3-4 hr	IV: (MI) 5 mg IV q 5 min × 3 doses PO: 50-400 mg/day in 2 divided doses (immediate release) or 1 dose (sustained release) CHF: metoprolol CR/XL 12.5-25 mg PO q.d., double dose q 2 wk as tolerated to target dose of 200 mg PO q.d. or max tolerated dose	Effect may be increased by the following drugs: amiodarone, cimetidine, fluoxetine, haloperidol, paroxetine, quinidine, and ritonavir.			MERIT-HF Study Group: Effect of metoprolol CR/XL in chronic heart failure: Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF). Lancet 1999;353: 2001-2007.
Nadolol	30%	1.9 ± 0.2 L/kg	30%	Renal	14-24 hr	20-320 mg PO q.d.	NS		Avoid using in patients with CrCl <30 mL/min	
Penbutolol	≈100%	ND	80-98%	Hepatic	5 hr	10-80 mg PO q.d.	NS		Drug has ISA.	
Pindolol	90%	2.3 ± 0.9 L/kg	40%	Hepatic	3-4 hr	10-60 mg/day in 2-3 divided doses	NS		Drug has ISA.	
Propranolol	35-70%	4.3 ± 0.6 L/kg	90%	Hepatic (CYP 2D6)	4 hr	PO: (immediate release) 20-320 mg/day in 2-4 divided doses PO: (sustained release) 60-320 mg/day in 1-2 divided doses. IV: 0.1 mg/kg divided into 3 doses given by slow IV push q 5 min	Effect may be increased by the following drugs: amiodarone, cimetidine, fluoxetine, haloperidol, paroxetine, quinidine, and ritonavir.

II. Nitrates										
Isosorbide dinitrate	22%; may increase with long-term use, 75% for extended release	3.9 L/kg	28%	Hepatic	1 hr (ISDN), 4.6 hr (I5MN)	PO: 10-40 mg PO t.i.d Extended release: 40-160 mg/day			A nitrate-free interval of 12 hr is desirable to minimize nitrate tolerance. Absorption is increased when taken on an empty stomach.	
Isosorbide mononitrate	93%	0.7 L/kg	Minimal	Hepatic	5 hr	Immediate release tablet: 10-20 mg PO b.i.d. (doses 7 hr apart) Extended release: 30-240 mg PO q.d.	Avoid concomitant adminstration of sildenafil, tadalafil, or vardenafil	Headache, dizziness, reflex tachycardia, orthostatic hypotension, contact dermatitis with patch		Kirsten R, Nelson K, Kirsten D, et al: Clinical pharmacokinetics of vasodilators: part 2. Clin Pharmacokinet 1998:35:9-36.
Nitroglycerin	SL = 38 ± 26% Top = 72 ± 20%	3.3 L/kg	60%	Hepatic	1-4 min	SL: 0.3-0.4 mg, up to 3 doses in 15 min Topical: 0.5-2 inches q 6-8 hr Patch: 0.2-0.8 mg/h (maintain a nitrate-free interval of 12 hr to minimize tolerance) IV: 5-10 mcg/min to start; increase by 10 mcg/min q 3-5 min until relief of angina, fall in BP or PCWP. Max dose usually 200 mcg/min, although higher doses have been used IC: 50-200 mcg for coronary vasodilation				

For abbreviations, see p. 864. For further discussion, see Chapter(s) 5-12, 14.
ISDN, isosorbide dinitrate; I5MN, isosorbide-5-mononitrate.

IIa. Additional Anti-anginal Agents										
Ranolazine	55%	ND	62%	Hepatic (CYP3A and 2D6)	7 h	500 mg PO b.i.d., may be titrated to max dose of 1000 mg PO b.i.d.	Effect of ranolazine may be increased by drugs that are potent and moderately potent inhibitors of CYP 3A which include (but is not limited to) the following: amiodarone, azole antifungals, clarithromycin, cyclosporine, diltiazem, erythromycin, grapefruit juice, imatinib, HIV protease inhibitors, verapamil. Medications that inhibit P-glycoprotein may increase the absorption of ranolazine. Ranolazine may increase digoxin concentrations.	↑ QT interval constipation, nausea, dizziness, headache	Ranolazine is contraindicated in patients taking other medications associated with prolongation of the QT interval. Ranolazine is contraindicated in patients with hepatic impairment and should not be used in patients with severe renal impairment.	Chaitman BR: Ranolazine for the treatment of chronic angina and potential use in other cardiovascular conditions. Circulation 2006; 113:2462-72.

III. Dihydropyridine Calcium Channel Blockers										
Amlodipine	60-65%	21 L/kg	93%	Hepatic (CYP 3A4)	30-50 hr	2.5-10 mg PO q.d.	Concentrations of dihydropyridine calcium channel blockers may be increased by the following: amiodarone, azole antifungals, clarithromycin, delavirdine, erythromycin, fluoxetine, fluvoxamine, grapefruit juice, metronidazole, nefazodone, protease inhibitors, zafirlukast. Concentrations may be decreased by the following: barbiturates, carbamazepine, nevirapine, phenobarbital, phenytoin, primidone, rifabutin, rifampin.	Hypotension, dizziness, flushing, headache, peripheral edema		Abernethy DR, Schwartz JB: Calcium-antagonist drugs. N Engl J Med 1999;341:1447-57.
Felodipine	20%	10 L/kg	>99%	Hepatic (CYP 3A4)	11-16 hr	2.5-20 mg PO q.d.				
Isradipine	15-24%	3 L/kg	95%	Hepatic (CYP 3A4)	8-12 hr	2.5-5 mg PO b.i.d.				
Nicardipine	35%	0.64 L/kg	95%	Hepatic (CYP 3A4)	2-4 hr	PO: (immediate release) 20-40 mg PO t.i.d. PO: (sustained release) 30-60 mg PO b.i.d. IV: (for patient previously receiving oral nicardipine) 20 mg PO q 8 hr = 0.5 mg/hr 30 mg PO q 8 hr = 1.2 mg/hr 40 mg PO q 8 hr = 2.2 mg/hr IV: (hypertansive emergency) 5-15 mg/hr				
Nifedipine	52 ± 37%	0.8 ± 0.1 L/kg	96%	Hepatic (CYP 3A4)	2-5 hr	Extended release: 30-90 mg PO q.d.				
Nimodipine	13%	1.7 L/kg	>95%	Hepatic (CYP 3A4)	1-2 hr	After subarachnoid hemorrhage: 60 mg PO q 4 hr × 21 days			Administer on an empty stomach to increase bioavailability.	
Nisoldipine	5%	4-5 L/kg	>99%	Hepatic (CYP 3A4)	7-12 hr	10-60 mg PO q.d.				

For abbreviations, see p. 864. For further discussion, see Chapter(s) 5-12, 30-40.

Table A1-1—cont'd

	F	V_d	Protein Binding	Elim	$T_{1/2}$	Dose	PKIN Drug Interactions	Clinical Cautions	Notes	Reference
IV. Nondihydropyridine Calcium Channel Blockers										
Diltiazem	40-60%	5.3 L/kg	77-93%	Hepatic	5 hr	PO: (immediate release) initially, 30-60 mg PO q 6-8 hr (max of 480 mg/day), once stable can convert to an equivalent dose of extended release PO: (extended release) 120-480 mg PO q.d. IV: (bolus dose) 0.25 mg/kg IV over 2 min, may repeat in 15 min with 0.35 mg/kg IV over 2 min IV: (infusion) 5-15 mg/h IC: 100-200 mcg for "no reflow" or "slow flow"	Inhibitor of CYP 3A4; leads to increases in concentrations of many drugs, including alprazolam, carbamazepine, cyclosporine, dihydropyridine calcium channel blockers, HMG-CoA inhibitors (atorvastatin, lovastatin, simvastatin), quinidine, warfarin, tacrolimus.	Conduction abnormalities, hypotension.	Avoid in patients with LV dysfunction. Diltiazem is contraindicated in patients taking ranolazine.	Abernethy DR, Schwartz JB: Calcium-antagonist drugs. N Engl J Med 1999;341:1447 1457.
Verapamil	20-35%	5 L/kg	90% ± 2%	Hepatic	4.5-12 hr	PO: (immediate release): 80-120 mg PO t.i.d. max dose 480 mg/days PO: (sustained release): 120-480 mg/day in 1-2 divided doses IV: (loading dose) 2.5-5 mg IV over 2-3 min, may repeat in 30 min with 5-10 mg if arrhythmia not suppressed. IC: 100-200 mcg for "no reflow" or "slow flow"	Inhibitor of CYP 3A4; leads to increases in concentrations of many drugs including alprazolam, carbamazepine, cyclosporine, dihydropyridine calcium channel blockers, HMG-CoA inhibitors, quinidine, warfarin, tacrolimus. May increase serum digoxin concentrations.	Conduction abnormalities, hypotension, constipation.	Avoid in patients with LV dysfunction. Verapamil is contraindicated in patients taking dofetilide. Verapamil is contraindicated in patients taking ranolazine.	

For abbreviations, see p. 864. For further discussion, see Chapter(s) 5-12, 19, 23.

Table A1-1—cont'd

V. Oral Antiplatelet Drugs—cont'd										
Clopidogrel	50%	ND	98%	Hepatic	8 hr (carboxylic acid derivative)	Prior to or at time of PCI: 300 mg-600 mg PO × 1 followed by 75 mg PO q.d. ACS: 300 mg PO × 1 followed by 75 mg PO q.d. Maintenance dose: 75 mg PO q.d.	NS	Rash, diarrhea, cases of thrombotic thrombocytopenic purpura have been reported. GI hemorrhage occurs less often than with aspirin.	Can be used in patients with an aspirin allergy. In the absence of a loading dose, takes 3-7 day for max platelet aggregation inhibition. If CABG planned, withhold for 5-7 days to minimize bleeding potential.	Quinn MJ, Fitzgerald DJ: Ticlopidine and clopidogrel. Circulation 1999; 100:1667-1672. Popma JJ, Berger P, Ohman EM, et al: Antithrombotic therapy during percutaneous coronary intervention: the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. Chest 2004;126 (3 Suppl): 576s-599s.
Ticlopidine	80-90%	ND	98%	Hepatic	12.6 hr after single dose; 4-5 days with repeated dosing	Post–stent placement (ideally started at least 6-24 hr prior to procedure): 500 mg PO × 1, followed by 250 mg that evening and then 250 mg PO b.i.d. Maintenance dose: 250 mg PO b.i.d.	Ticlopidine may increase concentrations of carbamazepine, phenytoin, and theophylline	Neutropenia = 2.4%; severe neutropenia = 0.8%; thrombotic thrombocytopenic purpura, rash, diarrhea, nausea, bleeding, ↑ cholesterol, cholestatic jaundice, ↑ LFTs.	CBC q 2 wk for first 3 mo of therapy. Can be used in patients with an aspirin allergy.	Quinn MJ, Fitzgerald DJ: Ticlopidine and clopidogrel. Circulation 1999; 100:1667-72.

For abbreviations, see p. 864. For further discussion, see Chapter(s) 5-12.

VI. Glycoprotein (GB) IIb/IIIa Antagonists										
Abciximab	N/A	ND	ND	Proteolytic breakdown	10-30 min; remains in circulation for at least 21 days in a platelet-bound state	PCI: 0.25 mg/kg IV bolus over 5 min given 10-60 min prior to PCI, then 0.125 mcg/kg/min (max 10 mcg/min) IV infusion for 12 hr after PCI ACS (unresponsive to standard medical therapy in whom PCI is planned within 24 hr): 0.25 mg/kg IV bolus over 5 min, followed by a 10 mcg/min IV infusion for 18-24 hr prior to PCI and continued until 1 hr after PCI (see notes)	NS	Bleeding, profound, thrombocytopenia (platelets < 50,000) = 0.4-1.1%; obtain platelet count 2-4 hr after abciximab bolus and then daily.	In ACS, an infusion for 12 hr after PCI is recommended to maximize efficacy; 6% of patients develop human antichimeric antibodies.	Lincoff AM, Califf RM, Topol EJ: Platelet glycoprotein IIb/IIIa receptor blockade in coronary artery disease. J Am Coll Cardiol 2000; 35:1103-15.
Eptifibatide	N/A	9.15 L	25%	Renal (50%)	2.5 hr	PCI (for patients with CrCl $\geq$ 50 mL/min): 180 mcg/kg bolus followed by CI of 2 mcg/kg/min and a second 180 mcg/kg bolus 10 min after the first bolus. A minimum of 12 hr of infusion is recommended. PCI (CrCl < 50 mL/min): 180 mcg/kg bolus followed by CI of 1 mcg/kg/min and a second 180 mcg/kg bolus 10 min after the first bolus. ACS (for patients with CrCl $\geq$ 50 mL/min): 180 mcg/kg bolus followed by CI of 2 mcg/kg/min ACS (CrCl < 50 mL/min): 180 mcg/kg bolus followed by CI of 1 mcg/kg/min.	NS	Bleeding, profound thrombocytopenia (platelets < 50,000) = 0-0.2%; obtain platelet count 6 hr after eptifibatide bolus and then daily.	Contra-indicated for patients on renal dialysis. Doses should be capped for patients weighing > 121 kg.	Lincoff AM, Califf RM, Topol EJ: Platelet glycoprotein IIb/IIIa receptor blockade in coronary artery disease. J Am Coll Cardiol 2000; 35: 1103-5. The PURSUIT Trial Investigators. Inhibition of platelet glycoprotein IIb/IIIa with eptifibatide in patients with acute coronary syndromes. IX. Thrombolytics										
Alteplase (tPA)	N/A	0.1 ± 0.01 L/kg	ND	Hepatic	5 min	ST-segment elevation MI: 15 mg IV bolus, followed by 0.75 mg/kg IV (up to 50 mg) over 30 min, followed by 0.5 mg/kg (up to 35 mg) over 60 min PE: 100 mg IV infusion over 2 hr Acute ischemic stroke: 0.9 mg/kg (maximum of 90 mg), give 10% initially as a bolus with the remainder given IV over 60 min	NS	Bleeding, intracranial hemorrhage.	To minimize bleeding, low-dose, weight-adjusted unfrac-tionated heparin should be used when administered with a fibrinolytic (see heparin).	The GUSTO Investigators: An international randomized trial comparing four thrombolytic strategies for acute myocardial infarction. N Engl J Med 1993;329:673-82.
Anistreplase	N/A	0.084 ± 0.027 L/kg	ND	Hepatic	1.2 ± 0.4 hr	ST-segment elevation MI: 30 U IV over 2-5 min	NS	Bleeding, intracranial hemorrhage, allergic reactions (similar to streptokinase).	Adjunct IV heparin is associated with increased bleeding and no improve-ment in outcome; therefore, reserve for patients at high risk or systemic or venous thrombo-embolism. If indicated, without a bolus, 6 hr after anistreplase, once aPTT is less than twice control value. Same allergic profile as streptokinase.	

Reteplase (rPA)	N/A	6 L	ND	Hepatic/ renal	13-16 min	ST-segment elevation MI: 10 units IV over 2 min, repeat × 1 dose in 30 min	NS	Bleeding, intracranial hemorrhage.		Martin U, Von Molendorff E, Akpan W: Pharmacokinetic and hemostatic properties of recombinant plasminogen activator BM 06.022 in healthy volunteers. Thromb Haemost 1991;66:569-74. The GUSTO-III Investigators: A comparison of reteplase with alteplase for acute myocardial infarction. N Engl J Med 1997;337: 1118-23.

IX. Thrombolytics—cont'd										
Streptokinase	N/A	0.08 ± 0.04 L/kg	ND	Reticuloendothelial system	83 min	ST-segment elevation MI: 1.5 MU IV over 60 min PE/DVT: 250,000 units IV over 30 min, followed by 100,000 U/hr for 24-72 hr Thrombosis: 250,000 units IV over 30 min, followed by 100,000 U/hr for 72 hr	N/A	Bleeding, intracranial hemorrhage. hypotension, allergic reactions.	If indicated, heparin is initiated without a bolus, 6 hr after the infusion of streptokinase once aPTT is less than twice control value. Use with caution in patients with previous exposure to streptokinase or anistreplase or recent streptococcal infection. Slowing the rate of infusion may minimize hypotension.	The GUSTO Investigators: An international randomized trial comparing four thrombolytic strategies for acute myocardial infarction. N Engl J Med 1993;329:673-82.

Tenecteplase	N/A	~Plasma volume	ND	Hepatic	Biphasic: initial = 20 min, terminal = 90-130 min	ST-segment elevation MI: IV bolus over 5-10 sec. Weight-based dosing: 30 mg if < 60 kg, 35 mg if 60-69 kg, 40 mg if 70-79 kg, 45 mg if 80-89 kg, 50 mg if ⩾ 90 kg. Total dose should not exceed 50 mg	NS	Bleeding (may cause fewer noncerebral bleeds and need for transfusion compared with alteplase), intracranial hemorrhage.		Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT-2) Investigators: Single-bolus tenecteplase compared with front-loaded alteplase in acute myocardial infarction: The ASSENT-2 double-blind randomised trial. Lancet 1999;354:716-22.

Table A1-1—cont'd

	F	V_d	Protein Binding	Elim	$T_{1/2}$	Dose	PKIN Drug Interactions	Clinical Cautions	Notes	Reference
XV. Antiarrhythmic Agents										
Adenosine	N/A	ND	ND	Cellular uptake and degradation	<10 sec	6 mg IV over 1-2 sec, if ineffective 12 mg can be given 2 min later and repeated again if necessary	Dipyridamole enhances pharmacologic effect of adenosine. Theophylline and caffeine inhibit the therapeutic actions of adenosine.	Chest discomfort, dyspnea, flushing, headache.		
Amiodarone	50%	66 L/kg	96%	Hepatic	~50 days	Atrial fibrillation (oral): 600-1200 mg/day × 1-2 wk, then 400 mg/day × 1 mo then 200 mg/day Ventricular arrhythmias (oral): 800-1600 mg/day × 1-3 wk, then 600-800 mg/day × 1 mo, then 400 mg/day VT: 150 mg IV over 10 min followed by 1 mg/min IV CI for 6 hr followed by 0.5 mg/min thereafter. Additional 150-mg doses can be given for recurrent arrhythmias. VF (pulseless VT): 300 mg IV bolus. If VF/pulseless VT recurs, consider administration of a second dose of 150 mg. IV infusion may be used with dosing as provided earlier. Serum drug concentration: 0.5-2.5 mcg/mL, although not well correlated with therapeutic or toxic effects.	Potent inhibitor of CYP P450 enzymes, increase concentrations of many drugs including alprazolam, carbamazepine, cyclosporine, dihydropyridine calcium channel blockers, digoxin, HMG-CoA inhibitors (atorvastatin, lovastatin, simvastatin), phenytoin, procainamide, quinidine, tacrolimus, triazolam, and warfarin.	Hypersensitivity pneumonitis, pulmonary alveolitis, sinus bradycardia, conduction abnormalities, ↑ QT interval, torsades de pointes (<1%), thyroid abnormalities, corneal deposits, optic neuritis, tremor, ataxia, peripheral neuropathy, blue-gray skin discoloration, photosensitivity, nausea, ↓ appetite, ↑ LFT.	Maximum IV daily dose = 2000 mg.	Hilleman D, Miller MA, Parker R, et al: Optimal management of amiodarone therapy: Efficacy and side effects. Pharmacotherapy 1998;18:138S-45S.
Disopyramide	80-90%	1.4-1.7 L/kg	50-65%	Renal/ hepatic (CYP 3A4)	6-9 hr, 12-43 hr in RI	Immediate release: Initially 150 mg PO q 6 hr (150 mg PO q 12 hr in moderate RI; 150 mg q 24 hr in severe RI), then increase to 200-300 mg PO q 6 hr (150-300 mg q 12-24 hr in RI) Serum drug concentration: 3-6 mcg/mL	Effects of disopyramide may be increased in patients receiving drugs that inhibit CYP 3A4. Effects of disopyramide may be decreased in patients receiving drugs that are inducers of CYP 3A4.	Anticholinergic (dry mouth, urinary retention, constipation, blurred vision), exacerbation of CHF, QT prolongation, bradycardia, conduction abnormalities.	To convert to the sustained-release product: divide the total daily dose of immediate release product by 2 and give q 12 hr.

Table A1-1—cont'd

	F	V_d	Protein Binding	Elim	$T_{1/2}$	Dose	PKIN Drug Interactions	Clinical Cautions	Notes	Reference
XV. Antiarrhythmic Agents—cont'd										
Dofetilide	~90	~3 L/kg	64%	Renal/hepatic (CYP 3A4)	8 hr	Patients with a CrCl >60 mL/min should receive a one-time 500 mcg dose. 2-3 hr after administering the dose, the patient's QTc should be measured. If no significant QTc prolongation is observed, the drug should be continued at 500 mcg PO b.i.d. If QTc increases by > 15% or if QTc exceeds 500 msec, (550 msec in patients with ventricular conduction abnormalities) the drug should be administered at 250 mcg PO b.i.d. CrCl (mL/min) 40-60: starting dose = 250 mcg PO b.i.d. If QTc increases by > 15% or exceeds 500 msec (550 msec in patients with ventricular conduction abnormalities) (after first dose), adjust dose to 125 mcg PO b.i.d. CrCl (mL/min) 20-39: starting dose = 125 mcg PO b.i.d. If QTc increases by >15% or exceeds 500 msec (550 msec in patients with ventricular conduction abnormalities) (after first dose), adjust dose to 125 mcg PO q.d. See notes for additional dosing/monitoring information.	Contraindicated with cimetidine, ketoconazole, megestrol acetate, prochlorperazine, trimethoprim, and verapamil secondary to inhibition of dofetilide tubular secretion. Contraindications with hydrochloro-thiazide due to risk of increased dofetilide concentrations and prolonged QTc. Amiodarone: Patients previously receiving amiodarone may be changed to dofetilide when amiodarone has been discontinued for 3 mo or there is documentation of an amiodarone serum concentration <0.3 mcg/mL. Class I or class III antiarrhythmics (excluding amiodarone): Dofetilide should not be started until 3 half-lives of the previous medication have passed. Avoid inhibitors of CYP 3A4.	Torsades de pointes (3%), dofetilide is contraindicated in patients with CrCl <20 mL/min or if base line QTc exceeds 440 ms (or if baseline QTc >500 msec in patients with ventricular conduction abnormalities)	When starting therapy or increasing dose, patients need to be hospitalized for at least 3 days for continuous ECG monitoring. With each succeeding dose during hospitalization, the patient's QTc should be measured 2-3 hr after drug administration. If at any point after the second dose the patient's QTc >500 msec (or if QTc >550 msec in patients with ventricular conduction abnormalities), dofetilide therapy should be terminated.	Kalus JS, Mauro VF: Dofetilide: A class III-specific antiarrhythmic agent. Ann Pharmacother 2000;34:44-56.

Flecainide	95%	8-10 L/kg	30-40%	Hepatic (CYP 2D6)/ renal	7-23 hr, may be pro-longed to 60 hr in elderly people, CHF, hepatic disease, or severe RI	Initially, 50-100 mg PO q 12 hr (50-100 mg PO q 24 hr in elderly, CHF, hepatic disease, or severe RI) and increase dose by 50-100 mg/day q 3-7 day depending on ECG findings. Max dose = 300-400 mg/day Serum drug concentration: 0.2-1 mcg/mL	Flecainide concentrations may be increased by the following drugs: amiodarone, cimetidine, fluoxetine haloperidol, paroxetine, quinidine, and ritonavir. Flecainide may increase serum digoxin concentrations.	Dizziness, visual disturbances, headache, proarrhythmic activity.		
Ibutilide	N/A	11 ± 4 L/kg	40%	Hepatic	6 hr	1 mg IV over 10 min (0.01 mg/kg for patients < 60 kg). Dose may be repeated in 10 min if no response	NS	Nausea, ↑ QT interval, torsades de pointes (1.7%); incidence of torsades de pointes may be increased in patients with CHF.	Patient should be monitored for pro-arrhythmias for at least 4 hr after a dose is given.	Cropp JS, Antal EG, Talbert RI: Ibutilide: A new class III antiarrhythmic agent. Pharmacotherapy 1997;17:1-9.
Lidocaine	N/A	1.1 L/kg (reduced in CHF and hepatic disease)	60-80%	Hepatic (CYP 3A4)	1.5-2 hr, 4-12 hr with cirrhosis or CHF	75 mg IV loading dose followed by 50 mg IV q 5 min × 3 (total dose 225 mg). Decrease loading dose for CHF or hepatic dysfunction. Infusion of 2 mg/min (1 mg/min in patients with moderate LVD, 0.5 mg/min in patients with shock, severe LVD, or significant hepatic dysfunction) Serum drug concentration: 2-5 mcg/mL	Drugs that inhibit CYP 3A4 may increase the effects of lidocaine.	Bradycardia, conduction abnormalities, dizziness, drowsiness, paresthesias, muscle twitching, confusion, vertigo, seizures (neurologic adverse effects are concentration related).

Table A1-1—cont'd

	F	V_d	Protein Binding	Elim	$T_{1/2}$	Dose	PKIN Drug Interactions	Clinical Cautions	Notes	Reference
XV. Antiarrhythmic Agents—cont'd										
Mexiletine	90%	6.6-10.8 L/kg	70%	Hepatic (CYP 2D6)	8-15 hr	Initially, 200 mg PO q 8 hr and increase dose q 1-3 day by 50 mg q 8 hr. Max dose = 900-1200 mg/day Serum drug concentration: Not well correlated with therapeutic or toxic effects	Mexiletine concentrations may be increased by the following drugs: amiodarone, cimetidine, fluoxetine, haloperidol, paroxetine, quinidine, and ritonavir.	Tremor, ataxia, confusion, paresthesias, rarely psychosis or seizures, proarrhythmic activity.	Take with food or antacid to reduce GI distress.	
Moricizine	35-45%	5.9-11.6 L/kg	95%	Hepatic/ renal	3-4 hr, in-creased in RI	Initially 200 mg PO q 8 hr and increase dose in 3- to 5-day intervals to 250 mg PO q 8 hr, then 300 mg PO q 8 hr depending on ECG changes and side effects Serum drug concentration: Not well correlated with therapeutic or toxic effects	May decrease theophylline concentrations. Cimetidine may increase moricizine concentrations.	Nausea, anorexia, dizziness, proarrhythmic activity, worsening of baseline conduction disturbances.		
Procainamide	70-85%	2.5 L/kg	15-25%	Renal/hepatic (active metabolite, NAPA–primarily renally eliminated)	Procain-amide: 4 hr (no RI), 8-24 hr (RI) NAPA: 8 hr (no RI), 12-70 hr (RI)	(IV/PO): Loading dose: no RI: 17 mg/kg, mild RI: 15 mg/kg, severe RI (CrCl <20 mL/min): 13 mg/kg Maintenance dose: no RI: 3 mg/kg/hr mild RI: 2 mg/kg hr severe RI (CrCl <20 mL/min): 1 mg/kg/hr Serum drug concentration: 4-10 mcg/mL (procainamide); <25 mcg/mL (NAPA)	Procainamide concentrations may be increased by the following drugs: amiodarone, cimetidine, ranitidine, trimethoprim.	Hypotension (parenteral administration), ↑QT interval, torsades de pointes, ↑QRS, ↑PR, drug-induced lupus.	Dose is based on total body weight. Infuse loading dose over 30-60 min. When converting IV to PO, stop IV infusion 4 hr after first oral sustained-release dose.	Nolan PE: Pharmacokinetics and pharmaco-dynamics of intravenous agents for ventricular arrhythymias. Pharmacotherapy 1997;17:65S-75S.
Propafenone	25-75%	3.6 ± 2.6 L/kg	85-95%	Hepatic (CYP 1A2, 2D6, 3A4)	2-32 hr	Extended-release capsule: Initiate with 225 mg PO q 12 hr and increase dose in 5-day intervals to 325 mg q 12 hr then 425 mg q 12 hr depending on ECG. 150 mg PO q 8 hr and increase dose in 3- to 5-day intervals to 225 mg PO q 8 hr then 300 mg PO q 8 hr depending on ECG changes Serum drug concentration: Not well correlated with therapeutic or toxic effects	May decrease the metabolism of warfarin (monitor) INR); may increase serum digoxin concentrations	Metallic taste, dizziness, worsening of asthma, proarrhythmic activity, syndrome of inappropriate antidiuretic hormone.	150 mg q 8 hr of immediate release tablets produces similar con-centrations as 325 mg q 12 of sustained release capsules	

Quinidine	60-80%	2.7 ± 1.2 L/kg (reduced in HF)	80%	Hepatic (CYP 3A4)/ renal	6 hr (increases up to 12 hr in elderly patients and those with hepatic disease)	Maintenance Sulfate (IR): ≤65 y: 600 mg PO q 6 hr >65 y: 300 mg PO q 6 hr severe renal impairment: 200 mg PO q 8 hr Sulfate (SR): ≤65 y: 600 mg PO q 8 hr >65 y: 300 mg PO q 8 hr severe renal impairment: 300 mg PO q 12 hr Gluconate (SR) ≤65y: 648 mg PO q 8 hr >65 y: 324 mg PO q 8 hr severe renal impairment: 324 mg PO q 12 hr Serum drug concentration: 2-6 mcg/mL	Quinidine is an inhibitor of CYP 2D6 and may increase the effect of the following drugs: amitryptyline, clozapine, codeine, desipramine, doxepin, fluoxetine haloperidol, imipramine, meperidine, metoprolol, morphine, oxycodone, paroxetine, perphenazine, propranolol, risperidone, thioridazine, tramadol, trazodone, and venlafaxine. Quinidine may increase digoxin and amiodarone concentrations. Drugs that inhibit CYP 3A4 may increase the effects of quinidine.	Cinchonism, ↑ QR interval, torsades de pointes, drug fever, pruritus, rash, thrombocytopenia.		Grace AA, Camm AJ: Quinidine. N Engl J Med 1998;338:35-44.

	F	V_d	Protein Binding	Elim	$T_{1/2}$	Dose	PKIN Drug Interactions	Clinical Cautions	Notes	Reference
XV. Antiarrhythmic Agents—cont'd										
Sotalol	90-100%	1.2-2.4 L/kg	Not bound	Renal	8-20 hr (up to 40 hr in severe RI)	Atrial fibrillation or atrial flutter: patients should be in a monitored setting for a min of 3 day on their maintenance dose, 80 mg PO b.i.d. (80 mg PO q.d., if CrCl = 40-60 mL/min). QT interval should be checked 2-4 hr after each dose. If the QTc is <500 msec after the patient has received 5-6 doses, then the patient can be discharged. Alternatively during hospitalization, the dose can be increased to 120 mg PO b.i.d. (120 mg PO q.d. if CrCl = 40-60 mL/min) and the patient followed for 5-6 doses. Max dose = 160 mg PO b.i.d. (160 mg PO q.d. if CrCl = 40-60 mL/min). Ventricular arrhythmias: During initiation and titration QT interval should be monitored 2-4 hr after each dose. Patients should be in a monitored setting for at least 3 days (or 5-6 doses if dosing is once daily) after dosage titration. 80 mg PO b.i.d initially (80 mg PO q.d if CrCl 30-60 mL/min). If necessary, the dose may be increased to 240-320 mg/day (120-160 mg/day if CrCl 30-60 mL/min). Doses as high as 480-640 mg/day should only be used when potential benefit outweighs risk of adverse events.	NS	Bradycardia, conduction disturbances, bronchospasm, exacerbation of CHF, ↑ QT interval, torsades de pointes.	Use for atrial arrhythmias is contraindicated in patients with CrCl <40 mL/min or in patients with baseline QTc interval >450 msec. When sotalol is being used for atrial arrhythmias, dose should be decreased or the drug discontinued if the QTc prolongs to ≥ 500 msec. When being used for ventricular arrhythmias, the sotalol dose should be decreased or the drug discontinued if the QTc prolongs to ≥ 550 msec. Most cases of torsades de pointes occur within 3 days of initiating therapy; incidence of torsades de pointes is dose related.	Bauman JL: Class III antiarrhythmic agents: The next wave. Pharmacotherapy 1997;17:76S-83S.

Reference for antiarrhythmic agents section: Kowey PR: Pharmacological effects of antiarrhythmic drugs. Review and update. Arch Intern Med 1998;158:325-32.
For abbreviations, see p. 864. For further discussion, see Chapter 19.

Table A1-1—cont'd

XVI. HMG-CoA Reductase Inhibitors										
Atorvastatin	12%	381 L	98%	Hepatic (CYP 3A4)	14 hr	10-80 mg PO q.d.	Serum concentrations of atorvastatin, lovastatin, and simvastatin may be ***increased*** by the following drugs: amiodarone, cimetidine, clarithromycin, cyclosporine, delavirdine, diltiazem, erythromycin, fluoxetine, fluconazole, fluvoxamine, grapefruit juice, indinavir, itraconazole, ketoconazole, nefazodone, nelfinavir, ranolazine, ritonavir, saquinavir, tacrolimus, verapamil, zafirlukast. Serum concentrations of atorvastatin, cerivastatin, lovastatin, and simvastatin may be ***decreased*** by the following drugs: barbiturates, carbamazepine, phenobarbital, phenytoin, primidone, rifabutin, rifampin.	Gastrointestinal upset, headaches, myalgias, ↑ creatine kinase, ↑ LFTs, rash, insomnia, nightmares. Contraindicated in pregnancy and in nursing mothers.	Can be taken any time of day because of long half-life.	
Lovastatin	5%	ND	>95%	Hepatic (CYP 3A4)	2 hr	10-80 mg daily (in 1-2 divided doses)			Bioavailability increased by administration with food; take with evening meal. Dose should not exceed 20 mg/day in patients taking fibric acid derivatives, niacin, or cyclosporine. Dose should not exceed 40 mg/day in patients taking amiodarone or verapamil.	Knopp RH: Drug treatment of lipid disorders. N Engl J Med 1999;341:498-511.
Simvastatin	5%	ND	95%	Hepatic (CYP 3A4)	1-2 hr	5-80 mg PO q.d.			Take in the evening. In patients taking gemfibrozil or cyclosporine, the simvastatin dose should not exceed 10 mg/day. In patients

XVI. HMG-CoA Reductase Inhibitors—cont'd										
									taking amiodarone or verapamil the simvastatin dose should not exceed 20 mg/day.	
Pravastatin	17%	0.46 L/kg	43-55%	Hepatic (sulfation)	1-2 hr	10-40 mg PO q.d.	NS	Gastrointestinal upset, headaches, myalgias, ↑ creatine kinase, ↑ LFTs, rash, insomnia, nightmares. Contraindicated in pregnancy and in nursing mothers.	Take in the evening. Food decreases absorption.	Knopp RH: Drug treatment of lipid disorders. N Engl J Med 1999; 341:498-511.
Fluvastatin	20-30%	0.42 L/kg	98%	Hepatic (CYP 2C9)	1.2 hr	Immediate release: 20-80 mg/day in 1-2 divided doses Extended release: 80 mg PO q.d.	Serum concentrations of fluvastatin may be increased by the following drugs: amiodarone, cimetidine, fluconazole, fluoxetine, fluvoxamine, itraconazole, ketoconazole, metronidazole, ticlopidine, zafirlukast. Serum concentrations of fluvastatin may be decreased by the following drugs: barbiturates, carbamazepine, phenobarbital, phenytoin, primidone, rifabutin, rifampin. Fluvastatin may increase the effect of warfarin.		Take in the evening.	

Rosuvastatin	20%	134 L	88%	Feces	19 hr	5-40 mg PO q.d.	Rosuvastatin concentrations may be increased by cyclosporine, gemfibrozil, and itraconazole. Rosuvastatin absorption may be decreased by antacids (administer rosuvastatin at least 2 hr before antacid) Rosuvastatin may increase the effect of warfarin	Same clinical cautions as listed for other HMG CoA reductase inhibitors.	Consider 5 mg PO q.d. as initial dose in Asian patients and patients with CrCl <30 mL/min. Dose should not exceed 10 mg/day for patients taking gemfibrozil. Dose should not exceed 5 mg/day for patients taking cyclosporine.	

For abbreviations, see p. 864. For further discussion, see Chapter(s) 26, 27.

XVII. Bile Resins										
Cholestyramine	Not absorbed from GI tract	N/A	N/A	Feces	N/A	4-16 g/day in 1-4 divided doses (max = 24 g/day)	Binds numerous medications. Resins should be administered at least 2 hr before or 6 hr after warfarin, theophylline, digoxin levothyroxine, and HMG-CoA reductase inhibitors.	Constipation, bloating, flatulence, impaired absorption of fat-soluble vitamins, ↑ triglycerides.	Mix each packet or scoop with 2-6 oz fluid.	Knoop RH: Drug treatment of lipid disorders. N Engl J Med 1999;341:498-511.
Colestipol	Not absorbed from GI tract	N/A	N/A	Feces	N/A	Granules: 5 g b.i.d. initially, increasing to a max of 30 g/day in 1-4 divided doses Tablets: 2 g b.i.d. initially, increasing to a max of 16 g/day in 1-4 divided doses			Mix granules with 2-6 oz fluid.	
Colesevelam	Not absorbed from GI tract	N/A	N/A	Feces	N/A	1.9 g (3 tabs) PO b.i.d. or 3.8 g (6 tabs) PO q.d. (max = 7 tabs/day)	Colesevelam may reduce verapamil concentrations. Colesevelam may be administered concurrently with HMG-CoA reductase inhibitors.	Constipation and dyspepsia. May impair vitamin K absorption	Take each dose with a meal.	

For abbreviations, see p. 864. For further discussion, see Chapter(s) 26, 27.

Table A1-1—cont'd

	F	V_d	Protein Binding	Elim	$T_{1/2}$	Dose	PKIN Drug Interactions	Clinical Cautions	Notes	Reference
XVIII. Fibric Acid Derivatives										
Fenofibrate	60-90%	0.9 L/kg	>99%	Renal	20 hr (prolonged with renal dysfunction)	Tablet (Tricor): 48 mg PO q.d. to start maximum dose = 145 mg/day Tablet (Triglide™): 50 mg PO q.d. to start maximum dose = 160 mg/day Micronized capsule (Lofibra): 67 mg PO q.d. to start maximum dose = 200 mg/day (take with meal) Micronized capsule (Antara): 43 mg PO q.d. to start maximum dose = 130 mg/day (take with meal)	Risk of myopathy is increased when administered concomitantly with HMG-CoA reductase inhibitors. May increase the effects of warfarin through protein binding displacement.	Dyspepsia, abdominal pain, diarrhea, cholelithiasis, ↑ LFTs. Use with caution if CrCl < 50 mL/min.	Absorption is increased when taken with food.	Balfour JA, McTavish D, Heel RC: Fenofibrate: A review of its pharmaco-dynamic dynamic and pharmacokinetic properties and therapeutic use in dyslipidaemia. Drugs 1990;40: 260–90.
Gemfibrozil	98%	0.14 L/kg	97%	Hepatic/ renal	1.5-2 hr	600 mg PO b.i.d.			Use with caution in patients with CrCl <50 mL/min. Contra-indicated in patients with severe renal dysfunction.	Knopp RH: Drug treatment of lipid disorders. N Engl J Med 1999;341: 498–511.

For abbreviations, see p. 864. For further discussion, see Chapter(s) 26, 27.

Appendix 2

Pacemakers and Implantable Cardioverter-Defibrillators

William H. Maisel

Pacemaker (PM) and implantable cardioverter-defibrillator (ICD) systems consist of a pulse generator and electrodes (leads). Devices may be single chamber, dual chamber, or biventricular. Chest roentgenogram appearance of typical PM and ICD systems is shown in Figure A2–1.

PART A—PACEMAKERS

Leads

A variety of pacing leads are commercially available. They vary with respect to fixation mechanism, insulation type, configuration (unipolar versus bipolar), and connector type (Table A2–1). *Lead impedance* may be used as a measure of lead integrity. A low lead impedance may be due to an insulation defect, while high lead impedances may indicate a lead fracture.

Basic Pacing Concepts

Stimulation threshold is the minimum electrical stimulus necessary to consistently capture the heart outside of the heart's refractory period. The threshold can be described by the "strength-duration curve" (Fig. A2–2), which plots amplitude (measured in volts) versus pulse width (measured in msec). Values on or above the curve will result in capture. Pacing at an output below threshold will result in *failure to capture* (Fig. A2–3). This should be distinguished from *no output* conditions (such as those due to a depleted pulse generator battery), where no pacing artifact is present.

Sensing is the ability of the pacemaker to detect the heart's intrinsic rhythm. *Intrinsic amplitude* refers to the size (measured in millivolts) of the detected electrical signal from the atrium or ventricle. *Sensitivity* is a programmable setting above which electrical signals will be interpreted as cardiac in origin and below which electrical signals will be ignored (Fig. A2–4). *Undersensing* is the failure of the pacemaker to detect the intrinsic cardiac electrical signal (see Fig. A2–4). *Oversensing* is the sensing of an inappropriate signal (either physiologic or nonphysiologic) (see Fig. A2–4). Table A2–2 lists some potential sources of electromagnetic interference that can cause oversensing. A magnet, when placed over a pacemaker, disables the pacemaker's ability to sense, resulting in continuous "asynchronous" pacing.

Pacemaker Programming Considerations

Mode—The programmable pacing mode determines in which chambers the pacemaker paces and senses and how it responds to sensed signals (Table A2–3).[1] Examples of the potential ECG appearance of proper dual chamber pacing are shown in Figure A2–5.

Rate Responsive Pacing—This is designed to result in an increase in heart rate proportional to an increase in metabolic demand. It is typically used for patients with sick sinus syndrome. A variety of sensors are available for detecting increases in metabolic demand (Table A2–4).

Pseudo Pacemaker Malfunction

There are a number of programming features that may result in the appearance of pacemaker malfunction, i.e. the pacemaker failing to pace at the programmed rate (Table A2–5).

PART B—IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

Like pacemakers, ICDs can be single chamber, dual chamber, or biventricular (see Fig. A2–1). An ICD system can be distinguished from a pacemaker system by the presence of one or two shocking coils (see Fig. A2–1). ICD generators consist of a battery, a capacitor, circuitry, and the device housing or "can."

Programmed Therapies for Ventricular Arrhythmias

ICDs continuously monitor the patient's heart rate. When prespecified, programmable detection criteria are met, the device delivers therapy to restore the patient's rhythm back to normal. Therapies are programmed according to heart rate or "zones." Each zone is programmable and specifies the heart rate range and duration of arrhythmia required before declaring an arrhythmia present and initiating delivery of therapy (Table A2–6).

ICDs can deliver two types of therapies to terminate ventricular arrhythmias: high-voltage therapies (i.e., shocks) or anti-tachycardia pacing (ATP). High-voltage shocks (typically 30 to 40 J maximum) are usually delivered from the ICD and SVC coil to the RV coil, although alternate shocking configurations may be used (Fig. A2–6). Modern devices deliver biphasic shocks (energy flow reverses direction during delivery), which are more energy efficient than older devices that delivered monophasic shocks. Some devices also allow for programming of the tilt (the drop in voltage during discharge), with 50% and 65% being the values most commonly used. ATP may be used to painlessly terminate ventricular

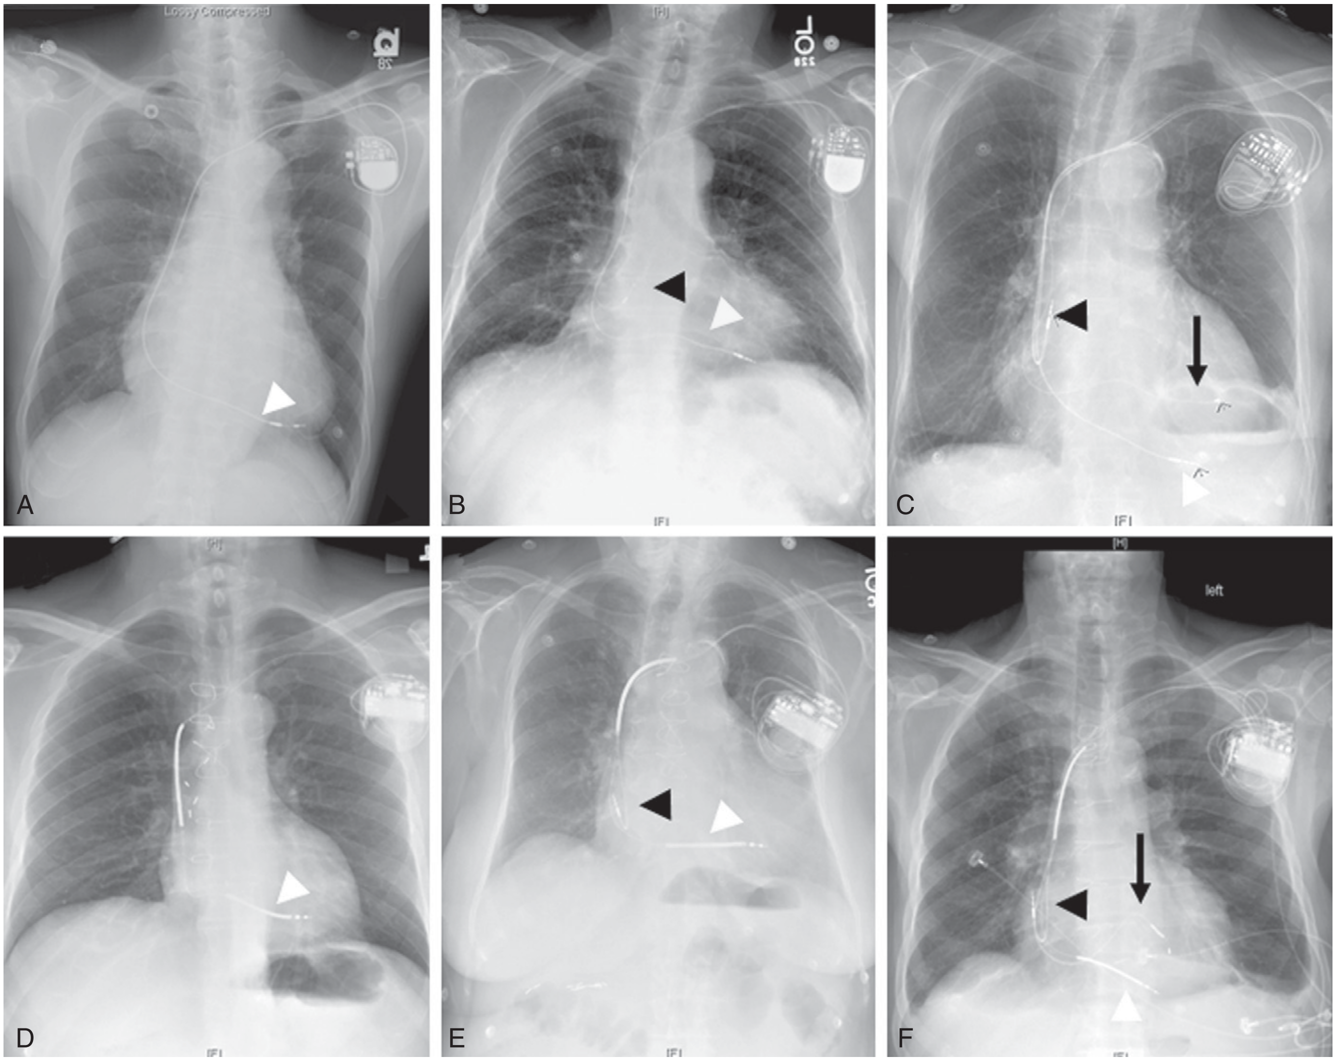

Figure A2–1 Chest roentgenogram appearance of standard pacemaker and implantable cardioverter-defibrillator (ICD) systems is shown. **A,** Single-chamber pacemaker; **B,** Dual-chamber pacemaker; **C,** Biventricular pacemaker; **D,** Single-chamber ICD; **E,** Dual-chamber ICD; **F,** Biventricular ICD. Single-chamber systems consist of a right ventricular (RV) electrode *(white arrowhead).* Dual chamber systems have a right atrial *(black arrowhead)* and RV electrode, while biventricular systems have a third lead positioned in the coronary sinus *(black arrow).*

tachycardia, typically by delivering 6 to 10 paced beats at a rate slightly faster than the tachycardia. ATP is successful at terminating even rapid VT up to 80% of the time.[2] A typical example of ICD programmed zones and therapies is displayed in Table A2–5.

The defibrillation threshold (DFT) or upper limit of vulnerability is tested in each ICD patient at implant and at intervals thereafter.[3] This value is the amount of energy required to terminate ventricular fibrillation and restore sinus rhythm. The maximum device output should be 7 to 10 J above the DFT or ULV to allow reliable defibrillation under clinical conditions.[4] A number of medications can affect the DFT, most notably antiarrhythmia drugs (Table A2–7).[5]

Magnet Operation

All modern ICDs are also pacemakers and, as such, they have the ability to treat not only rapid heart rhythms but slow ones as well. ICDs differ from pacemakers, however, in their response to magnet application. Although pacemakers revert to asynchronous pacing in the presence of a magnet, ICDs do not. For most ICDs, magnets deactivate tachyarrhythmia detection (sensing) while the magnet is directly over the device. Removal of the magnet restores device function to normal.

"Inappropriate Shocks"

An inappropriate shock is the delivery of a shock to the patient for a reason other than a sustained ventricular arrhythmia. Rapid heart rates of nonventricular origin (sinus tachycardia or atrial fibrillation with a rapid ventricular response rate) resulting in ICD shocks occur in 12% of ICD patients.[6] Environmental noise or "noise" due to a lead abnormality (insulation breech or lead fracture) may also lead to inappropriate shocks.

Table A2–1 Pacing Electrode Features

Type	Comment
Fixation Mechanism	
Transvenous, passive fixation	Tines become lodged in trabeculations. Lower pacing threshold, higher dislodgement rate.
Transvenous, active fixation	Helix or screw extends into endocardial tissue to secure lead. Higher pacing thresholds, lower dislodgement rate.
Epicardial	Surgically implanted on outer surface of heart. Typically higher pacing thresholds. May be used for patients with mechanical tricuspid valve, those with difficult coronary sinus access requiring LV pacing, or those requiring PM undergoing concurrent cardiac surgery.
Insulation	
Polyurethane	Easier to pass, more rigid, less durable, thinner.
Silicone	Higher coefficient of friction, therefore less "slippery," less rigid, more durable, thicker.
Configuration	
Unipolar	Sensing and pacing between the lead tip (distal electrode) and the pacemaker pulse generator. Bigger "antenna," therefore more prone to oversensing.
Bipolar	Sensing and pacing between two electrodes separated by several millimeters (proximal and distal) located on a single lead. Smaller "antenna," therefore less prone to oversensing.
Connector Type	
IS-1 bipolar, IS-1 unipolar, 3.2 mm C, 3.2 mm LP, 4.75 mm, 4.75 mm bifurcated, 5 mm UNI, 5 mm, 5 mm bifurcated, 5/6 mm UNI, 6 mm bifurcated, 6 mm linear bipolar, 6.1 mm, 6.5 mm, VS-1, VS-1A, VS-1B	Lead connector and generator header must be compatible. IS-1 is most common connector in use today.

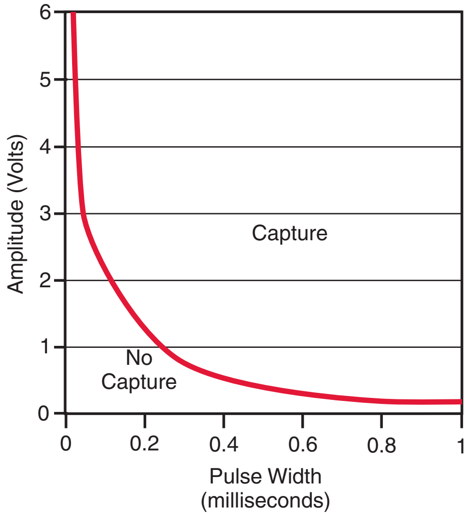

Figure A2–2 A strength-duration curve is shown. It describes the relationship between the amplitude (in volts) and the pulse width (in milliseconds). Values on or above the curve result in capture. Values below the curve will result in failure to capture.

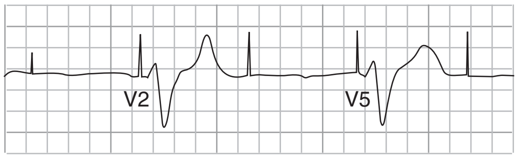

Figure A2–3 An example of intermittent failure to capture is shown. Pacing spikes can be seen marching steadily through the tracing, but every other beat fails to elicit ventricular depolarization. This can occur due to elevated pacing thresholds, a low programmed pacemaker output, a depleted pulse generator battery, lead abnormality, or a prolonged refractory period.

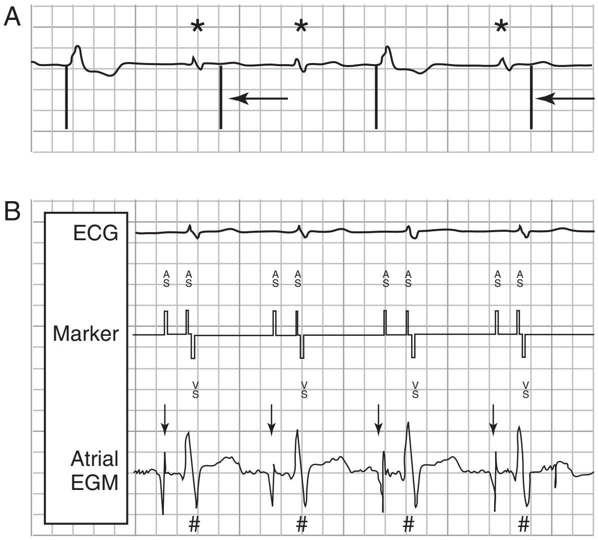

Figure A2–4 **A,** Undersensing of the QRS complex is demonstrated. The first and fourth QRS complexes are ventricular-paced beats. Native QRS complexes (*), however, are not appropriately sensed, resulting in a failure to inhibit pacing. As a result, inappropriate ventricular pacing spikes are present (←). Because they occur in the ventricular refractory period, they result in failure to capture. Reprogramming the pacemaker to a more sensitive setting overcame this problem. The pacing threshold was not elevated. **B,** Atrial oversensing is present. The atrial electrogram (EGM) *(bottom)* obtained during routine pacemaker interrogation demonstrates sensing of the intrinsic atrial signal (↓) and "far-field" oversensing of the ventricular signal (#). This is confirmed by the marker channel (AS = atrial sensed event, VS = ventricular sensed event).

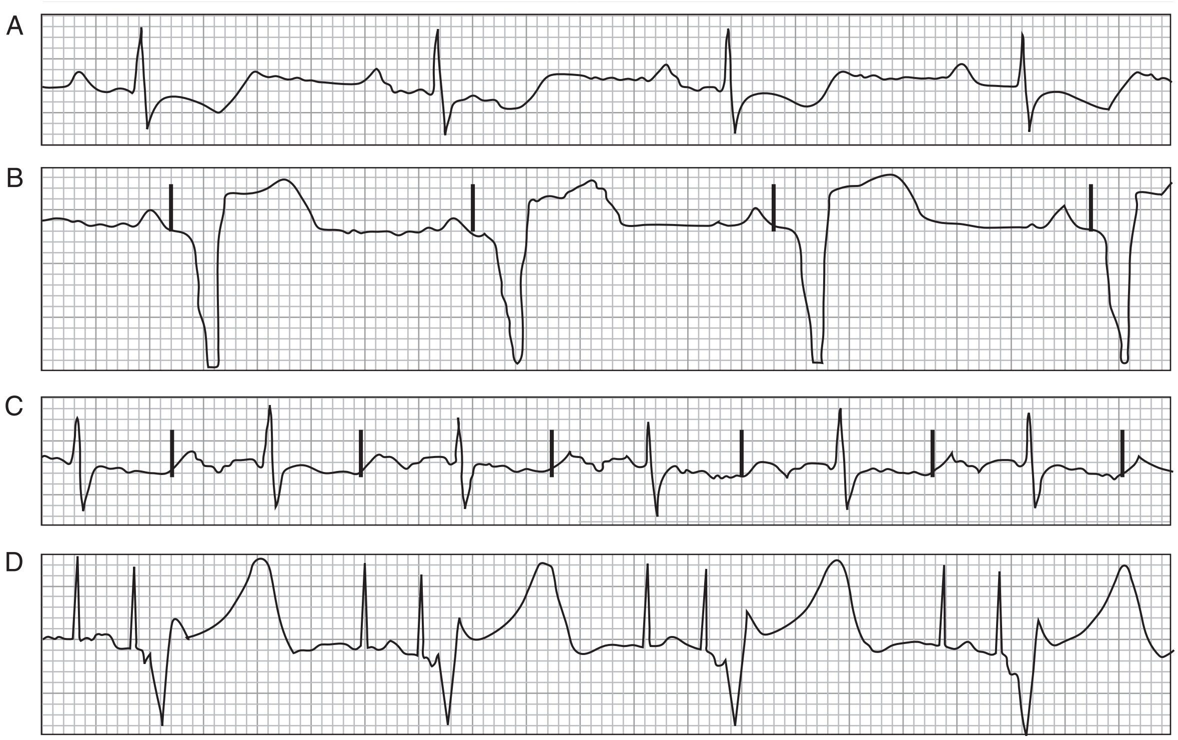

Figure A2–5 Examples of the potential ECG appearance of proper dual-chamber pacing are shown. **A,** Sinus rhythm without pacing. **B,** Sinus rhythm with ventricular pacing. **C,** Atrial pacing with intact atrioventricular conduction. **D,** Dual-chamber pacing.

Table A2–4 Sensors for Rate Responsive Pacing

Type of Sensor	Description	Comments
Motion/activity sensor	**Detects physical movement and increases rate according to level of activity.**	**Brisk response to exercise but does not respond well to other physiologic stresses, such as emotional stress.**
Examples:		
Piezoelectric crystal	Mechanical force causes change in crystal structure that generates voltage.	Can be activated by nonphysiologic stimuli (e.g., vibration while riding in a car).
Accelerometer	Converts change in velocity in anterior-posterior (AP) direction into electrical signal.	May not provide adequate response to activities without movement in AP direction (e.g., weight lifting).
Minute ventilation	**Measures changes in electrical impedance across chest as surrogate marker for respiratory rate.**	**Good correlation with metabolic workload. Does not respond as quickly as motion/activity sensors to onset of exercise.**
Physiologic Sensors	**Assessment of true physiologic measure.**	**Rarely stand-alone sensor for rate responsive pacing. Accuracy varies.**
Examples:		
QT duration	Measured from onset of QRS to end of the T wave	Interval affected by autonomic tone and heart rate. Good rate-adaptive measure. Does not respond well to non–exercise-related stress.
Others:		
pH body temperature force of ventricular contraction	Variety of physiologic measures may correlate with activity	May be part of multisensor PMs in future. Not accurate enough for stand-alone, rate-responsive sensor function.

Table A2–5 Causes of Pseudo-Pacemaker Malfunction

Feature	Description
Mode switch	Device switches from tracking mode (such as DDD) to non–tracking mode (such as DDI) in response to sustained atrial arrhythmia. Mode switch pacing rate may be separately programmable or may be lower rate limit of the pacemaker.
Hysteresis	Allows the rate to fall below the programmed lower rate of the pacemaker following an intrinsic beat.
Rate drop response	Delivers pacing at a programmed high rate (e.g., 100 beats/min) for a limited time in response to a drop in heart rate. Used for patients with neurocardiogenic syncope.
Rate responsive pacing	Increases heart rate in response to activity.
Sleep mode	Allows programming of different lower rate for bedtime hours to minimize pacing and conserve the battery.

DDD, DDI—See Table A2–3 for description of pacing modes.

Most ICDs have programmable features that may reduce the chances of a patient receiving an inappropriate shock (Table A2–8).

Routine Follow-Up

ICD patients require routine outpatient follow-up every 3 to 6 months. At each visit, device interrogation is performed to determine if any significant arrhythmias have occurred in the interval since the patient was last seen. Other parameters that are also routinely checked are battery voltage; full energy charge time (6 to 10 seconds in a new device, 12 to 18 seconds in a device near elective replacement); pacing threshold; intrinsic amplitude; and lead impedance.

Table A2–6 Typical Implantable Cardioverter-Defibrillator Programming

	VT Zone	VF Zone
Heart rate	170-200 beats/min	>200 beats/min
Cycle length	300-350 msec	<300 msec
Detection duration	16 intervals	2 sec
Therapy 1	Burst pacing	24 J
Therapy 2	24 J	35 J
Therapy 3	35 J	35 J
Therapy 4	35 J	35 J
Therapy 5	35 J	35 J

VF, ventricular fibrillation; VT, ventricular tachycardia.
An example of typical ICD programming for tachyarrhythmia detection and treatment is shown. The VT zone is programmed to respond to arrhythmias in the 170 to 200 beat/min range (cycle length 300 to 350 msec). In this case, if 16 intervals are within the programmed VT range, then the device will begin to deliver therapy. Anti-tachycardia pacing (ATP) will be attempted first. If the arrhythmia persists, a series of shocks will be delivered, with the device automatically withholding additional therapy if the rhythm falls below the rate cutoff. If the heart rate is greater than 200 beats/min for 2 sec, then the VF therapies will apply. The first programmed shock is typically 10 J above the defibrillation threshold, with the remainder of the therapies programmed to maximum output.

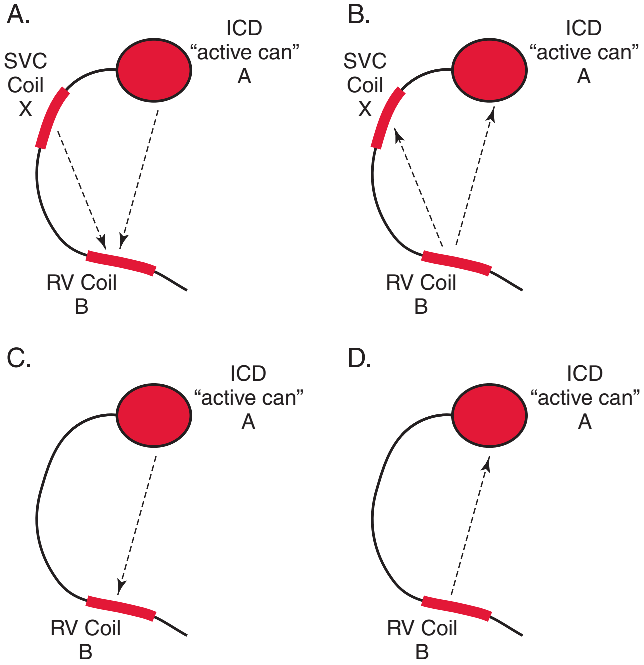

Figure A2–6 A variety of shocking circuit configurations are shown. Transvenous ICD leads may be dual coil (6A and 6B) or single coil (6C and 6D). For dual coil leads, energy is delivered from (A) the ICD ("active can") and SVC coil to the RV coil ("initial" polarity or "AX to B") or (B) from the RV coil to the SVC coil and ICD ("reversed" polarity or "B to AX"). For single-coil leads, energy delivery is from the (C) ICD to the RV coil ("initial" polarity or "A to B") or (D) RV coil to ICD ("reversed" polarity or "B to A"). Dual coil systems have DFTs 5-7 J lower, on average, than single-coil systems. Mean DFT is approximately equal with standard or reversed polarity, although DFT can vary by 5-7 J with different polarity in individual patients. Occasionally, an epicardial system may be encountered, in which energy delivery is between two surgically placed epicardial patches or between an epicardial patch and active can (not shown).

Table A2–7 Medications that can Affect the Defibrillation Threshold

Medication	Effect on DFT
Amiodarone	Increase
Bretylium	Varies
Disopyramide	Increase
Flecainide	Increase
Lidocaine	Increase
Mexiletine	Increase
NAPA	Decrease
Procainamide	Varies
Propafenone	Varies
Sotalol	Decrease
Verapamil	Increase

DFT, defibrillation threshold.

Table A2–8 Arrhythmia Discriminators

Discriminator	How It Works	Clinical Implications
Stability	Measures beat-to-beat variation in arrhythmia cycle length. Withholds therapy for irregular rhythms.	Effective at discriminating between ventricular tachycardia (usually very regular) and rapid atrial fibrillation (usually irregular).
Onset	Measures how sudden the arrhythmia onset was. Withholds therapy unless the arrhythmia begins suddenly.	Effective at discriminating sinus tachycardia from ventricular tachycardia. Ventricular tachycardia is usually sudden in onset, while the heart rate increases more gradually for patients with sinus tachycardia.
Morphology	Compares the QRS configuration during arrhythmia to the baseline QRS configuration. Withholds therapy if the arrhythmia QRS is similar to the baseline QRS.	Can help avoid inappropriate shocks for supraventricular arrhythmias.

Circulatory Support Devices

James C. Fang and Gregory S. Couper

A wide variety of mechanical cardiac support devices are commercially available in the United States (Table A3–1).[1] They cover a spectrum of effectiveness (hemodynamic power) and invasiveness. Generally, the more completely a device replaces native cardiac function, the more invasive and potentially complicated the implantation procedure becomes. Historically, the purpose of such devices was to provide days to weeks of circulatory support, but today their use has been extended to provide months to years of circulatory support to "bridge" patients to transplantation or myocardial recovery. For patients who are not appropriate for transplantation, a left ventricular assist device (LVAD, HeartMate I XVE) is now also approved for permanent circulatory support.

The least powerful mechanical cardiac assist device is the intra-aortic balloon pump (IABP). The most effective application of the IABP is in ischemic heart failure. Through a combination of diastolic augmentation of coronary blood flow and systolic unloading of the left ventricle, the cardiac output may be supplemented by 15% to 20%. The IABP is also the least invasive device because it can be routinely inserted percutaneously, occasionally without fluoroscopic guidance. Greater hemodynamic support can be achieved with percutaneous cardiopulmonary bypass systems (Bard CPS ReAct System, CR Bard, Billerica, Mass). Their use is primarily limited to the cardiac catheterization laboratory for temporary hemodynamic support during high-risk coronary interventions. Notably, they are also limited by an inability to unload the left ventricle completely and therefore can be used only as short-term support until percutaneous or surgical revascularization can be accomplished. The Tandem Heart PTVA (CardiacAssist, Pittsburgh, Pa) can also be placed percutaneously and provides up to 4 L/min of blood flow using an extracorporeal centrifugal pump. It can provide left ventricular unloading because the inflow cannula sits in the left atrium across the interatrial septum via a transseptal puncture. However, large-bore percutaneous catheters (15 to 17 Fr) are required to provide adequate flow rates into the femoral artery.[2] Ventricular assist devices (VADs) and total artificial hearts (TAHs) can supply 100% of cardiac output under most circumstances. In some conditions the output of VADs can be supplemented by output of the native ventricles. Because the TAH requires removal of the native ventricles, there is no native cardiac function, which is problematic in the event of device failure. In contrast, VADs can ultimately be "backed up" by native ventricular function. In general, implantation of a VAD or TAH requires full open-heart surgery approaches including additional surgical exposure in the abdomen for various components. Newer VADs, such as axial flow pumps, are smaller and can be implanted through a thoracotomy, even while off cardiopulmonary bypass. Most currently available devices have percutaneous catheters or leads. Future devices will be fully implantable with transcutaneous electromagnetic energy transmission providing power or monitoring for internal electrical motors, or both.

PHYSIOLOGY OF MECHANICAL CARDIAC SUPPORT

Intra-Aortic Balloon Pump Counterpulsation

As a mechanical cardiac assist device, the IABP is capable of augmenting cardiac output by a modest degree (generally ≤ 25%). Optimal counterpulsation produces several favorable physiologic effects. Balloon inflation creates an augmented diastolic blood pressure and increase in coronary perfusion pressure. Deflation during the isovolumic phase of systole results in early left ventricular systolic unloading and increases stroke volume. Figure A3–1 depicts a typical arterial tracing during alternate beat support (1:2 timing) with appropriate timing of balloon inflation and deflation. Stroke volume rises because of a decrease in left ventricular afterload resulting from IABP counterpulsation. The isovolumic phase of systole is shortened, and forward ejection occurs earlier. In some decompensated patients, this is sufficient to reestablish an adequate cardiac output, especially if there is an ischemic component to their cardiac failure. Given mixed populations of patients, it has been difficult to ascertain whether left ventricular systolic unloading or aortic diastolic augmentation is the dominant physiologic effect. Right ventricular systolic unloading has also been accomplished with IABP counterpulsation in the pulmonary artery when catastrophic right ventricular failure occurs during cardiac surgery.

Current consoles allow automatic triggering of the balloon pump by native QRS signals, pacing spikes, or pulse pressure detection. Improvements in console and catheter designs have enabled more rapid shuttling of the helium gas in and out of the balloon. As a consequence, there has been improved ability to provide effective counterpulsation despite irregular or rapid rhythms, although there are limits to this ability in individual patients. Usually, an IABP catheter is inserted through an 8 Fr delivery sheath, although smaller arterial access can be achieved if an insertion sheath is not used.

Ventricular Assist Devices and Total Artificial Heart

VADs are powerful pumps and, depending on the specific pump design, can provide most or all of the normal cardiac output under many physiologic conditions. VADs are connected to the left or right heart structures (atria or ventricles and to the corresponding great artery) diverting the blood away from the supported side, essentially bypassing it.

Table A3–1 Representative Examples of Mechanical Assist Devices*

Device	Flow Pattern	BiVAD	Usual Duration of Support	Anticoagulation	Ambulatory	Out-of-Hospital Use	Relative Advantages	Relative Disadvantages
Percutaneous								
Intra-aortic balloon pump†	Cyclic	No	Day/wk	Heparin/Dextran	No	No	Rapid, minimally invasive insertion, minimally thrombotic	Minor boost in cardiac output. Bedridden status
CardiacAssist Tandem Heart PTVA†	Continuous	No	Day/wk	Heparin	No	No	Provides flow up to 4L/min	Large bore percutaneous catheters, transseptal puncture required
Extracorporeal Pneumatic Pumps								
• Abiomed BVS 5000†	Pulsatile	Yes	Day/wk	Heparin	No	No	Low cost, simple automatic operation of VAD/console	Bleeding; thrombogenicity
• Abiomed AB 5000†	Pulsatile	Yes	Wk/mo	Heparin	Yes	No	Compatible with BVS 5000 system	Bleeding
• Thoratec PVAD†	Pulsatile	Yes	Day/wk/mo	Low-dose heparin Coumadin ± antiplatelet therapy	Yes	Yes	Increased mobility, reasonably low thrombogenicity	Relatively large portable console
• Centrifugal pumps Biomedicus† Sarns-3M Terumo† St. Jude†	Continuous	Yes	Day/wk	Heparin	No	No	Simple implant	Bleeding; lack of automatic operation, constant monitoring by hospital staff
• ECMO	Continuous	Yes	Day/wk	Heparin	No	No	Full cardiac and pulmonary support	Bleeding; complexity of operation and monitoring. Potential to fail to unload adequately

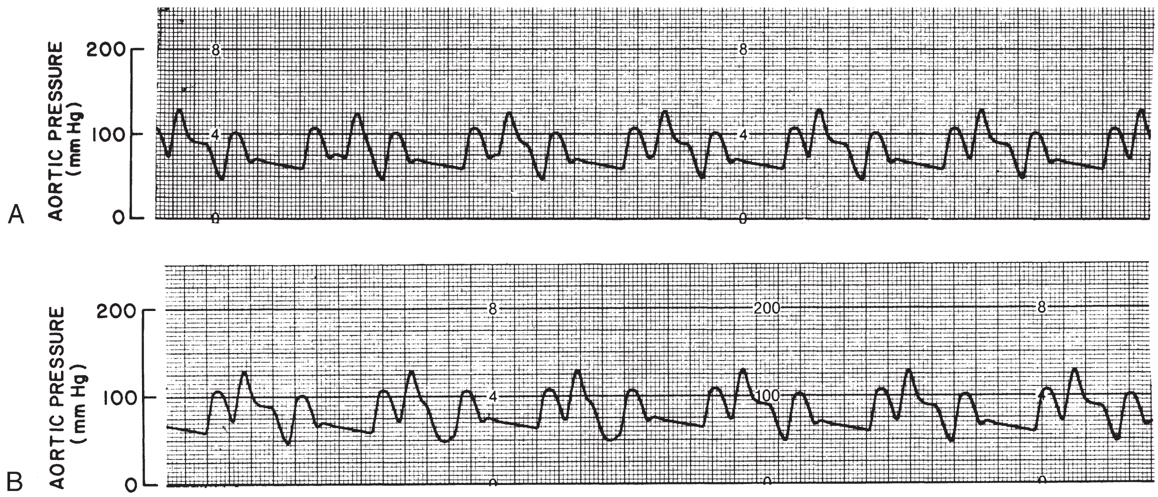

Figure A3–1 **A,** The timing of balloon inflation is adjusted until it occurs late in diastole, uncovering the dicrotic notch. Subsequently, inflation timing is moved earlier in the cardiac cycle until the dicrotic notch on the central aortic tracing just disappears (beat 4). The augmented pressure will rise as inflation timing is moved earlier. **B,** Deflation knob is moved toward the right (later in the cardiac cycle) until the end-diastolic dip is 10 to 15 mm Hg below the patient's unassisted diastolic pressure. This provides a maximal lowering of the patient's unassisted systolic pressure. (From Baim DS, Grossman W [eds]: Cardiac Catheterization, Angiography, and Intervention. Baltimore, Williams & Wilkins, 1996, p 426.)

Cannula length depends on the device, chambers cannulated, and position of the blood pump relative to the heart. The native heart remains to recover or, in the rare event of VAD failure, resume native cardiac output. The TAH completely replaces the function of the removed native ventricles. As a result, failure of the TAH is immediately fatal.

Blood may be pumped using the devices in two basic fashions: (1) pulsatile flow or (2) minimally pulsatile-continuous flow. The pulsatile flow pumps create normal or sinusoidal pulse waves, often indistinguishable from normal arterial pulse contours (Fig. A3–2). They displace blood volume at physiologic rates, requiring a compensatory volume shift (usually of air) into a compliance chamber or externally to prevent generating a vacuum during the cycle. The pump may be driven by an external pneumatic pump (console) or an internal electric motor. The Thoratec HeartMate I XVE (Thoratec, Pleasanton, CA) is configured for backup pneumatic pumping in the event of internal electrical failure. Examples of pneumatic pumps include the Abiomed BVS 5000 (Abiomed Cardiovascular, Inc., Danvers, MA), the Thoratec PVAD (Thoratec Corp., Pleasanton, CA), the Thoratec Pneumatic HeartMate (Thoratec, Berkeley, CA), and the Cardiowest TAH (SynCardia Systems, Tuscon, AZ). Electric pumps include the Thoratec HeartMate I XVE and the Novacor VADs (WorldHeart, Ottawa, Canada).

Continuous flow pumps are based on centrifugal or axial flow designs. Cyclic variations in flow and outlet pressure may occur as a result of native cardiac activity, resulting in low-amplitude pulse pressure. Greater pulsatility may be achieved through the short-term addition of an IABP. Centrifugal blood pumps were among the first to gain popularity as short-term VADs or in extracorporeal membrane oxygenation (ECMO) systems. Blood volumes remain constant and low (relative to pulsatile pumps) within most rotary pumps, resulting in a much smaller size of blood pumps and cannulas. Similarly, axial flow pumps are smaller and allow for internal implantation in smaller patients, such as women and children (body surface area [BSA] < 1.5 m^2). Finally, durability may be greater with axial flow pumps because they can be powered using magnetically driven and levitated impellers. A large number of promising rotary pumps, both axial and centrifugal, are currently in clinical investigational human trials.

IMPORTANT CLINICAL FACTORS IN MECHANICAL CARDIAC ASSIST

Fulminant Ventricular Arrhythmias

Frequent preoperative ventricular tachycardia or occasional ventricular fibrillation may be tolerable and treatable after LVAD implantation. In fact, the arrhythmias may resolve with resting of the left ventricle. The presence of a mechanical VAD may also result in sufficient hemodynamic stability to allow mapping and ablation of ventricular tachycardia. On occasion, ventricular arrhythmias may worsen after device implantation, presumably due to re-entry around the ventricular cannulation site. In general, post-VAD ventricular arrhythmias should be controlled either pharmacologically or by ablation because sustained ventricular arrhythmias compromise optimal VAD flows and can lead to intraventricular thrombus formation.

However, biventricular assist devices (BiVADs) and, depending on the intent, the TAH provide the most reliable and stable forms of support when fulminant or malignant patterns of ventricular arrhythmias are present. ECMO is temporarily acceptable, especially in the circumstance of cardiac arrest. It may be used as a bridge to an alternative device following stabilization for 1 to 2 days. An atrial septostomy may be required to ensure unloading of the left heart and avoidance of pulmonary edema. This strategy is crucial if the left heart is not ejecting at all.

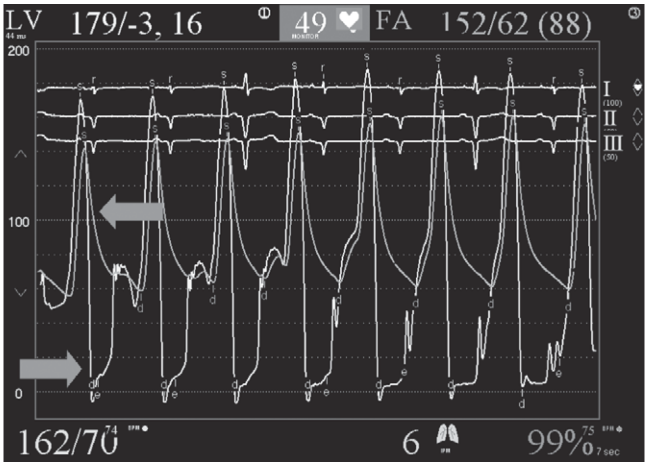

Figure A3–2 (See also Color Plate A3–2.) Simultaneous recording of intraVAD *(right arrow)* and femoral artery pressure *(left arrow)*. Femoral artery waveform similar to native ejection except for increased pulse pressure.

Advanced Hepatic or Renal Dysfunction

Secondary organ dysfunction results from a combination of acute shock, chronic low cardiac output, and passive congestion secondary to right heart failure. When multiple organs exhibit secondary dysfunction, serious consideration should be given to biventricular support rather than isolated left ventricular support. The BiVAD or TAH eliminates problems of right heart failure and marginal cardiac output sometimes seen early after isolated LVAD implantation.

Right Heart Failure

Essentially a clinical diagnosis following isolated LVAD implantation, this problem results in limitation of cardiac output, tricuspid regurgitation, and elevated right atrial pressure with visceral congestion, ascites, and peripheral edema. It is the consequence of interaction between the right ventricle and the afterload (or impedance) of the pulmonary arterial bed. The mismatch of poor right ventricular function (generally defined by a RVEDP or CVP > 20 mm Hg) with normal or low pulmonary arterial pressure and resistance predicts the highest risk for requiring a right ventricular assist device (RVAD) in conjunction with an LVAD.[3] Pharmacologic therapy following isolated LVAD implantation is directed toward inotropic support of the right ventricle and vasodilation (preferentially selective) of the pulmonary arterial tree. With time and chronic unloading of the left ventricle, pulmonary vascular resistance will fall and may allow for weaning of right ventricular inotropic support.

Patient's Size

In patients with a BSA greater than 1.5 m^2, most implantable devices readily fit the thoracic and abdominal cavities. Extremely large patients (BSA > 2.5 m^2) require devices capable of pumping > 6 L/min. Small patients with a BSA < 1.5 m^2 may not be suitable for the implantable pulsatile VADs or TAHs; extracorporeal VADs may be a better option. When BSA is < 1.2 m^2, the Thoratec PVAD may function best because stroke volume can be decreased commensurate with the patient's size. Centrifugal VAD or ECMO is a short-term option in smaller patients, especially in the pediatric population. As reviewed previously, the newer rotary pumps may be implantable over a broader size range than current implantable VADs or TAHs.

Anticoagulation

The use of mechanical devices to support the circulation necessitates the use of anticoagulants, antiplatelet agents, or both to prevent thromboembolic complications. The IABP generally requires systemic anticoagulation with a target activated partial thromboplastin time (aPTT) of 50 to 70 seconds using heparin. For short-term support VADs, such as the Abiomed device, anticoagulation is usually achieved with unfractionated heparin and a target activated clotting time (ACT) of 150 to 200 seconds. Anticoagulation with long-term support VADs, such as the Thoratec device, typically requires warfarin with a target International Normalized Ratio (INR) of 2.0 to 2.5. In contrast, the HeartMate VAD requires only aspirin for anticoagulation because of the formation of a pseudointimal layer in the blood-contacting portion of the titanium housing. However, in all cases of anticoagulation, the therapeutic goals must be individualized to prevent bleeding complications.

Heparin-induced thrombocytopenia (HIT) is an increasingly common management problem in mechanical circulatory support therapy. A number of agents including argatroban, bivalirudin, and fondaparinux have been used by various centers for postoperative care, but there are no current universally accepted strategies. In contrast to heparin, there are no antidotes to the direct antithrombins or anti-Xa agents, a situation that complicates the management of perioperative bleeding and stroke when these drugs are used.

Duration of Support

Bridge to Recovery for Acute Cardiac Failure (Fig. A3–3)

Successful support to recovery following open-heart surgery or myocardial infarction occurs when myocardial stunning is the dominant process. Appropriate selection of patients generally results in use of the device for less than 7 to 10 days. A distinct onset of myocardial dysfunction and acute heart failure characterize fulminant myocarditis. The duration of support required in this setting is highly variable and may last for weeks. Accordingly, a device capable of this duration of support should be chosen. However, the criteria to determine adequacy of myocardial recovery remain unclear and in most cases, myocardial recovery will be uncommon.[4-6]

Bridge to Transplantation (Fig. A3–4)

Numerous patient-related factors affect the length of time that the device is used while waiting for a transplant. A long wait can be anticipated if the patient is of large size or has been highly sensitized to human leukocyte antigens. The position of the patient on a transplant list depends on the current logistics of the regional organ bank (number of patients at the same status and with the same blood type), which can vary over time.

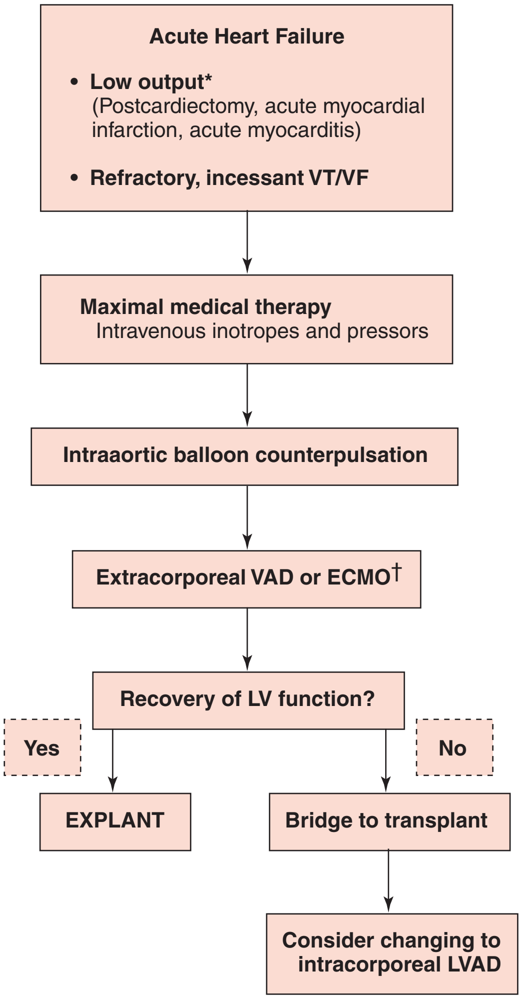

Figure A3–3 Acute heart failure. ECMO, extracorporeal membrane oxygenation; LV, left ventricle; LVAD, left ventricular assist device; VAD, ventricular assist device; VF, ventricular fibrillation; VT, ventricular tachycardia. *Low output may be defined by but not limited to cardiac index < 2 L/min/m^2, systolic blood pressure < 80 mm Hg, wedge pressure > 20. †See Chapter 17 for discussion regarding preoperative factors to consider before VAD placement.

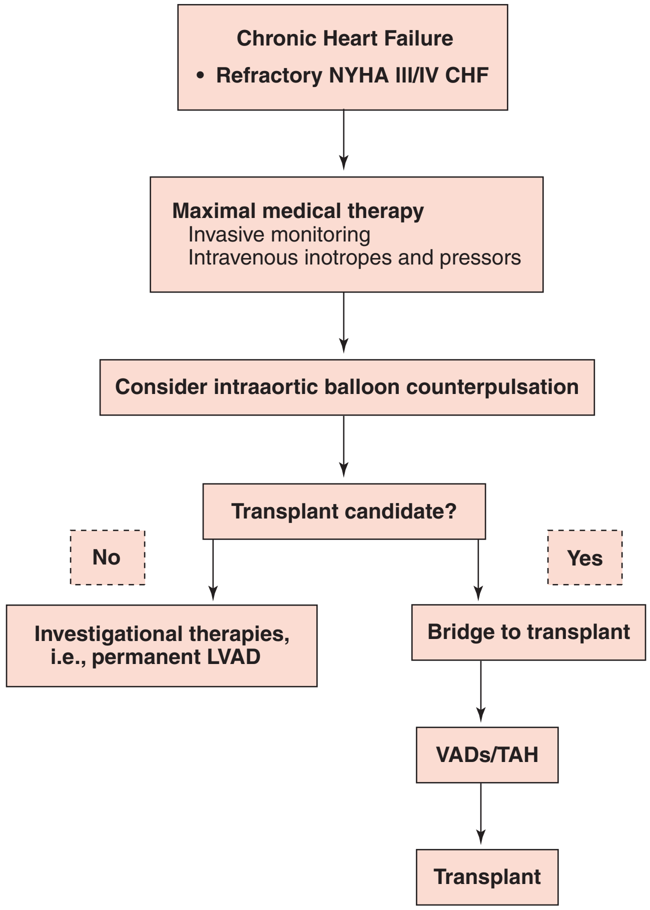

Figure A3–4 Chronic heart failure. LVAD, left ventricular assist device; TAH, total artificial heart; VADs, ventricular assist devices.

Particular patient-related problems require prolonged mechanical support before cardiac transplantation for resolution. Examples include advanced multi-organ dysfunction, severe physical debility, malnutrition with cachexia, and severe pulmonary arterial hypertension.

Possible candidates for transplantation need to meet typical inclusion and exclusion guidelines (see Chapter 17). During prolonged support, implantable LVADs offer the advantage of discharge to home, avoiding further nosocomial complications.

PERMANENT SUPPORT (DESTINATION THERAPY)

The landmark REMATCH trial established the superiority of VAD support over medical management (i.e., intravenous inotropic support) for endstage heart failure in patients deemed not appropriate for cardiac transplantation.[7] The Centers for Medicare and Medicaid Reimbursement and the FDA have established guidelines for selection of patients. These criteria include the presence of medically refractory New York Heart Association class IV heart failure, the determination that the patient is not a transplant candidate, and the patient's life expectancy of less than 2 years. However, it should be noted that device failure is a major limitation with this strategy and often occurs within 18 months of implantation. Replacement of the VAD or its dysfunctional parts (i.e., inflow valve regurgitation) can be performed but is fraught with the usual problems associated with major recurrent cardiovascular surgery (see later). Currently, only the Thoratec HeartMate XVE LVAS is approved in the United States for destination therapy.

Conversion of Devices

When the intent of support shifts from an initial short-term bridge to recovery to longer duration support, conversion from a short-term support device, such as a centrifugal VAD, ECMO, or an extracorporeal VAD (i.e., Abiomed), to a device with long-term support capability may be necessary. In the absence of ongoing severe ventricular arrhythmias, hepatic

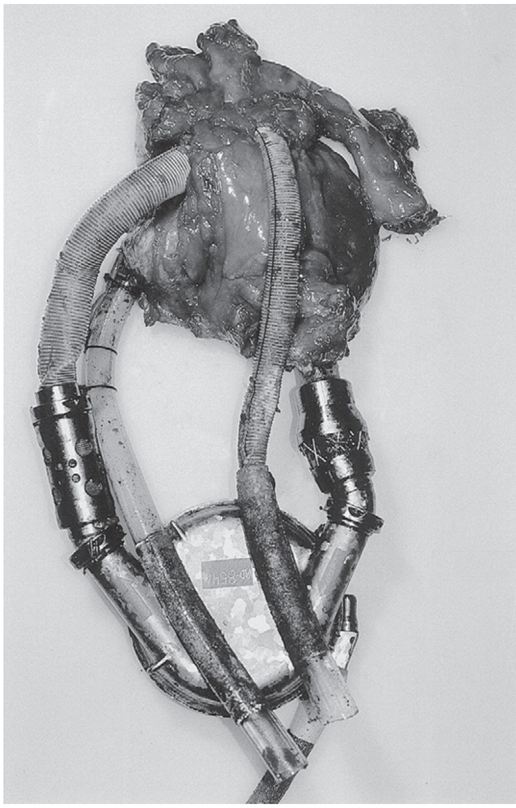

Figure A3–5 (See also Color Plate A3–5.) Explanted heart demonstrating use of two different ventricular assist devices for "hybrid" biventricular support, involving both intracorporeal and extracorporeal systems. Left ventricular assist device is the Thoratec HeartMate with inflow cannula in the left ventricular apex and outflow cannula (Dacron tubing on left of photograph) in the ascending aorta. Right ventricular assist device is the Thoratec (extracorporeal device not shown) with inflow cannula in right atrium and outflow cannula (Dacron tubing in middle of photograph) in main pulmonary artery. (Courtesy Marc Barry, MD, and Greg Couper, MD, Brigham and Women's Hospital, Boston.)

and renal insufficiency, or right ventricular failure, conversion to an isolated LVAD is likely to be successful. When the clinical situation requires prolonged biventricular assist, devices such as the Thoratec VAD or TAH are the best solution, avoiding hybrid systems (Fig. A3–5) that typically result in lower success rates.

DEVICE DYSFUNCTION AND INFECTION

Device failure is an inevitable complication of currently approved device technology, attributable to the "wear and tear" introduced to mechanical systems that face variable stresses and strains. In contrast, the newer continuous flow pumps may obviate this issue due to the electromagnetic system that drives the impellers. The most common device malfunctions involve either degeneration of the inflow valve leading to VAD "regurgitation" and bearing wear in the motor that leads to pump failure. Recent modifications to VAD design and software have improved the longevity of these devices. Diagnosis of the presence of such mechanical problems can generally be made by waveform analysis, exit filter analysis, device fluoroscopy, echocardiography,[8] and cardiac catheterization.[9] Infections generally involve the percutaneous driveline and can be managed by careful surgical wound care and antibiotic therapy. Unresponsive infections require surgical creation of a new percutaneous driveline track or even device explantation.
